Now that we have seen how evolution occurs and how phylogenies can be used to study evolutionary relationships, we are ready to consider the process of speciation. Speciation is what leads to the splitting events on the tree of life, and is the process that results in the millions of species that constitute biodiversity.

CHAPTER SUMMARY

22.1 What Is Phylogeny?

- **Phylogeny** is the history of descent of organisms from their common ancestor. Groups of evolutionarily related species are represented as related branches in a **phylogenetic tree**. **Review Figure 22.2**

- A group of species that consists of all the evolutionary descendants of a common ancestor is called a **clade**. Named clades and species are called **taxa**.
- **Homologies** are similar traits that have been inherited from a common ancestor. **Review Figure 22.4**

- A trait that is shared by two or more taxa and is derived through evolution from a common ancestral form is called a **synapomorphy**.
- Similar traits may occur among species that do not result from common ancestry. **Convergent evolution** and **evolutionary reversals** can give rise to such traits, which are called **homoplasies**.

22.2 How Are Phylogenetic Trees Constructed?

SEE WEB ACTIVITY 22.1

- Phylogenetic trees can be inferred from synapomorphies using the principle of **parsimony**. **Review Figure 22.5**
- Sources of phylogenetic information include morphology, patterns of development, the fossil record, behavioral traits, and molecular traits such as DNA and protein sequences.
- Phylogenetic trees can also be inferred with **maximum likelihood** methods, which calculate the probability that a particular tree will have generated the observed data.

22.3 How Do Biologists Use Phylogenetic Trees?

- Phylogenetic trees are used to reconstruct the past and understand the origin of traits. **Review Figure 22.8**
- Phylogenetic trees are used to make appropriate evolutionary comparisons among living organisms.
- Biologists can use phylogenetic trees to reconstruct ancestral states. **SEE ANIMATED TUTORIAL 22.1**
- Phylogenetic trees may include estimates of times of divergence of lineages determined by **molecular clock** analysis. **Review Figure 22.12**

22.4 How Does Phylogeny Relate to Classification?

- Taxonomists organize biological diversity on the basis of evolutionary history.
- Taxa in modern classifications are expected to be **monophyletic** groups. **Paraphyletic** and **polyphyletic** groups are not considered appropriate taxonomic units. **Review Figure 22.14, WEB ACTIVITY 22.2**
- Several sets of rules govern the use of scientific names, with the goal of providing unique and universal names for biological taxa.

SELF-QUIZ

1. A *clade* is
 - a. a type of phylogenetic tree.
 - b. a group of evolutionarily related species that share a common ancestor.
 - c. a tool for constructing phylogenetic trees.
 - d. an extinct species.
 - e. an ancestral species.
2. Phylogenetic trees may be constructed for
 - a. genes.
 - b. species.
 - c. major evolutionary groups.
 - d. viruses.
 - e. All of the above.
3. A shared derived trait, used as the basis for inferring a monophyletic group, is called
 - a. a synapomorphy.
 - b. a homoplasy.
 - c. a parallel trait.
 - d. a convergent trait.
 - e. a phylogeny.
4. The parsimony principle can be used to infer phylogenetic trees because
 - a. evolution is nearly always parsimonious.
 - b. it is logical to adopt the simplest hypothesis capable of explaining the known facts.
 - c. once a trait changes, it never reverses condition.
 - d. all species have an equal probability of evolving.
 - e. closely related species are always very similar to one another.
5. Convergent evolution and evolutionary reversal are two sources of
 - a. homology.
 - b. parsimony.
 - c. synapomorphy.
 - d. monophyly.
 - e. homoplasy.
6. Which of the following are commonly used to infer phylogenetic relationships among plants but not among animals?
 - a. Nuclear genes
 - b. Chloroplast genes
 - c. Mitochondrial genes
 - d. Ribosomal RNA genes
 - e. Protein-coding genes
7. Which of the following is *not* true of maximum likelihood or parsimony methods for inferring phylogeny?
 - a. The maximum likelihood method requires an explicit model of evolutionary character change.
 - b. The parsimony method is computationally easier than the maximum likelihood method.
 - c. The maximum likelihood method is easier to treat in a statistical framework.
 - d. The maximum likelihood method is most often used with molecular data.
 - e. Parsimony is usually used to infer time on a phylogenetic tree.
8. Taxonomists strive to include taxa in biological classifications that are
 - a. monophyletic.
 - b. paraphyletic.
 - c. polyphyletic.
 - d. homoplastic.
 - e. monomorphic.
9. Which of the following groups have separate sets of rules for nomenclature?
 - a. Animals
 - b. Plants and fungi
 - c. Bacteria
 - d. Viruses
 - e. All of the above

10. If two scientific names are proposed for the same species, how do taxonomists decide which name should be used?
 - a. The name that provides the most accurate description of the organism is used.
 - b. The name that was proposed most recently is used.
 - c. The name that was used in the most recent taxonomic revision is used.
 - d. The first name to be proposed is used, unless that name was previously used for another species.
 - e. Taxonomists use whichever name they prefer.

FOR DISCUSSION

1. Why are taxonomists concerned with identifying species that share a particular common ancestor?
2. How are fossils used to identify ancestral and derived traits of organisms? How can fossils be integrated into phylogenetic analyses?
3. The parsimony principle is often used to construct phylogenetic trees. What are the limitations of parsimony, and why do some biologists prefer model-based approaches, such as maximum likelihood methods?
4. A student of the evolution of frogs has proposed a strikingly new classification of frogs based on an analysis of a few mitochondrial genes from about 10 percent of frog species.
 - Should frog taxonomists immediately accept the new classification? Why or why not?
5. What are some of the assumptions that go into a molecular clock analysis? How could these assumptions be violated? How could molecular clock analyses be modified to consider these additional sources of variation?
6. Classification systems summarize much information about organisms and enable us to remember the traits of many organisms. From your general knowledge, how many traits can you associate with the following names: conifer, fern, bird, mammal?

ADDITIONAL INVESTIGATION

West Nile virus kills birds of many species and can cause fatal encephalitis (inflammation of the brain) in humans and horses. The virus was first isolated in Africa (where it is thought to be endemic) in the 1930s, and by the 1990s it had been found throughout much of Eurasia. West Nile virus was not found in

North America until 1999, but since that time it has spread rapidly across most of the United States. The genome of West Nile virus evolves quickly. How could you use phylogenetic analysis to investigate the geographic origin of the West Nile virus that was introduced into North America in 1999?

WORKING WITH DATA (GO TO yourBioPortal.com)

Constructing a Phylogenetic Tree In this exercise based on Figure 22.7, you will use a subset of the DNA sequences from the experimental lineages to reconstruct the evolutionary rela-

tionships among the viruses. You will also use these data to reconstruct the DNA sequences of the viral ancestors.

Catching speciation in the act

When biologists first explored the Cuatro Ciénegas basin of northern Mexico, they found many organisms that are not found anywhere else in the world. So far researchers have described about 150 *species* of plants and animals that are restricted to this small region. Even though Cuatro Ciénegas is in a desert, about 30 of these unique species are aquatic, living in the isolated springs and marshes of the basin. An unusual aquatic box turtle, beautiful cichlid fishes, and tiny crustaceans are among the many aquatic species that are confined to Cuatro Ciénegas. Why are so many different species found here and nowhere else?

Biologists and geologists found that, over the past several million years, this desert oasis has repeatedly been isolated by a succession of geological events that cut it off from the river systems and mountain ranges of northern Mexico. Many different *speciation events* associated with these geological events make Cuatro Ciénegas a natural laboratory for studying speciation by geographic isolation.

Each time gene flow between organisms in the basin and the surrounding areas ceased, populations living inside and outside the basin began to diverge from one another. Over thousands of generations of such isolation, new species developed. These new species no longer share the same gene pool, are adapted to different environments, and look different from one another. And—extremely important—the organisms have diverged to the point that they are no longer capable of reproducing with one another—one of the hallmarks of distinct species.

Although speciation is often studied in natural settings such as Cuatro Ciénegas, some aspects of speciation can be studied in controlled laboratory experiments, using organisms with short generation times. For example, William Rice and George Salt conducted an experiment in which fruit flies were allowed to choose food sources in different habitats, where mating also took place. The habitats were vials in different parts of an experimental cage. The habitats differed in three parameters: (1) light; (2) the direction in which the fruit flies could move (up or down);

and (3) concentrations of two aromatic chemicals, ethanol and acetaldehyde. In just 35 generations, two groups of flies were genetically and reproductively isolated from one another because they had evolved distinct preferences for different habitats. In controlled experiments like these, biologists are beginning to study and understand the genetic details of speciation.

A Natural Laboratory A swimmer surveys several of the fish species that are isolated in the desert oasis of the Cuatro Ciénegas basin in northern Mexico.

Experimental Subjects Fruit flies of the genus *Drosophila* are easily reared in the laboratory. Their short generation time (7–10 days from newly laid egg to reproductive adult) makes them ideal subjects for controlled experiments on speciation.

The *origin of species*—the splitting and diverging of a single lineage into two or more distinct and evolutionarily independent lineages—is one of the most important phenomena in biological science. Charles Darwin recognized its preeminence when he chose the title of *The Origin of Species*. But without the underlying knowledge supplied by the modern science of genetics, Darwin was primarily viewing the consequences of speciation, not its underlying causes. Today biologists are actively searching for and finding answers to the many questions about the process of speciation, something biologists have been known to call “the mystery of mysteries.”

IN THIS CHAPTER we will describe what species are and discuss how Earth’s millions of species came into being. We will examine the mechanisms by which a lineage splits into new species and how such separations are maintained. Finally, we will look at different factors that can make speciation a rapid or a very slow process.

CHAPTER OUTLINE

- 23.1** What Are Species?
- 23.2** How Do New Species Arise?
- 23.3** What Happens When Newly Formed Species Come Together?
- 23.4** Why Do Rates of Speciation Vary?

23.1 What Are Species?

Although “species” is a useful and commonly used term in biology, the concept of “species” sometimes varies among different biologists. Biologists are interested in several different aspects of the divergence of biological lineages. Different biologists think about species differently because they ask different questions about species: How can we recognize and identify species? How do new species arise? How do different species remain separate? Why do rates of speciation differ among groups? In answering these questions, biologists focus on different attributes of species, leading to several different ways of thinking about what species are and how they form. Most of the various *species concepts* proposed by biologists are not mutually exclusive—they are just different ways of approaching the question “What are species?”

We can recognize many species by their appearance

Biological diversity does not always vary in a smooth, incremental way; groups of organisms often differ in distinct, obvious ways. People have long recognized groups of similar organisms that mate with one another, and there are usually distinct morphological breaks between these groups. Groups of organisms that mate with one another are commonly called *species* (note that this is both the plural and singular form of the word). Someone who is knowledgeable about a group of organisms, such as birds or flowering plants, usually can distinguish the different species found in a particular area simply by looking at them. Standard field guides to birds, mammals, insects, and wildflowers are possible only because many species change little in appearance over large geographic distances. A casual birdwatcher can easily recognize male red-winged blackbirds (*Agelaius phoeniceus*) from the east and west coasts of North America as members of the same species (**Figure 23.1A**).

More than 250 years ago, the Swedish biologist Carolus Linnaeus developed the binomial system of biological nomenclature by which species are named today (see Section 22.4). Linnaeus described thousands of species, and because he knew nothing about genetics or the mating behavior of the organisms he was naming, he classified them only on the basis of their appearance. Linnaeus differentiated species using a **morphological species concept**, a construct that assumes a species consists of individuals that “look alike,” and that individuals that don’t look alike belong to different species. Although Linnaeus did not know it, members of many of the groups that he classified as species by their appearance look alike because they share many of the alleles that code for their body structures.

23.1 Members of the Same Species Look Alike—or Not

(A) Both of these male red-winged blackbirds are members of the same species—*Agelaius phoeniceus*—even though one is from the eastern United States and the other is from western Canada. Despite the geographic distance, the two individuals are morphologically very similar. (B) Red-winged blackbirds are sexually dimorphic, which means the female of the species looks quite different from the male.

The morphological species concept has limitations, however. In some cases, for instance, not all members of a species look alike. For example, males, females, and young individuals do not always resemble one another closely (**Figure 23.1B**). The morphological species concept is of little use in the case of *cryptic species*, instances in which two or more morphologically indistinguishable species do not interbreed. Biologists therefore cannot always rely on appearance alone in determining whether individual organisms are members of the same or different species. Several additional types of information (especially behavioral and genetic data) are used today to help biologists differentiate species.

Species are reproductively isolated lineages on the tree of life

Evolutionary biologists often think of species as branches on the tree of life, which is known as a **lineage species concept**. Under this concept, each species has a history that starts at a speciation event (one lineage on the tree splits into two) and ends either at extinction or another speciation event, at which time the species produces two daughter species. The process of lineage splitting may be gradual, and thus take thousands of generations to complete. On the other hand, one ancestral lineage may be split into two as a result of a sudden geological event, such as a volcanic eruption that isolates two parts of ancestral species range. Either way, the lineage species concept treats speciation as the process by which one species splits into two or more daughter species, which thereafter evolve as distinct lineages. The gradual nature of some splitting events means that at a single point in time, the final outcome of the process may not be clear. In these cases it is often impractical to try to decide whether the partially isolated populations of the *incipient species* will continue to diverge and become fully isolated from one another, or perhaps merge again in the future.

The most important component that determines long-term isolation of sexually reproducing lineages from one another is the development of **reproductive isolation**, a state in which two populations can no longer exchange genes. If individuals of a population mate and reproduce with one another, but not with

individuals of other populations, they constitute a distinct group within which genes recombine. In other words, they comprise an independent evolutionary lineage—a separate branch on the tree of life.

It was recognition of the importance of reproductive isolation that brought Ernst Mayr to propose the **biological species concept**: “Species are groups of actually or potentially interbreeding natural populations which are reproductively isolated from other such groups.” The terms “actually” and “potentially” are important elements of the definition. “Actually” says that the individuals live in the same area and interbreed with one another. “Potentially” says that although the individuals do not live in the same area, and therefore cannot interbreed, other information suggests that they would do so if they did get together. This widely used concept of species does not apply to organisms that reproduce asexually, and it is limited to a single point in evolutionary time.

These various concepts of species are not entirely incompatible; they simply emphasize different aspects of species. The morphological species concept emphasizes the practicality of humans recognizing species, although it underestimates or overestimates the actual number of species in some cases. Mayr’s biological species concept emphasizes that reproductive isolation is what keeps sexual lineages on the tree of life separated from one another. The lineage species concept embraces the idea that sexual species are maintained by reproductive isolation, while recognizing the existence of asexual species. The lineage species concept also allows biologists to consider species through evolutionary time, which we will discuss in the next section.

Virtually all species exhibit some degree of genetic recombination among individuals, even if recombination is relatively rare (see Section 21.4). Significant reproductive isolation between species is thus necessary for lineages to remain distinct through evolutionary time. Reproductive isolation is also responsible for the morphological distinctiveness of most species, because genetic mutations that result in morphological changes cannot spread between reproductively isolated species. Therefore, no matter which species concept we emphasize, the evolution of reproductive isolation is important for understanding the origin of species.

23.1 RECAP

Species are distinct lineages on the tree of life. Speciation is usually a gradual process as one lineage divides into two. Over time, lineages of sexual species remain distinct from one another because they have become reproductively isolated.

- Explain how the various species concepts emphasize different attributes of species. **See pp. 482–483**
- Why is the biological species concept not applicable to asexually reproducing organisms?
- Do you understand why reproductive isolation is an important component of all of the species concepts discussed here? **See p. 483**

Although Charles Darwin titled his groundbreaking book *The Origin of Species*, it did not extensively discuss the processes of speciation. He devoted most of his attention to demonstrating that individual species are altered by natural selection over time. We will next discuss the many things that biologists have learned about speciation since Darwin's time.

23.2 How Do New Species Arise?

Not all evolutionary changes result in new species. A single lineage may change over time without giving rise to a new species. Speciation, in contrast, usually requires the evolution of reproductive isolation within a species whose members formerly exchanged genes. But if a genetic change prevents reproduction between individuals of a species, how can such a change spread through a species in the first place?

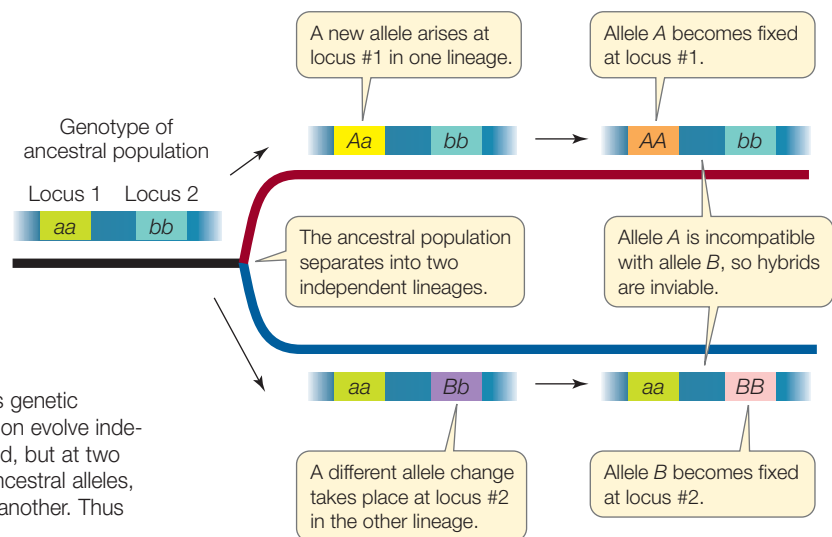

Gene incompatibilities can produce reproductive isolation in two daughter species

If a new allele that causes reproductive incompatibility arises in a population, it cannot spread through the population, because no other individuals are reproductively compatible with the individual that carries the new allele. So how can one reproductively cohesive lineage ever split into two reproductively isolated species? Several early geneticists, including Theodosius Dobzhansky and Hermann Joseph Muller, developed a genetic model to explain this apparent conundrum (**Figure 23.2**).

23.2 The Dobzhansky-Muller Model In this simple two-locus genetic model, two populations isolated from the same ancestral population evolve independently. In each descendant lineage, a new allele becomes fixed, but at two different loci. Neither of the new alleles is incompatible with the ancestral alleles, but the two new alleles at the two loci are incompatible with one another. Thus the two descendant lineages are reproductively incompatible.

The Dobzhansky-Muller model is quite simple. First, assume that a single ancestral population is divided into two (by the formation of a new mountain range, for instance). In one of the descendant populations, a new allele (*A*) arises and becomes fixed (see **Figure 23.2**). In the other population, another new allele (*B*) becomes fixed *at a different gene locus*. Neither new allele at either gene results in any loss of reproductive compatibility. However, the two new forms of these two genes have never occurred together in the same organism. The products of many genes must work together, and it is quite likely that the new protein forms encoded by these two genes are not compatible with one another. If the two populations come back together, they may still be able to interbreed, or **hybridize**. However, the hybrid offspring will have a new combination of genes that may be functionally inferior, or even lethal. Of course, this will not happen with all new combinations of genes, but over time isolated populations will accumulate many allele differences at many gene loci. Thus, we expect that genetic incompatibility will develop through time in the two isolated populations.

Many empirical examples support the Dobzhansky-Muller model, which works not only for pairs of individual genes but also for some kinds of chromosomal rearrangements. For example, bats of the genus *Rhogeessa* exhibit considerable variation in centric fusions of their chromosomes. The chromosomes of the various species contain the same basic chromosomal arms, but in some species two acrocentric (one-armed) chromosomes have fused to form larger, metacentric (two-armed) chromosomes. A polymorphism in this character causes few, if any, problems in meiosis, because the respective chromosomes can still align and assort normally. Therefore, a given centric fusion can become fixed in a population. However, if a *different* centric fusion becomes fixed in a second population, then hybrids between the two populations can no longer produce normal gametes in meiosis (**Figure 23.3**). Most of the closely related species of *Rhogeessa* display different combinations of these centric fusions, and are thereby reproductively isolated from one another.

23.3 Speciation by Centric Fusion In this chromosomal version of the Dobzhansky–Muller model of speciation, two independent centric fusions of one-armed chromosomes occur in two sister lineages. When polymorphic, neither centric fusion event by itself results in major difficulties at meiosis. However, the independent centric fusions are incompatible at meiosis, because the three different chromosomes involved in these fusions cannot pair normally, leading to sterility of the F_1 hybrid. Most of the species in the bat genus *Rhogeessa* differ from one another by such centric fusions.

Reproductive isolation develops with increasing genetic divergence

As pairs of species diverge genetically, they become increasingly reproductively isolated from one another (Figure 23.4). Both the rate at which reproductive isolation develops and the mechanisms that produce it vary from group to group. Nonetheless, reproductive incompatibility has been shown to develop gradually in many groups of plants, animals, and fungi, reflecting the slow pace at which incompatible genes accumulate in each lineage. In some cases, complete reproductive isolation may take millions of years to develop. In other cases (as with the chromosomal fusions of *Rhogeessa* described above), reproductive isolation can develop over just a few generations.

Partial reproductive isolation has evolved in strains of *Phlox drummondii* artificially isolated by humans. In 1835, Thomas Drummond, after whom this species of garden plant is named, collected seeds in Texas and distributed them to nurseries in Europe. Over the next 80 years, the European nurseries established more than 200 true-breeding strains of this phlox, which differed in flower size and color and plant growth form. The plant

23.4 Reproductive Isolation Increases with Time of Separation

This positive relationship between genetic distance and reproductive isolation, shown here for pairs of *Drosophila* species, has been observed in many groups of plants, animals, and fungi (each dot represents a comparison of one species pair).

breeders did not select directly for reproductive incompatibility between strains, but in subsequent experiments in which fertilization rates were measured and compared, biologists found that reproductive compatibility between strains had been reduced by 14 to 50 percent, depending on the strain.

Many laboratory experiments have demonstrated the gradual evolution of reproductive incompatibility during isolation. We described one such experiment in the opening of this chapter. These laboratory experiments are also consistent with our observations of naturally isolated populations, as described for the unique species of the Cuatro Ciénegas basin in the chapter opening.

Geographic barriers give rise to allopatric speciation

Speciation that results when a population is divided by a physical barrier is known as **allopatric speciation** (Greek *allos*, “other”; *patra*, “homeland”), also called *geographic speciation* (Figure 23.5). Allopatric speciation is thought to be the dominant mode of speciation in most groups of organisms. The physical barrier that divides the range of a species may be a water body, a mountain range, or other inhospitable habitat for terrestrial organisms, or dry land for aquatic organisms. Barriers can form when continents drift, sea levels rise, glaciers advance and retreat, or climates change. These processes continue to generate

23.5 Allopatric Speciation Allopatric speciation may result when a population is divided into two separate populations by a physical barrier, such as rising sea levels.

physical barriers today. The populations separated by such barriers are often, but not always, initially large. They evolve differences for a variety of reasons, including genetic drift (see Section 21.1), but especially because the environments in which they live are, or become, different.

Allopatric speciation may also result when some members of a population cross an existing barrier and found a new, isolated population. Many of the more than 800 species of *Drosophila* found in the Hawaiian archipelago are restricted to a single island. We know that these species are the descendants of new populations founded by individuals dispersing among the islands because the closest relative of a species on one island is often a species on a neighboring island rather than a species on the same island. Biologists who have studied the chromosomes of these fruit flies estimate that speciation in this group of *Drosophila* has resulted from at least 45 such founder events (**Figure 23.6**).

The 14 species of finches found in the Galápagos, an archipelago 1,000 kilometers off the coast of Ecuador, were gener-

ated by allopatric speciation. Darwin's finches (as they are usually called, because Darwin was the first scientist to study them) arose in the Galápagos from a single South American species that colonized the islands. Today the 14 species differ strikingly from their closest mainland relative and from one another (**Figure 23.7**). The islands of the Galápagos archipelago are sufficiently far apart that finches move among them only infrequently. In addition, environmental conditions differ from island to island. Some are relatively flat and arid; others have forested mountain slopes. Finch populations on different islands have differentiated over millions of years to the point that, when occasional immigrants arrive from other islands, they either do not breed with the residents or, if they do, the resulting offspring do not survive as well as the offspring of established island residents. The genetic distinctness and cohesiveness of the different finch species are thus maintained.

GO TO Animated Tutorial 23.1 • Founder Events and Allopatric Speciation

Sympatric speciation occurs without physical barriers

Although physical isolation is usually required for speciation, under some circumstances speciation can occur without it. A partition of a gene pool without physical isolation is called **sympatric speciation** (Greek *sym*, “together with”). Given that speciation is usually a gradual process, how can reproductive isolation develop when individuals have frequent opportunities

23.6 Founder Events Lead to Allopatric Speciation The large number of species of picture-winged *Drosophila* in the Hawaiian Islands is the result of founder events: the founding of new populations by individuals dispersing among the islands. The islands, which were formed in sequence as Earth's crust moved over a volcanic “hot spot,” vary in age.

23.7 Allopatric Speciation among Darwin's Finches

The descendants of the ancestral finch that colonized the Galápagos archipelago several million years ago evolved into 14 different species whose members are variously adapted to feed on seeds, buds, and insects. (The fourteenth species, not pictured here, lives in Cocos Island, farther north in the Pacific Ocean.)

ANCESTOR FINCH
from South
American
mainland

Seed eaters

Bills of seed eaters are adapted for harvesting and crushing seeds.

Large ground finch
(*Geospiza magnirostris*)

Medium ground finch
(*G. fortis*)

Small ground finch
(*G. fuliginosa*)

Sharp-billed ground finch
(*G. difficilis*)

Large cactus finch
(*G. conirostris*)

Cactus finch
(*G. scandens*)

Bud eater The bud eater's heavy bill is adapted for grasping and wrenching buds from branches.

Vegetarian finch
(*Platyspiza crassirostris*)

Small tree finch
(*Camarhynchus parvulus*)

Large tree finch
(*C. psittacula*)

Medium tree finch
(*C. pauper*)

Mangrove finch
(*C. heliobates*)

Woodpecker finch
(*C. pallidus*)

Insect eaters

The bills of insect eaters vary because they eat different types and sizes of insects and they capture them in different ways.

Warbler finch
(*Certhidea olivacea*)

Large-billed finches can crush large, hard seeds.

Small-billed finches cannot crush large seeds well, but are adept at handling small seeds.

Cactus finches are adapted to opening cactus fruits and extracting the seeds.

The large tree finch uses its heavy bill to twist apart wood to reach larvae inside.

The small and medium tree finches and mangrove finch pick insects from leaves and branches and explore crevices for hidden prey.

The woodpecker finch uses its long beak to probe dead wood, crevices, and bark for insects.

The warbler finch uses quick motions to capture insects on plant surfaces.

to mate with one another? Sympatric speciation may occur with some form of disruptive selection in which certain genotypes have a preference for distinct microhabitats where mating takes place. The experiment described in the opening of this chapter shows that this kind of disruptive selection can take place in the laboratory, but does it also occur in nature?

Sympatric speciation via disruptive selection appears to be happening in the apple maggot fly (*Rhagoletis pomonella*) in eastern North America. Until the mid-1800s, *Rhagoletis* flies courted, mated, and deposited their eggs only on hawthorn fruits. About 150 years ago, some *Rhagoletis* flies began to lay their eggs on apples, which European immigrants had introduced into eastern North America. Apple trees are closely related to hawthorns, but the smell of the fruits differs, and the apple fruits appear earlier than those of hawthorns. Some early-emerging female *Rhagoletis* laid their eggs on apples and evolved a genetic preference for the smell of apples. Their offspring inherited this genetic preference for apples for mating and egg deposition. When the offspring sought out apple trees for these purposes, they mated with other flies reared on apples, which shared the same preferences.

Today the two groups of *Rhagoletis pomonella* in the eastern United States may be on the way to becoming distinct species. One group mates and lays eggs primarily on hawthorn fruits, the other on apples. The two incipient species are partly reproductively isolated because they mate primarily with individuals raised on the same fruit and because they emerge from their pupae at different times of the year. In addition, the apple-feeding flies have evolved so that they now grow more rapidly on apples than they originally did.

Sympatric speciation via ecological isolation, as appears to be happening in *Rhagoletis pomonella*, may be widespread among insects, many of which feed on only a single plant species. The most common means of sympatric speciation, however, is **polyploidy**, or the duplication of sets of chromosomes within individuals (see Section 11.5). Polyploidy can arise either from chromosome duplication in a single species (**autopolyploidy**) or from the combining of the chromosomes of two different species (**allopolyploidy**).

An autopolyploid individual originates when (for example) two accidentally unreduced diploid gametes (with

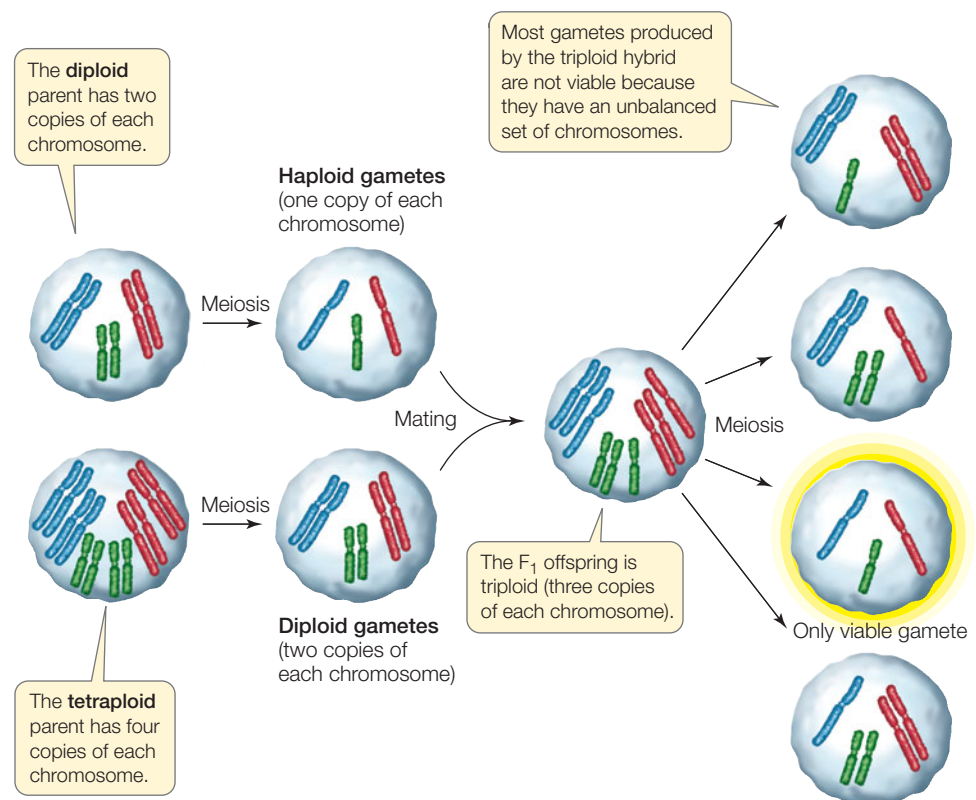

two sets of chromosomes) combine to form a tetraploid individual (with four sets of chromosomes). Tetraploid and diploid individuals of the same species are reproductively isolated because their hybrid offspring are triploid and are usually sterile; they cannot produce viable gametes because their chromosomes do not segregate evenly during meiosis (**Figure 23.8**). So a tetraploid individual cannot produce viable offspring by mating with a diploid individual—but it *can* do so if it self-fertilizes or mates with another tetraploid. Thus polyploidy can result in complete reproductive isolation in two generations—an important exception to the general rule that speciation is a gradual process.

Allopolyploids may also be produced when individuals of two different (but closely related) species interbreed. Such hybridization often disrupts normal meiosis, which can result in chromosomal doubling. Allopolyploids are often fertile because each of the chromosomes has a nearly identical partner with which to pair during meiosis.

Speciation by polyploidy has been particularly important in the evolution of plants. Botanists estimate that about 70 percent of flowering plant species and 95 percent of fern species are the result of recent polyploidization. Some of these arose from hybridization between two species, followed by chromosomal duplication and self-fertilization. Many other species diverged from polyploid ancestors, so the new species also shared the duplicated sets of chromosomes. New species may arise by means of polyploidy more easily among plants than among animals because plants of many species can reproduce by self-fertilization. In addition, if polyploidy arises in several offspring of a single parent, the siblings can fertilize one another.

23.8 Tetraploids Are Reproductively Isolated from Their Diploid Ancestors

Even if the triploid offspring of a diploid and a tetraploid parent survives and reaches sexual maturity, most of the gametes it produces have aneuploid (unbalanced) numbers of chromosomes. Such triploid individuals are effectively sterile. (For simplicity, the diagram shows only three chromosomes; most species have many more than that.)

23.2 RECAP

Allopatric speciation results from the separation of populations by geographic barriers; it is the dominant mode of speciation among most groups of organisms. Sympatric speciation may result from ecological isolation, but among plants and some animals, polyploidy is the most common cause of sympatric speciation.

- How can speciation via polyploidy happen in two generations? [See p. 488](#)
- Explain why an effective barrier to gene flow for one species may not effectively isolate another species.

GO TO Animated Tutorial 23.2 • Speciation Mechanisms

Polyploidy, as we have just seen, can result in a new species that is completely reproductively isolated from its parent species in two generations, but most populations separated by a physical barrier become reproductively isolated only very slowly. Let's see how reproductive isolation may become established once two populations have separated from each other.

23.3 What Happens When Newly Formed Species Come Together?

As discussed in the previous section, once a barrier to gene flow is established, reproductive isolation can develop through genetic divergence. Over many generations, genetic differences accumulate that reduce the probability that members of the two populations can mate and produce viable offspring. In this way, reproductive isolation evolves as a by-product of the genetic changes in the two populations. What types of mechanisms prevent or reduce gene flow between populations, leading to reproductive isolation? Reproductive isolating mechanisms fall into two major categories: **prezygotic reproductive barriers** act *before* fertilization to prevent individuals of different species or populations from mating, whereas **postzygotic reproductive barriers** act *after* fertilization to prevent the development of viable offspring, or to reduce the offsprings' fertility.

Prezygotic barriers prevent fertilization

Prezygotic mechanisms come into play before fertilization and can involve several kinds of reproductive isolation.

HABITAT ISOLATION When individuals of different species evolve genetic preferences for different habitats in which they live or mate, they may never come into contact during their respective mating periods. The *Rhagoletis* flies in the eastern United States (discussed in Section 23.2) experienced such habitat isolation, as did the *Drosophila* in the experiment described in the opening of this chapter.

23.9 Temporal Isolation in the Breeding Seasons of Three Species of Frogs

(A) The peak breeding seasons of three species of *Rana* overlap when the species are physically separated (allopatry). (B) When two or more species of *Rana* occupy the same territory (sympatry), overlap between peak breeding seasons of each species is greatly reduced or eliminated. In areas where only one species is found, the breeding seasons are broader. Selection against hybridization in areas of overlap helps reinforce the prezygotic isolating mechanism.

TEMPORAL ISOLATION Many organisms have distinct mating seasons. If two closely related species breed at different times of the year (or different times of day), the two may never have an opportunity to hybridize. For example, in sympatric populations of three closely related leopard frogs, each species breeds at a different time of year (**Figure 23.9**). Although there is some overlap in the breeding seasons, the opportunities for hybridization are minimized.

MECHANICAL ISOLATION Differences in the sizes and shapes of reproductive organs may prevent the union of gametes from different species. With animals, this may involve a match in the shape of reproductive organs between males and females, so that reproduction between species with mismatching structures is not physically possible. In plants, the mechanical isolation between species may involve a pollinator. For example, orchids of the genus *Cryptostylis* produce flowers that look and smell like the females of particular species of wasps (**Figure 23.10**). When a male wasp visits and attempts to mate with the flower (thinking it is a female wasp), the mating action results in transfer of

23.10 Mechanical Isolation through Mimicry Many orchid species maintain reproductive isolation because their flowers look and smell like a specific species of bee or wasp, inducing copulatory actions on the part of that specific pollinator insect. The placement of the anthers and stigmas on the flower results in transfer of pollen from the flower to the insect that “mates” with it, and then from the insect to the next flower with which it attempts to mate. Shown here are an Australian orchid (*Cryptostylis* sp.) and its pollinator, a male wasp of the genus *Lissopimpla*.

pollen between the flower and wasp as a result of appropriately configured anthers and stigmas on the flower. Insects that visit the flower but do not attempt to mate with it do not trigger the transfer of pollen between the insect and flower.

BEHAVIORAL ISOLATION Individuals of a species may reject, or fail to recognize, individuals of other species as potential mating partners. For example, the breeding calls of male frogs quickly diverge between related species (Figure 23.11). Female frogs respond to and approach calls from males of their own species, but ignore the calls of even closely related species.

Gastrophryne olivacea

Gastrophryne carolinensis

23.11 Behavioral Isolation in the Mating Calls of Male Frogs The males of most species of frogs produce species-specific calls. The calls of the two closely related frog species in this figure differ in their dominant frequency (a high-frequency sound wave results in a high-pitched sound; a low frequency results in a low-pitched sound). Female frogs are attracted to the calls of males of their own species. Note that the calls of the two species are more distinct in areas of sympatry than in areas of allopatry (an example of reinforcement).

Sometimes the mate choice of one species is mediated by the behavior of individuals of other species. For example, whether two plant species hybridize may depend on the food preferences of their pollinators. The floral traits of plants, including their color and shape, can enhance reproductive isolation either by influencing which pollinators are attracted to the flowers or by altering where pollen is deposited on the bodies of pollinators. A plant whose flowers are pendant (Figure 23.12A) will be pollinated by an animal with different physical characteristics than a plant in which the flowers grow upright (Figure 23.12B). Because each pollinator prefers (and is adapted to) a different type of flower, the pollinators rarely transfer pollen from one plant species to the other.

Such isolation by pollinator behavior is seen in the case of two sympatric species of columbines (*Aquilegia*) in the mountains of California that have diverged in flower color, structure, and orientation. *Aquilegia formosa* has pendant flowers with short spurs (spikelike, nectar-containing structures) and is pollinated by hummingbirds (Figure 23.12C). *A. pubescens* has upright, lighter-colored flowers with long spurs and is pollinated by hawkmoths (Figure 23.12D). The difference in pollinators means that these two species are effectively reproductively isolated even though they populate the same geographic range.

GAMETIC ISOLATION Sperm of one species may not attach to the eggs of another species because the eggs do not release the appropriate attractive chemicals, or the sperm may be unable to penetrate the egg because the two gametes are chemically in-

(A)

(B)

(C) *Aquilegia formosa*(D) *Aquilegia pubescens*

23.12 Floral Morphology is Associated with Pollinator Morphology

(A) This hummingbird's morphology and behavior are adapted to approach plants whose flowers are pendant (hanging downward). (B) The nectar-extracting proboscis of this hawkmoth is adapted to flowers that grow upright. (C) *Aquilegia formosa* flowers are normally pendant and are pollinated by hummingbirds. (D) Flowers of *A. pubescens* are normally upright, which facilitates pollination by hawkmoths. In addition, the long floral spurs appear to restrict access by some other potential pollinators.

- **Hybrid infertility.** Hybrids may mature normally but be infertile. For example, the offspring of matings between horses and donkeys—mules—are healthy but sterile; they produce no descendants.

Although natural selection does not directly favor the evolution of postzygotic reproductive barriers, if hybrid offspring survive poorly, natural selection may favor the evolution of prezygotic barriers. This happens because individuals that mate with individuals of the other population will leave fewer surviving descendants than individuals that mate only within their own population. In this case, individuals that can avoid mating with members of the other population have a selective advantage, and any trait that favors such avoidance will be favored by natural selection. Such strengthening of prezygotic barriers is known as **reinforcement**.

Donald Levin of the University of Texas noticed that individuals of *Phlox drummondii* in most of the range of the species in Texas have pink flowers. Where *P. drummondii* is sympatric with the pink-flowered *P. cuspidata*, however, *P. drummondii* has red flowers. No other *Phlox* species has red flowers. Levin performed an experiment whose results showed that reinforcement might explain the evolution of red flowers where the two species are sympatric (**Figure 23.13**).

Reinforcement can also be detected by comparing sympatric and allopatric populations of potentially hybridizing species. If reinforcement is occurring, then sympatric pairs of closely related species should evolve more effective prezygotic reproductive barriers than do allopatric populations of the same species. The examples of temporal isolation shown in Figure 23.9 and of behavioral isolation shown in Figure 23.11 illustrate reinforcement of prezygotic barriers. The breeding seasons of the sympatric populations of frogs (Figure 23.9) overlap much less than do those of the corresponding allopatric populations. Similarly, the frequencies of the frog mating calls illustrated in Figure 23.11 are more divergent in sympatric populations than in allopatric populations. In both cases, there appears to have been selection against hybrids in areas of sympatry, so individuals that do not produce hybrids are more likely to leave more genes to future generations.

compatible. Thus, even though individuals of the two species may attempt to mate, the gametes never fuse into a zygote. For example, gametic isolation has arisen between species of sea urchins. A protein known as bindin occurs in sea urchin sperm and functions in attaching ("binding") the sperm to eggs. All sea urchins produce this egg-recognition protein, but the gene sequence diverges rapidly between species. The sperm protein evolves so that it will only bind to eggs of the same species, thus preventing interspecific hybridization.

Postzygotic barriers can isolate species after fertilization

If individuals of two different populations lack complete prezygotic reproductive barriers, postzygotic reproductive barriers may prevent the species from merging. Genetic differences that accumulate while the populations are isolated from each other may reduce the survival and reproduction of hybrid offspring in any of several ways:

- **Low hybrid zygote viability.** Hybrid zygotes may fail to mature normally, either dying during development or developing such severe abnormalities that they cannot mate as adults.
- **Low hybrid adult viability.** Hybrid offspring may simply have lower survivorship than offspring resulting from within-population matings.

INVESTIGATING LIFE

23.13 Flower Color Reinforces a Reproductive Barrier in *Phlox*

Most *Phlox drummondii* flowers are pink, but in regions where they are sympatric with *P. cuspidata*—which is always pink—most *P. drummondii* individuals are red. Most pollinators preferentially visit flowers of one color or the other. In this experiment, Donald Levin explored whether flower color reinforces a prezygotic reproductive barrier, lessening the chances of interspecific hybridization.

HYPOTHESIS Red-flowered *P. drummondii* are less likely to hybridize with *P. cuspidata* than are pink-flowered *P. drummondii*.

METHOD

1. Introduce equal numbers of red- and pink-flowered *P. drummondii* individuals into an area with many pink-flowered *P. cuspidata*.

2. After the flowering season ends, measure hybridization by assessing the genetic composition of the seeds produced by *P. drummondii* plants of both colors.

RESULTS

Of the seeds produced by pink-flowered *P. drummondii*, 38% were hybrids with *P. cuspidata*. Only 13% of the seeds produced by red-flowered individuals were genetic hybrids.

CONCLUSION *P. drummondii* and *P. cuspidata* are less likely to hybridize if the flowers of the two species differ in color.

FURTHER INVESTIGATION: This experiment did not address the probable reproduction advantages for individual *Phlox* plants of donating and receiving primarily intraspecific pollen. Can you design an experiment to measure such an advantage?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

During the process of reinforcement, closely related species may form hybrids in areas where their ranges overlap, and they may continue to do so for many years. Let's examine what happens when reproductive barriers do not completely prevent individuals from different populations from mating and producing offspring.

Hybrid zones may form if reproductive isolation is incomplete

If contact is reestablished between formerly isolated populations before complete reproductive isolation has developed, members of the two populations may interbreed. Three outcomes of such interbreeding are possible:

- If hybrid offspring are as fit as those resulting from matings within each population, hybrids will mate with individuals of both parental species. The gene pools will gradually become completely mixed, resulting in one species.
- If hybrid offspring are less fit, complete reproductive isolation may evolve as reinforcement strengthens prezygotic reproductive barriers.
- Even if hybrid offspring are at some disadvantage, a narrow **hybrid zone**—a region in which genetically distinct populations come together and produce offspring of mixed ancestry—may develop in the absence of reinforcement, or before reinforcement is complete.

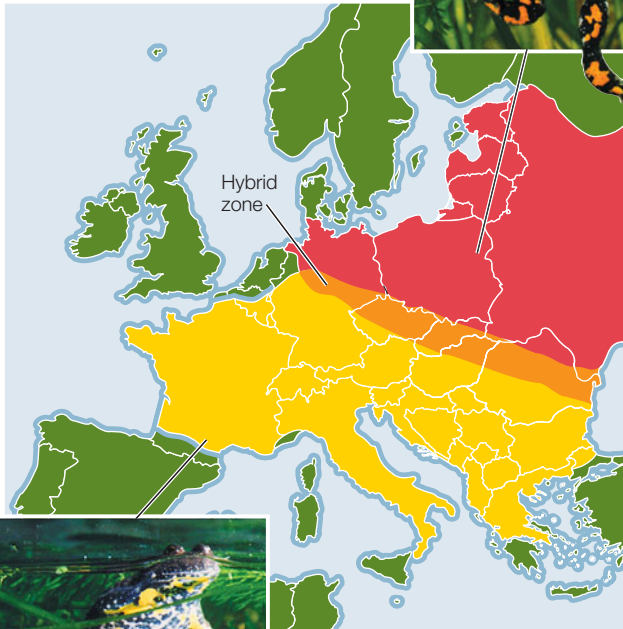

When a hybrid zone first forms, most hybrids are offspring of crosses between purebred individuals of the two populations. However, subsequent generations include a variety of individuals with different proportions of their genes derived from the original two populations. Thus hybrid zones contain recombinant individuals resulting from many generations of hybridization. Detailed genetic studies can tell us much about why hybrid zones may be narrow and stable for long periods of time.

The hybrid zone between two species of European toads of the genus *Bombina* has been studied intensively. The fire-bellied toad (*B. bombina*) lives in eastern Europe; the closely related yellow-bellied toad (*B. variegata*) lives in western and southern Europe. The ranges of the two species overlap in a long but very narrow zone stretching 4,800 kilometers from eastern Germany to the Black Sea (**Figure 23.14**). Hybrids between the two species suffer from a range of defects, many of which are lethal. Those hybrids that survive often have skeletal abnormalities, such as misshapen mouths, ribs that are fused to vertebrae, and a reduced number of vertebrae. By following the fates of thousands of toads from the hybrid zone, investigators found that a hybrid toad is on average only half as fit as a purebred individual. The

23.14 Hybrid Zones May Be Long and Narrow

The narrow zone in Europe where fire-bellied toads meet and hybridize with yellow-bellied toads stretches across Europe. This hybrid zone has been stable for hundreds of years and has never expanded, and no reinforcement has evolved.

B. bombina (fire-bellied toad)

B. variegata
(yellow-bellied toad)

hybrid zone thus remains narrow because there is strong selection against hybrids, and because adult toads do not move over long distances. The zone has persisted for hundreds of years, however, because many individuals of both species continue to move short distances into it, constantly replenishing the hybrid population.

23.3 RECAP

Reproductive isolation may result from prezygotic or postzygotic reproductive barriers. Lower fitness of hybrids in contact zones can lead to the reinforcement of prezygotic reproductive barriers.

- Describe various kinds of prezygotic and postzygotic reproductive barriers. **See pp. 489–491**
- Why is reinforcement of prezygotic barriers likely if hybrid offspring survive more poorly than offspring produced by within-population matings? **See p. 491**

Some groups of organisms have many species, others only a few. Hundreds of species of *Drosophila* evolved in the small area of the Hawaiian Islands over about 20 million years. In contrast, there are only a few species of horseshoe crabs in the world, and only one species of ginkgo tree, even though these latter groups have persisted for hundreds of millions of years. Why do different groups of organisms have such different rates of speciation?

23.4 Why Do Rates of Speciation Vary?

Rates of speciation (the proportion of existing species that split to form new species over a given period of time) vary greatly because many factors influence the likelihood that a lineage will split to form two or more species. What are some of the factors that influence the probability of a given lineage splitting into two?

Populations of species that have specialized diets may be more likely to diverge than are populations that have generalized diets. To investigate the effects of diet on rates of speciation, Charles Mitter and colleagues compared species richness in some closely related groups of true bugs (hemipterans). The common ancestor of these groups was a predator that fed on other insects, but a dietary shift to herbivory (eating plants) evolved at least twice in the groups under study. The herbivorous groups have many more species than those that are predatory (**Figure 23.15**). Herbivorous bugs typically specialize on one or a few closely related species of plants, whereas predatory bugs tend to feed on many different species of insects. High diversity of host plants can thus lead to a correspondingly high diversity in the herbivorous specialists.

Speciation rates in plants are faster in animal-pollinated than in wind-pollinated plants. Animal-pollinated groups have, on average, 2.4 times as many species as related groups pollinated by wind. Among animal-pollinated plants, speciation rates are correlated with pollinator specialization. In columbines (*Aquilegia*), the rate of evolution of new species has been about three times faster in lineages that have long nectar spurs than in lineages that lack spurs. Why do nectar spurs increase the spe-

23.15 Dietary Shifts Can Promote Speciation Herbivorous groups of hemipteran insects have speciated several times faster than closely related predatory groups.

ciation rate? Apparently it is because having longer spurs restricts the number of pollinator species that visit the flowers, thus increasing opportunities for reproductive isolation (see Figure 23.12).

The mechanisms of sexual selection (see Section 21.2) appear to result in increased rates of speciation. Some of the most striking examples of sexual selection are found in birds with promiscuous mating systems. Bird-watchers travel thousands of miles to Papua New Guinea to witness the mating displays of male birds of paradise, some of which have long, brightly colored tail feathers and look distinctly different than the females (*sexual dimorphism*). In many of these 33 species, males assemble at display grounds, called *leks*, and females come there to choose a male with whom to copulate. After mating, the females leave the display grounds, build their nests, lay their eggs, and feed their offspring with no help from the males. The males remain to court more females (**Figure 23.16A**).

The closest relatives of the birds of paradise are the manucodes. Male and female manucodes differ only slightly in size and plumage (so they are *sexually monomorphic*). They form monogamous pair bonds, and both sexes contribute to raising the young. There are only 5 species of manucodes (**Figure 23.16B**), compared with 33 species of birds of paradise. This

is just one comparison, and by itself would not be convincing evidence that sexually dimorphic clades of birds have higher rates of speciation than do monomorphic clades. However, when biologists compare all the examples of birds in which one clade is sexually dimorphic, and the most closely related clade is sexually monomorphic, the sexually dimorphic clades are significantly more likely to contain more species. But why would sexual dimorphism be associated with a higher rate of speciation?

Animals with complex sexually selected behaviors are likely to form new species at a high rate because they make sophisticated discriminations among potential mating partners. They distinguish members of their own species from members of other species, and they make subtle discriminations among members of their own species on the basis of size, shape, appearance, and behavior. Such discriminations can greatly influence which individuals are most successful in mating and producing offspring, and may lead to rapid evolution of prezygotic reproductive barriers among populations.

Speciation rates are usually higher in species with poor dispersal abilities than in species with good dispersal abilities, because even narrow barriers can be effective in dividing a species whose members are highly sedentary. The Hawaiian Islands have about 1,000 species of land snails, many of which are restricted to a single valley. Because snails move only short distances, the high ridges that separate the valleys are effective barriers to their dispersal.

The proliferation of a large number of daughter species from a single ancestor is called an **evolutionary radiation**. If the rapid proliferation of species results in an array of species that live in a variety of environments and differ in the characteristics they use to exploit those environments, the radiation is said to be **adaptive**. Several remarkable adaptive radiations have occurred in the Hawaiian Islands. In addition to its 1,000 species of land snails, the native biota of the Hawaiian Islands includes 1,000 species of flowering plants, 10,000 species of insects, and more than 100 bird species. However, there were no amphibians, no terrestrial reptiles, and only one native terrestrial mammal—a bat—on the islands until humans introduced additional species. The 10,000 known native species of insects on Hawaii are believed to have evolved from only about 400 immigrant species; only 7 immigrant species are believed to account for all the native Hawaiian land birds. Similarly, as we saw earlier in this chapter, an adaptive radiation in the Galápagos archipelago resulted in the 14 species of Darwin's finches, which differ strikingly in the size and shape of their bills and, accordingly, in the food resources they use (see Figure 23.7).

The 28 species of Hawaiian sunflowers called silverswords are an impressive example of an adaptive radiation in plants. DNA sequences show that these species share a relatively recent common ancestor with a species of tarweed from the Pacific coast of North America (**Figure 23.17**). Whereas all mainland tarweeds are small, upright herbs (nonwoody plants), the silverswords include prostrate and upright herbs, shrubs, trees, and vines. Silversword species occupy nearly all the habitats of the Hawaiian Islands, from sea level to above timberline

(A) *Paradisaea minor*

(B) *Manucodia comrii*

23.16 Sexual Selection in Birds Can Lead to Higher Speciation Rates (A) Birds of paradise and (B) manucodes are closely related bird groups of the South Pacific. However, speciation rates are much higher among the sexually dimorphic, polygynous birds of paradise (33 species) than among manucodes (5 species).

Wilkesia hobbii*Madia sativa* (tarweed)*Argyroxiphium sandwicense**Dubautia menziesii*

23.17 Rapid Evolution among Hawaiian Silverswords The Hawaiian silverswords, three closely related genera of the sunflower family, are believed to have descended from a single common ancestor (a plant similar to the tarweed; upper right) that colonized Hawaii from the Pacific coast of North America. The four plants shown here are more closely related than they appear to be based on their morphology.

in the mountains. Despite their extraordinary morphological diversification, the silverswords are genetically very similar.

The Hawaiian silverswords are more diverse in size and shape than the mainland tarweeds because the tarweed ancestors first arrived on islands that harbored very few plant species. In particular, there were few trees and shrubs, because such large-seeded plants rarely disperse to oceanic islands. Trees and shrubs have evolved from nonwoody ancestors on many oceanic islands. On the mainland, however, tarweeds live in ecological communities that contain many tree and shrub species in lineages with long evolutionary histories. In those environments, opportunities to exploit the “tree” way of life had already been preempted.

23.4 RECAP

Dispersal ability, dietary specialization, and mechanisms of sexual selection affect rates of speciation. Speciation rates in plants can depend on mechanisms of pollination. Open ecological niches present opportunities for evolutionary radiations.

- Explain how pollinator specialization in plants and sexual selection in animals can increase rates of speciation. **See pp. 493–494**
- Why do adaptive radiations often occur when a founder species invades an isolated geographic area? **See p. 494**

The processes described in this chapter, operating over billions of years, have produced a world in which life is organized into millions of species, each adapted to live in a particular environment and to use environmental resources in a particular way. In the next chapter we consider how species evolve at the level of their genes and genomes.

CHAPTER SUMMARY

23.1 What Are Species?

- **Speciation** is the process by which one species splits into two or more daughter species, which thereafter evolve as distinct lineages.
- The **biological species concept** distinguishes species on the basis of **reproductive isolation**.
- The **morphological species concept** distinguishes species on the basis of physical similarities; it often underestimates or overestimates the actual number of reproductively isolated species.
- The **lineage species concept** recognizes evolutionarily independent lineages as species, allowing biologists to consider species over evolutionary time.

23.2 How Do New Species Arise?

- Speciation usually results from the interruption of gene flow within a population.
- The Dobzhansky-Muller model describes how reproductive isolation can develop between two descendant species. **Review Figure 23.2**
- **Allopatric speciation**, which results when populations are separated by a physical barrier, is the dominant mode of speciation. This type of speciation may follow from founder events, in which some members of a population cross a barrier and found a new, isolated population. **Review Figure 23.5, ANIMATED TUTORIAL 23.1**

- **Sympatric speciation** results when the genomes of two groups diverge in the absence of physical isolation. It can result from disruptive selection for two or more distinct microhabitats.
- Sympatric speciation can occur within two generations via **polyploidy**, an increase in the number of chromosomes sets. Polyploidy may arise from chromosome duplications within a species (**autopolyploidy**) or from hybridization that results in combining the chromosomes of two species (**allopolyploidy**). **Review Figure 23.8**

SEE ANIMATED TUTORIAL 23.2

23.3 What Happens When Newly Formed Species Come Together?

- **Prezygotic barriers** to reproduction operate before fertilization; **postzygotic barriers** to reproduction operate after fertilization. Prezygotic barriers may be favored by natural selection if postzygotic barriers are incomplete. **Review Figures 23.9, 23.11**
- **Hybrid zones** may form when previously separated populations come into contact and reproductive isolation is incomplete. **Review Figure 23.14**

23.4 Why Do Rates of Speciation Vary?

- Dispersal ability, dietary specialization, type of pollination, and sexual selection all influence speciation rates. **Review Figure 23.15**

SEE WEB ACTIVITY 23.1 for a concept review of this chapter.

SELF-QUIZ

- The biological species concept defines a species as a group of
 - actually interbreeding natural populations that are reproductively isolated from other such groups.
 - potentially interbreeding natural populations that are reproductively isolated from other such groups.
 - actually or potentially interbreeding natural populations that are reproductively isolated from other such groups.
 - actually or potentially interbreeding natural populations that are reproductively connected to other such groups.
 - actually interbreeding natural populations that are reproductively connected to other such groups.
- Which of the following is *not* a condition expected to favor allopatric speciation?
 - Continents drift apart and separate previously connected lineages.
 - A mountain range separates formerly connected populations.
 - Different environments on two sides of a barrier cause populations to diverge.
 - The range of a species is separated by loss of intermediate habitat.
 - Tetraploid individuals arise in one part of the range of a species.
- Finches speciated in the Galápagos Islands because
 - the Galápagos Islands are not far from the mainland.
 - the Galápagos Islands are thought to promote sympatric speciation in birds.
 - hybridization across different island populations of finches led to high levels of polyploidy.
 - the islands of the Galápagos archipelago are sufficiently isolated from one another that there is little migration among them.
 - the islands of the Galápagos archipelago are close enough to one another that there is considerable migration among them.
- Which of the following is *not* a potential prezygotic reproductive barrier?
 - Temporal segregation of breeding seasons
 - Differences in chemicals that attract mates
 - Hybrid infertility
 - Spatial segregation of mating sites
 - Sperm that cannot penetrate an egg
- A common means of sympatric speciation is
 - polyploidy.
 - hybrid infertility.
 - temporal segregation of breeding seasons.
 - spatial segregation of mating sites.
 - imposition of a geographic barrier.
- Narrow hybrid zones may persist for long times because
 - hybrids are always at a disadvantage.
 - hybrids have an advantage only in narrow zones.
 - hybrid individuals never move far from their birthplaces.
 - individuals that move into the zone have not previously encountered individuals of the other species, so reinforcement of reproductive barriers has not occurred.
 - Narrow hybrid zones are artifacts because biologists generally restrict their studies to contact zones between species.

7. Which statement about speciation is *not* true?
 - a. It always takes thousands of years.
 - b. Reproductive isolation may develop slowly between diverging lineages.
 - c. Among animals, it usually requires a physical barrier.
 - d. Among plants, it often happens as a result of polyploidy.
 - e. It has produced the millions of species living today.
8. Which of the following is often associated with higher rates of speciation?
 - a. Sexually dimorphic compared with sexually monomorphic birds
 - b. Insects with specialized diets compared with insects with generalized diets
 - c. Species with low dispersal ability compared with species with high dispersal ability
 - d. Plants with animal pollination compared with plants with wind pollination
 - e. All of the above
9. Evolutionary radiations
 - a. happen often on continents but rarely on island archipelagoes.
 - b. characterize birds and plants but not other groups of organisms.
 - c. have happened on continents as well as on islands.
 - d. require major reorganizations of the genome.
 - e. never happen in species-poor environments.
10. Speciation is an important component of evolution because it
 - a. generates the variation on which natural selection acts.
 - b. generates the variation on which genetic drift and mutations act.
 - c. enabled Charles Darwin to perceive the mechanisms of evolution.
 - d. generates the high extinction rates that drive evolutionary change.
 - e. has resulted in a world with millions of species, each adapted for a particular way of life.

FOR DISCUSSION

1. The North American snow goose has two distinct color forms, blue and white. Matings between the two color forms are common. However, blue individuals pair with blue individuals and white individuals pair with white individuals much more frequently than would be expected by chance. Suppose that blue and white snow geese are equally frequent in a population, and that 75 percent of all mated pairs consist of two individuals of the same color. What would you conclude about speciation processes in these geese? What if 100 percent of pairs were the same color?
2. Suppose pairs of snow geese of mixed colors were found only in a narrow zone within the broad Arctic breeding range of the geese, with blue geese found on one side and white geese found on the other side of this narrow zone. Would your answer to Question 1 remain the same?
3. Although many butterfly species are divided into local populations among which there is little gene flow, these species often show relatively little morphological variation among populations. Describe the studies you would conduct to determine what maintains this morphological similarity.
4. Evolutionary radiations are common and easily studied on oceanic islands. In what types of *mainland* situations would you expect to find major evolutionary radiations? Why?
5. Fruit flies of the genus *Drosophila* are distributed worldwide, but 30 to 40 percent of all the species in the genus are found on the Hawaiian Islands (which comprise far less than 1% of Earth's total land area). What might account for this distribution pattern?
6. What factors can cause extinction rates to exceed speciation rates in a clade? Name some clades in which human activities are increasing extinction rates without increasing speciation rates.
7. If it is true that natural selection does not directly favor lower viability of hybrids, why is it that hybrid individuals so often have lowered viability?

ADDITIONAL INVESTIGATION

In the two *Aquilegia* species shown in Figure 23.12, the orientation of the flowers and the length of flower spurs are associated with the respective pollinator species (hummingbirds and hawkmoths). Columbine flowers vary in other ways as well; for

example, they differ in color, and probably in odor. What experiments could you design to determine the traits that various pollinators use to distinguish among the flowers of different columbine species?

WORKING WITH DATA (GO TO yourBioPortal.com)

Examining Evidence for Reinforcement of Prezygotic Barriers

In this exercise based on Figure 23.13, you will examine some of the data collected by Don Levin to study reinforcement of

prezygotic reproductive barriers in *Phlox*. You will also critique the study design of the experiment, and consider alternative explanations for the results.

Shocking evolution

Some fishes, including the famous electric eel of Central and South America, can produce high-voltage discharges of electricity (up to 650 volts) that they use to stun their prey. A variety of other fish species are known to produce somewhat weaker electric discharges. Most of these latter species live in murky water where visual cues are limited; they use electric signals to locate (but not to stun) their prey. Electric signals also allow them to communicate with other individuals of their own species.

Electric organs have evolved independently in several fish lineages. How did these organs evolve? Let's consider first the physical basis of the electrical signal. *Voltage-gated sodium channels* are large proteins that underlie the generation and propagation of rapid electrical signals in nerve, muscle, and heart tissues (see Chapter 45). Electric signals are transmitted along nerves to muscles as the sodium channels embedded in cell membranes are stimulated to open. These channels control the concentration of positively charged sodium ions (Na^+) on the inside relative to the outside of cells, resulting in an electric charge

that is transmitted across the surface of the muscle, leading to muscular contraction.

Most vertebrates have a number of different copies of the genes encoding the several proteins that make up the sodium channel. These copies arose through a series of *gene duplications* in the distant past of vertebrate genome evolution. Such duplications allowed for the specialization of protein function, making it possible for different sodium channels to exist in different types of tissue. In the case of electric fishes, one of the sodium channel genes ordinarily expressed in muscle diverged and a new functional protein evolved. Changes in a relatively small number of nucleotide positions in the gene resulted in modified sodium channels, allowing the development of a new organ with a unique function—the generation of externally transmitted electric energy.

The “living battery” electric organ differs from skeletal muscle in important ways. The organ is composed of many *electrocytes*, each of which is a derived muscle cell capable of producing a small electric charge. Electrocytes

are stacked in series, much like the plates in a car battery. Rather than producing muscle contraction and movement, however, the organ generates an electric discharge. This signal is species-specific, which allows intraspecific communication and also serves as an isolating mechanism between species (see Chapter 23).

The repeated evolution of electric organs from muscle tissue is facilitated by relatively simple molecular changes

An Electric Fish The elephant-nose fish (*Gnathonemus petersi*), a river-dwelling species from West Africa, is one of many fishes in which weakly discharging electric organs have evolved via modifications in sodium channel proteins.

A High-Voltage Electric Fish This torpedo ray can put out as much as 220 volts of electricity. So far this particular species remains unidentified; it has been found only in a single bay among the islands of Komodo National Park, Indonesia.

in certain genes, changes that result in major functional changes to sodium channels. Gene duplication facilitates the process, since “extra” genes allow for such specialization in protein function. Finally, interspecific differences in sodium channel function result from additional changes in nucleotide sequences of the respective genes. These small differences allow different species of fishes to use different communication signals, which improves intraspecific communication while reducing interspecific interference.

The evolution of sodium channels is just one example of how an understanding of the evolution of genes and genomes helps biologists understand the diversity of life on Earth. Molecular investigations also allow biologists to observe the process of evolution directly in the laboratory, and to use evolutionary principles to produce new molecules with useful functions.

IN THIS CHAPTER we will see how molecular biologists infer both the patterns and the causes of molecular evolution from studies of nucleic acids and proteins. We will explore how the functions of molecules change, how genomes change in size, and where new genes come from. Finally, we will explore some practical applications of molecular evolution for producing new molecules with novel functions.

CHAPTER OUTLINE

- 24.1** How Are Genomes Used to Study Evolution?
- 24.2** What Do Genomes Reveal About Evolutionary Processes?
- 24.3** How Do Genomes Gain and Maintain Functions?
- 24.4** What Are Some Applications of Molecular Evolution?

24.1 How Are Genomes Used to Study Evolution?

An organism’s **genome** is the full set of genes it contains, as well as any noncoding regions of the DNA (or in the case of some viruses, RNA). Most of the genes of eukaryotic organisms are found on chromosomes in the nucleus, but genes are also present in chloroplasts and mitochondria. In organisms that reproduce sexually, both males and females transmit nuclear genes, but mitochondrial and chloroplast genes usually are transmitted only via the cytoplasm of one of the two gametes (usually from the female parent).

Genomes must be replicated to be transmitted from parents to offspring. DNA replication does not occur without error, however. Mistakes in DNA replication—mutations—provide much of the raw material for evolutionary change. Mutations are essential for the long-term survival of life, because they are the initial source of the genetic variation that permits organisms to evolve in response to changes in their environment.

A particular copy of a gene will not be passed on to successive generations unless an individual with that copy survives and reproduces. Therefore, the capacity to cooperate with different combinations of other genes is likely to increase the probability that a particular allele will become fixed in a population. Moreover, the degree and timing of a gene’s expression are affected by its location in the genome. For these reasons, the genes of an individual organism can be viewed as interacting members of a group, among which there are divisions of labor but also strong interdependencies.

A genome, then, is not simply a random collection of genes in random order along chromosomes. Rather, it is a complex set of integrated genes, regulatory sequences, and structural elements, as well as vast stretches of noncoding DNA that may have little direct function. The positions of genes, as well as their sequences, are subject to evolutionary change, as are the extent and location of noncoding DNA. All of these changes can affect the phenotype of an organism. Biologists have now sequenced the complete genomes of a large number of organisms, including humans. This information is helping us to understand how and why organisms differ, how they function, and how they have evolved.

Evolution of genomes results in biological diversity

The field of **molecular evolution** investigates the mechanisms and consequences of the evolution of macromolecules. Molecular evolutionists study relationships between the structures of genes and proteins and the functions of organisms. They also

examine molecular variation to reconstruct evolutionary history and to study the mechanisms and consequences of evolution. The molecules of special interest to molecular evolutionists are nucleic acids (DNA and RNA) and proteins. Students of this field ask questions such as: What does molecular variation tell us about a gene's function? Why do the genomes of different organisms vary in size? What evolutionary forces shape patterns of variation among genomes? And a crucial question from an evolutionary perspective, How do genomes acquire new functions? Investigations into the evolution of particular nucleic acids and proteins are instrumental in reconstructing the evolutionary histories of genes and in determining which organisms carry them. Ultimately, molecular evolutionists hope to explain the molecular basis of biological diversity.

The evolution of nucleic acids and proteins depends on genetic variation introduced by mutations. One of several ways in which genes evolve is by means of *nucleotide substitutions*. In genes that encode proteins, nucleotide substitutions sometimes result in amino acid replacements that can change the charge, the structure (secondary or tertiary), and other chemical and physical properties of the encoded protein. Phenotypic changes in the protein often affect the way that protein functions in the organism.

Evolutionary changes in genes and proteins can be identified by comparing the nucleotide or amino acid sequences of different organisms. The longer two sequences have been evolving separately, the more differences they accumulate (bearing in mind that different genes in the same species evolve at different rates). Determining when changes in nucleotide or amino acid sequences occurred is a first step toward inferring their causes. Knowledge of the pattern and rate of evolutionary change in a given macromolecule is useful in reconstructing the evolutionary history of groups of organisms.

To compare genes or proteins across different organisms, biologists need a way to identify homologous parts of molecules. (Recall from Section 22.1 that *homologous* features are shared by two or more species and have been inherited from a common ancestor.) Homologous parts of a protein can be traced to homologous amino acid sequences. And, since nucleotide sequences encode amino acid sequences, the concept of homology extends down to the level of individual nucleotide positions. Therefore, one of the first steps in studying the evolution of genes or proteins is to align homologous positions in the nucleotide or amino acid sequence of interest.

Genes and proteins are compared through sequence alignment

Once the DNA or amino acid sequences of molecules from different organisms have been determined, they can be compared. Homologous positions can be identified only if we first pinpoint the locations of deletions

TOOLS FOR INVESTIGATING LIFE

24.1 Amino Acid Sequence Alignment

Amino acid sequence alignment is a way of arranging protein sequences to identify regions of homology between the sequences. Gaps are inserted between the amino acid residues to align similar residues in columns. Differences and similarities between each pair of aligned sequences are then summarized in a similarity matrix. Homologous DNA sequences can be aligned in a similar manner.

1 Two amino acid sequences seem quite different...

2 ...but if we insert a gap in Sequence 2, there is nearly complete alignment.

3 With this alignment established, we can compare additional sequences.

Similarity matrix

		Sequence number					
		1	2	3	4	5	6
Sequence number	1		2	2	1	2	1
	2	5		0	3	4	3
	3	5	7		3	4	3
	4	6	4	4		1	2
	5	5	3	3	6		2
	6	6	4	4	5	5	

Numbers above the diagonal line are the number of differences.

Numbers below the diagonal line are similarities.

and insertions that have occurred in the molecules of interest in the time since the organisms diverged from a common ancestor. A simple hypothetical example illustrates this **sequence alignment** technique. In **Figure 24.1** we compare two amino acid sequences (1 and 2) from homologous proteins in different organisms. The two sequences at first appear to differ in both the number and identity of their amino acids, but if we insert a gap after the first amino acid in Sequence 2 (after leucine), similarities in the two sequences become more obvious. This gap represents the occurrence of one of two evolutionary events: an insertion of an amino acid in the longer protein, or a deletion of an amino acid in the shorter protein.

Having adjusted for this insertion or deletion event, we can see that the two sequences differ by only one amino acid at position 6 (serine or phenylalanine). Adding a single gap—that is, identifying a deletion or an insertion—*aligns* these sequences. Longer sequences and those that have diverged more extensively require more elaborate adjustments. Explicit models (incorporated into computer algorithms) have been developed to account for the relative probabilities of deletions, insertions, and particular amino acid replacements.

Having aligned the sequences, we can compare them by counting the number of nucleotides or amino acids that differ between them. Summing the number of similar and different amino acids in each pair of sequences allows us to construct a **similarity matrix**, which gives us a measure of the minimum number of changes that have occurred during the divergence between each pair of organisms (see Figure 24.1).

yourBioPortal.com

GO TO Web Activity 24.2 • Similarity Matrix Construction

Models of sequence evolution are used to calculate evolutionary divergence

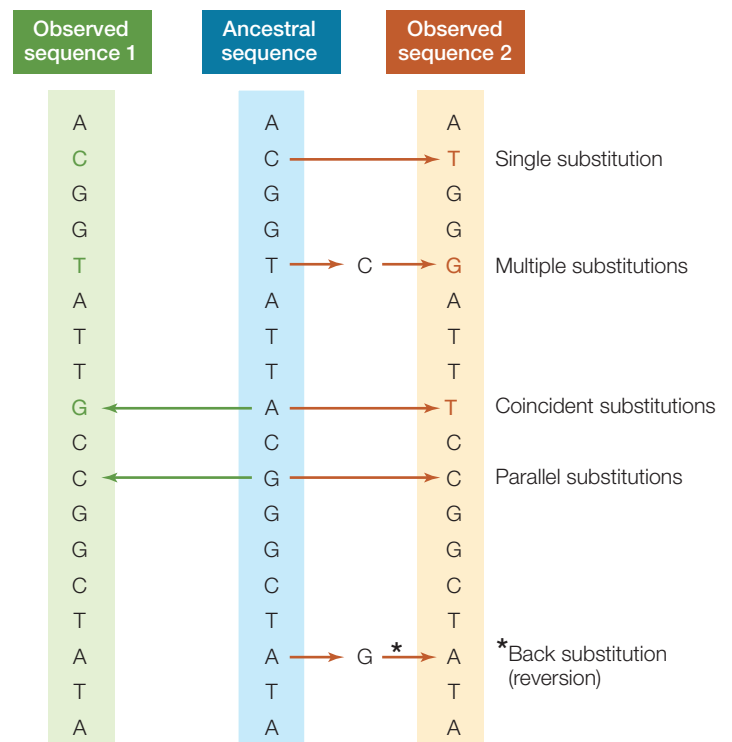

The sequence comparison procedure illustrated in Figure 24.1 gives a simple count of the number of differences and similarities between the proteins of two species. In the context of two aligned DNA sequences, we can count the number of differences at homologous nucleotide positions, and this count indicates the minimum number of nucleotide changes that must have occurred since the two sequences diverged from a common ancestral sequence.

Although it is useful in determining a *minimum* number of changes between two sequences, the count provided by sequence alignment almost certainly underestimates the actual number of changes that have occurred since the sequences diverged. Any given change counted in a similarity matrix of DNA sequences may result from multiple substitution events

that occurred at a given nucleotide position over time. As illustrated in **Figure 24.2**, any of the following events may have occurred at a given nucleotide position that would not be revealed by a simple count of similarities and differences between two DNA sequences:

- **Multiple substitutions.** More than one change occurs at a given position between the ancestral sequence and at least one of the observed sequences.
- **Coincident substitutions.** At a given position, different substitutions occur between the ancestral sequence and each observed sequence.
- **Parallel substitutions.** The same substitution occurs independently between the ancestral sequence and each observed sequence.
- **Back substitutions** (also called *reversions*). In a variation on multiple substitutions, after a change at a given position, a subsequent substitution changes the position back to the ancestral state.

To correct for undercounting of substitutions, molecular evolutionists have developed mathematical models that describe how DNA (and protein) sequences evolve. These models take into account the relative rates of change from one nucleotide to another; for example, *transitions* (changes between the two purines, $A \leftrightarrow G$, or between the two pyrimidines, $C \leftrightarrow T$) are more frequent than *transversions* (a purine is replaced by a pyrimidine, or vice versa). Models also include parameters such as the different rates of substitution across different parts of a gene and the proportions of each nucleotide present in a given sequence. Once such parameters have been estimated, the model

24.2 Multiple Substitutions Are Not Reflected in Pairwise Sequence Comparisons

Two observed sequences are descended from a common ancestral sequence (center) through a series of substitutions. Although the two observed sequences differ in only three nucleotide differences (colored letters), these three differences resulted from a total of nine substitutions (arrows).

24.3 Amino Acid Sequences of Cytochrome c The amino acid sequences shown in the table were obtained from analyses of the enzyme cytochrome c from 33 species of plants, fungi, and animals. Note the lack of variation across the sequences at positions 70–80, suggesting that this region is under strong stabilizing selection and that changing its amino acid sequence would impair the protein's function. The computer graphics at the upper left are created from these sequences and show the three-dimensional structures of tuna and rice cytochrome c. Alpha helices are in red, and the molecule's heme group is shown in yellow.

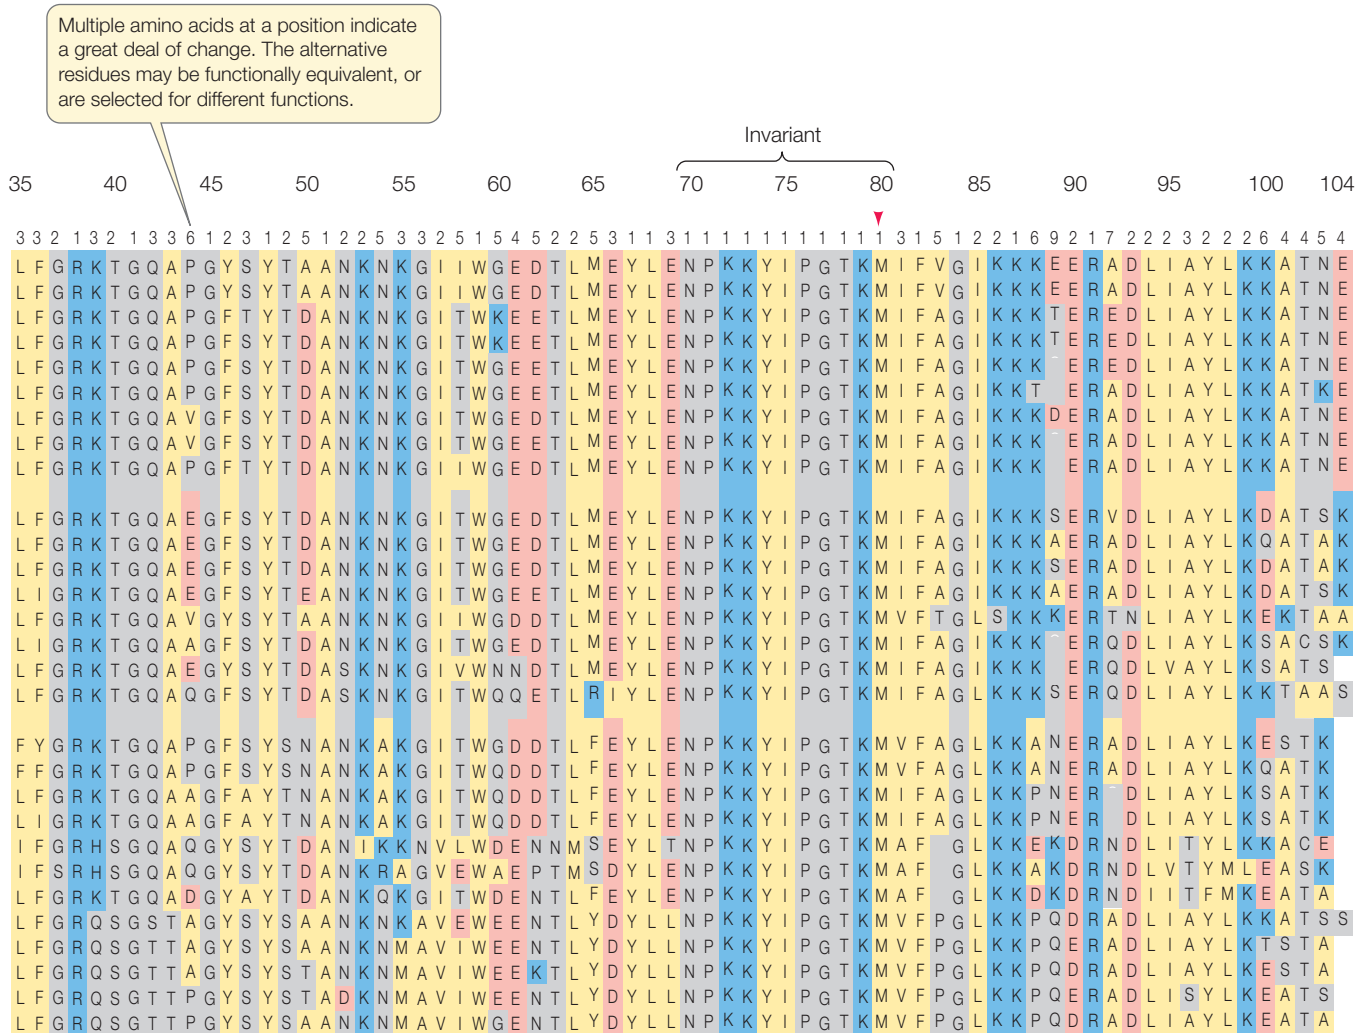

Gaps indicate insertion and/or deletion events.

is used to correct for multiple substitutions, coincident substitutions, parallel substitutions, and back substitutions. The revised estimate accounts for the *total* number of substitutions likely to have occurred between two sequences, which is almost always greater than the observed number of differences.

As sequence information becomes available for more and more genes in an ever-expanding database, sequence alignments can be extended across multiple homologous sequences, and the minimum number of insertions, deletions, and substitutions can be summed across homologous genes of an entire group of organisms. Similar databases have also been constructed for homologous proteins. **Figure 24.3** shows aligned data for cytochrome c protein sequences in 33 species of animals, plants, and fungi. Such information is used extensively in determining evolutionary relationships among species.

Experimental studies examine molecular evolution directly

Although molecular evolutionists are often interested in naturally evolved genes and proteins, molecular and phenotypic evolution can also be observed directly in the laboratory. Increasingly, evolutionary biologists are studying evolution experimentally. Because substitution rates are related to generation time rather than to absolute time, most of these experiments use unicellular organisms or viruses with short generations. Viruses, bacteria, and unicellular eukaryotes (such as the yeasts) can be cultured in large populations in the laboratory, and many of these organisms can evolve rapidly. In the case of some RNA viruses, the natural substitution rate may be as high as 1 substitution per 1,000 nucleotides per generation. Therefore, in a virus of a few thousand nucleotides, one

or more substitutions are expected (on average) every generation, and these changes can easily be determined by sequencing the entire genome (because of its small size). Generation time may be only tens of minutes (rather than years or decades, as in humans), so biologists can directly observe substantial molecular evolution in a controlled population over the course of days, weeks, or months.

An example of an experimental evolutionary study is shown in **Figure 24.4**. Paul Rainey and Michael Travisano wanted to examine a potential cause of adaptive radiations, which are a major source of biological diversity (see Section 23.4). For instance, near the beginning of the Cenozoic era, mammals rapidly diversified into species as diverse as elephants, moles, whales, and bats. While Rainey and Travisano clearly couldn't experimentally manipulate mammals over many millions of years, they could test the idea that heterogeneous environments with unoccupied niches lead to adaptive radiation by experimentally manipulating a bacterial lineage.

Rainey and Travisano inoculated several flasks containing culture medium with the same strain of the bacterium *Pseudomonas fluorescens*. They then shook some of the cultures

to maintain a constantly uniform environment. Others they left alone (static cultures), allowing them to develop a spatially distinct structure. In the static cultures, the environment on the surface film of the medium differed from that on the walls of the flasks and from parts of the culture not touching any surfaces.

When the cultures were started, the ancestral phenotype of the bacterium produced a smooth colony, which the investigators called a "smooth morph." In just a few days, however, the static cultures consistently and independently developed two other morphs: a "wrinkly spreader" and a "fuzzy spreader." The researchers determined that the two new morphs had a genetic basis and were adaptively superior in some of the environments found within the static cultures. For example, the "wrinkly spreader" cells adhered firmly to one another as well as to surfaces, and thus were able to form a mat across the surface of the medium, where they could compete successfully for oxygen.

DNA sequencing of the genomes of these morphs showed that the same phenotypes had evolved repeatedly, and that many different substitutions could produce the same phenotypes. The homogeneous shaken cultures, in contrast, showed no evolution in phenotype. The same mutations occurred in the

INVESTIGATING LIFE

24.4 Evolution in a Heterogeneous Environment

Rainey and Travisano cultured the rapidly evolving bacterium *Pseudomonas fluorescens* in homogeneous and heterogeneous environments to examine the relationship between phenotypic diversity and environmental variability.

HYPOTHESIS Heterogeneous environments are more conducive to the evolution of phenotypic diversity than are homogeneous environments.

METHOD One colony of *Pseudomonas fluorescens* (all of a single genotype) is used to inoculate many replicate cultures.

RESULTS In the shaken flasks, the ancestral morph persisted; the uniform environment did not result in morphological diversification. In the static flasks, two new morphotypes regularly arose, each adapted to a different local environment. Molecular analysis revealed that the mutations that produce these phenotypes arose in both shaken and static cultures, but the mutations did not persist in the uniform (shaken) environment because the phenotypes they produced were selectively disadvantageous under homogeneous conditions.

Smooth morph (ancestral)

"Wrinkly spreader"

"Fuzzy spreader"

CONCLUSION Phenotypic change and diversification are enhanced in a heterogeneous environment.

FURTHER INVESTIGATION: Do you think the two evolved phenotypes could compete in the homogeneous environment if they were introduced after having become successfully established in the heterogeneous environment? How would you test your hypothesis?

Go to yourBioPortal.com for original citations, discussions, and relevant links for INVESTIGATING LIFE figures.

shaken cultures but did not persist, because the novel phenotypes they produced were selectively disadvantageous (i.e., less fit) under the "shaken" environmental conditions.

Experimental molecular evolutionary studies are used for a wide variety of purposes and have greatly expanded the abil-

ity of evolutionary biologists to test evolutionary concepts and principles. Biologists now routinely study evolution in the laboratory and, as we will see later in this chapter, use in vitro evolutionary techniques to produce novel molecules that perform new functions with industrial and pharmaceutical uses.

24.5 When One Nucleotide Does or Doesn't Make a Difference

(A) Synonymous substitutions do not change the amino acid specified and do not affect protein function; such substitutions are less likely to be subject to natural selection. (B) Nonsynonymous substitutions do change the amino acid sequence and are likely to have an effect (often deleterious) on protein function; such substitutions are targets for natural selection.

24.1 RECAP

The genomes of all organisms evolve over time, as can be detected by direct observation in the laboratory, as well as by aligning genes and proteins between species. Experimental studies of molecular evolution allow biologists to study many processes of evolution directly under controlled conditions.

- How do biologists align nucleotide and amino acid sequences they wish to compare, and how do they calculate the minimum number of changes that have occurred between pairs of aligned sequences? **See pp. 500–501 and Figure 24.1**
- Explain why a simple count of nucleotide differences between two sequences underestimates the actual number of nucleotide substitutions since the sequences diverged. **See Figure 24.2**

We have seen that molecular evolutionists can directly observe the evolution of genomes over time, and can compare the genomes of different organisms and reconstruct the changes that have occurred during their evolution. Let's turn now to the question of how genomes change and examine some of the consequences of those changes.

24.2 What Do Genomes Reveal About Evolutionary Processes?

A *mutation*, as we saw in Chapter 15, is any change in the genetic material. A nucleotide substitution is one type of mutation. Many nucleotide substitutions have no effect on phenotype, even if the change occurs in a gene that encodes a protein, because most amino acids are specified by more than one codon (see Figure 14.6). A substitution that does not change the encoded amino acid is known as a **synonymous substitution** or **silent substitution** (Figure 24.5A). Synonymous substitutions do not affect the functioning of a protein (although they may have other effects, such as changes in mRNA stability or translation rates; see Section 14.5), and are therefore less likely to be influenced by natural selection.

A nucleotide substitution that *does* change the amino acid sequence encoded by a gene is known as a **nonsynonymous substitution**, also known as a *missense substitution* (Figure 24.5B). In general, nonsynonymous substitutions are more likely to be deleterious to the organism. But not every amino acid replacement alters a protein's shape and charge (and hence its functional properties). Therefore, some nonsynonymous substitutions may also be selectively neutral, or nearly so. Conversely, an amino acid replacement that confers an advantage to the organism would result in positive selection for the corresponding nonsynonymous substitution.

The rate of nonsynonymous nucleotide substitutions in several mammalian protein-coding genes is about 3×10^{-9} substitutions per position per year. Synonymous substitutions in these genes have occurred about five times more frequently than nonsynonymous substitutions. In other words, *substitution rates are highest at nucleotide positions that do not change the amino acid being expressed* (Figure 24.6). The rate of substitution is even higher in **pseudogenes**, which are duplicate copies of genes that are no longer functional.

As we saw Chapter 21, most natural populations harbor far more genetic variation than we would expect to find if genetic

24.6 Rates of Substitution Differ Rates of nonsynonymous substitution typically are much lower than rates of synonymous substitution and the substitution rate in pseudogenes. This pattern reflects differing levels of functional constraints.

variation were influenced by natural selection alone. This discovery, combined with the knowledge that many mutations do not change molecular function, stimulated the development of the *neutral theory* of molecular evolution.

Much of evolution is neutral

In 1968, Motoo Kimura proposed the *neutral theory of molecular evolution*. Kimura suggested that, at the molecular level, the majority of variants we observe in most populations are selectively neutral; that is, they confer neither an advantage nor a disadvantage on their bearers. Therefore, these neutral variants accumulate through genetic drift rather than through positive selection.

The rate of fixation of neutral mutations by genetic drift is independent of population size. To see why this is so, consider a population of size N and a neutral mutation rate μ (mu) per gamete per generation at a locus. The number of new mutations would be, on average, $\mu \times 2N$, because $2N$ gene copies are available to mutate in a population of diploid organisms. The probability that a given mutation will be fixed by drift alone is its frequency, which equals $1/(2N)$ for a newly arisen mutation. We can multiply these two terms to get the rate of fixation of neutral mutations in a given population of N individuals:

$$2N\mu \frac{1}{2N} = \mu$$

Therefore, the rate of fixation of neutral mutations depends only on the neutral mutation rate μ and is independent of population size. A given mutation is more likely to appear in a large population than in a small one, but any mutation that does appear is more likely to become fixed in a small population. These two influences of population size cancel each other out.

Therefore, the rate of fixation of neutral mutations is equal to the mutation rate. As long as the underlying mutation rate is constant, macromolecules evolving in different populations should diverge from one another in neutral changes at a constant rate. Empirically, the rate of evolution of particular genes and proteins is often relatively constant over time, and therefore can be used as a “molecular clock.” As we described in Section 22.3, molecular clocks can be used to calculate evolutionary divergence times between species.

Although much of the genetic variation we observe in populations is the result of neutral evolution, the neutral theory does not imply that most mutations have no effect on the organism. Many mutations are never observed in populations because they are lethal or strongly detrimental to the organism and are thus quickly removed from the population through natural selection. Similarly, mutations that confer a selective advantage tend to be quickly fixed in populations, so they do not result in variation at the population level either. Nonetheless, if we compare homologous proteins from different populations or species, some amino acid positions will remain constant under purifying selection, others will vary through neutral genetic drift, and still others will differ between species as a result of positive selection for change. How can these evolutionary processes be distinguished?

Positive and purifying selection can be detected in the genome

As we have just seen, substitutions in a protein-coding gene can be either synonymous or nonsynonymous, depending on whether they change the resulting amino acid sequence of the protein. The relative rates of synonymous and nonsynonymous substitutions are expected to differ in regions of genes that are evolving neutrally, under positive selection for change, or staying unchanged under purifying selection.

- If a given amino acid in a protein can be one of many alternatives (without changing the protein’s function), then an amino acid replacement is *neutral* with respect to the fitness of an organism. In this case, the rates of synonymous and nonsynonymous substitutions in the corresponding DNA sequences are expected to be very similar, so the ratio of the two rates would be close to 1.
- If a given amino acid position is under *positive selection for change*, the rate of nonsynonymous substitutions is expected to exceed the rate of synonymous substitutions in the corresponding DNA sequences.
- If a given amino acid position is under *purifying selection*, then the rate of synonymous substitutions in the corresponding DNA sequences is expected to be much higher than the rate of nonsynonymous substitutions.

By comparing the gene sequences that encode proteins from many species, scientists can determine the history and timing of synonymous and nonsynonymous substitutions. This information can be mapped on a phylogenetic tree, as we saw in Chapter 22.

Regions of genes that are evolving under neutral, purifying, or positive selection can be identified by comparing the nature and rates of substitutions across the phylogenetic tree. The evolution of lysozyme illustrates how and why particular positions of a gene sequence might be under different modes of selection.

The enzyme lysozyme (see Figure 3.8) is found in almost all animals. It is produced in the tears, saliva, and milk of mammals and in the albumen (whites) of bird eggs. Lysozyme digests the cell walls of bacteria, rupturing and killing them. As a result, it plays an important role as a first line of defense against invading bacteria. Most animals defend themselves against bacteria by digesting them, which is probably why most animals have lysozyme. Some animals also use lysozyme in the digestion of food.

Among mammals, a mode of digestion called *foregut fermentation* has evolved twice. In mammals with this mode of digestion, the foregut—the posterior esophagus and/or the stomach—has been converted into a chamber in which bacteria break down ingested plant matter by fermentation. Foregut fermenters can obtain nutrients from the otherwise indigestible cellulose that makes up a large proportion of plant tissue. Foregut fermentation evolved independently in ruminants (a group of hooved mammals that includes cattle) and in certain leaf-eating monkeys, such as langurs. We know these evolutionary events were independent, because both langurs and ruminants have close relatives that are not foregut fermenters.

In both foregut-fermenting lineages, the enzyme lysozyme has been modified to play a new, nondefensive role. This lysozyme ruptures some of the bacteria that live in the foregut, releasing nutrients metabolized by the bacteria, which the mammal then absorbs. How many changes in the lysozyme molecule were needed to allow it to perform this function amid the digestive enzymes and acidic conditions of the mammalian foregut? To answer this question, molecular evolutionists compared the lysozyme-coding sequences in foregut fermenters with those in several of their nonfermenting relatives. They determined which amino acids differed and which were shared among the species (**Figure 24.7A**), as well as the rates of synonymous and nonsynonymous substitutions in lysozyme genes across the evolutionary history of the sampled species.

For many of the amino acid positions of lysozyme, the rate of synonymous substitutions (in the corresponding gene) is much higher than the rate of nonsynonymous substitutions. This observation indicates that many of the amino acids that make up lysozyme are evolving under purifying selection. In other words, there is selection against change in the protein at these positions, and the observed amino acids must therefore be critical for lysozyme function. At other positions, several different amino acids function equally well, and the corresponding regions of the genes have similar rates of synonymous and nonsynonymous substitutions. The most striking finding is that amino acid replacements in lysozyme happened at a much higher rate in the lineage leading to langurs than in any other primates. The high rate of nonsynonymous substitutions in the langur lysozyme gene shows that lysozyme went through a period of rapid change in adapting to the stomachs of langurs. Moreover, the lysozymes of langurs and cattle share five amino acid replacements, all of which lie on the surface of the lysozyme molecule, well away from the enzyme's active site. Several of these shared replacements involve changes from arginine to lysine, which makes the proteins more resistant to at-

tack by the stomach enzyme pepsin. By understanding the functional significance of amino acid replacements, molecular evolutionists can explain the observed changes in amino acid sequences in terms of changes in the functioning of the protein.

A large body of fossil, morphological, and molecular evidence shows that langurs and cattle do not share a recent common ancestor. However, langur and ruminant lysozymes share several amino acids that neither mammal shares with the lysozymes of its own closer relatives. The lysozymes of these two mammals have undergone *evolutionary convergence* at some amino acid positions despite their very different ancestry. The amino acids they share give these lysozymes the ability to lyse the bacteria that ferment plant material in the foregut.

The hoatzin, an unusual leaf-eating South American bird and the only known avian foregut fermenter, offers another remarkable story of the convergent evolution of lysozyme (**Figure 24.7B**). Many birds have an enlarged esophageal chamber called a *crop*. The crop of the hoatzin contains lysozyme and bacteria and acts as a fermenting chamber. Many of the amino acid replacements that occurred in the adaptation of hoatzin crop lysozyme are identical to those that evolved in ruminants and langurs. Thus, even though the hoatzin and foregut-fermenting mammals have not shared a common ancestor in hundreds of millions of years, they have all evolved similar adaptations in their lysozymes that enable them to recover nutrients from their fermenting bacteria.

Genome size and organization also evolve

We know that genome size varies tremendously among organisms. Across broad taxonomic categories, there is some correlation between genome size and organismal complexity. The

24.7 Convergent Molecular Evolution of Lysozyme (A) The number of amino acid differences in the lysozymes of several pairs of mammals are shown above the diagonal line; the number of convergent similarities between these same pairs are shown below the diagonal. The two foregut-fermenting species share convergent amino acid replacements related to this digestive adaptation. (B) The hoatzin—the only known foregut-fermenting bird species—has been evolving independently from mammals for hundreds of millions of years but has independently evolved similar modifications to lysozyme.

24.8 Genome Size Varies Widely This figure shows the number of genes from a sample of organisms with fully sequenced genomes, arranged by their evolutionary relationships. Bacteria and archaea typically have fewer genes than most eukaryotes. Among eukaryotes, multicellular organisms with tissue organization (plants and animals; blue branches) have more genes than single-celled organisms (red branches) or multicellular organisms that lack pronounced tissue organization (green branches).

genome of the tiny bacterium *Mycoplasma genitalium* has only 470 genes. *Rickettsia prowazekii*, the bacterium that causes typhus, has 634 genes. *Homo sapiens*, by contrast, has about 23,000 protein-coding genes. **Figure 24.8** shows the number of genes from a sample of organisms with fully sequenced genomes, arranged by their evolutionary relationships. As this figure reveals, however, a larger genome does not always indicate greater complexity (compare rice to the other plants, for example). It is not surprising that more complex genetic instructions are needed for building and maintaining a large, multicellular organism than a small, single-celled bacterium. What is surprising is that some organisms, such as lungfishes, some salamanders, and lilies, have about 40 times as much DNA as humans do. Structurally, a lungfish or a lily is not 40 times more complex than a human. So why does genome size vary so much?

Differences in genome size are not so great if we take into account only the portion of DNA that actually encodes RNAs or proteins. The organisms with the largest total amounts of nuclear DNA (some ferns and flowering plants) have 80,000 times as much DNA as do the bacteria with the smallest genomes, but no species has more than about 100 times as many protein-coding genes as a bacterium. Therefore, much of the variation in genome size lies not in the number of functional genes but in the amount of noncoding DNA (**Figure 24.9**).

Why do the cells of most eukaryotic organisms have so much noncoding DNA? Does this noncoding DNA have a function, or is it “junk”? Although some of this DNA does not appear to have a direct function, it can alter the expression of the surrounding genes. The degree or timing of gene expression can be changed dramatically depending on the gene’s position relative to noncoding sequences. Other regions of noncoding DNA consist of pseudogenes that are simply carried in the genome because the cost of doing so is very small. These pseudogenes may become the raw material for the evolution of new genes with novel functions. Some noncoding sequences function in maintaining chromosomal structure. Still others consist of parasitic transposable elements that spread through populations because they reproduce faster than the host genome.

24.9 A Large Proportion of DNA Is Noncoding Most of the DNA of bacteria and yeasts encodes RNAs or proteins, but a large percentage of the DNA of multicellular species is noncoding.

Investigators can use retrotransposons to estimate the rates at which species lose DNA. Retrotransposons are transposable elements (see Figure 17.5) that copy themselves through an RNA intermediate. The most common type of retrotransposon carries duplicated sequences at each end, called long terminal repeats, or LTRs. Occasionally, LTRs recombine in the host genome, so that the DNA between them is excised. When this happens, one recombined LTR is left behind. The number of such “orphaned” LTRs in a genome is a measure of how many retrotransposons have been lost. By comparing the number of LTRs in the genomes of Hawaiian crickets (*Laupala*) and fruit flies (*Drosophila*), investigators found that *Laupala* loses DNA more than 40 times more slowly than does *Drosophila*. Therefore, it is not surprising that the genome of *Laupala* is much larger than that of *Drosophila*.

Why do species differ so greatly in the rate at which they gain or lose apparently functionless DNA? One hypothesis is that genome size is related to the rate at which the organism develops, which may be under selection pressure. Large genomes can slow down the rate of development and thus alter the relative timing of expression of particular genes. As discussed in Section 20.2, changes in the timing of gene expression (*heterochrony*) can produce major changes in phenotype. Thus, although some noncoding DNA sequences may have no direct function, they may still affect the development of the organism.

Another hypothesis is that the proportion of noncoding DNA is related primarily to population size. Noncoding sequences that are only slightly deleterious to the organism are likely to be purged by selection most efficiently in species with large population sizes. In species with small populations, the effects of genetic drift can overwhelm selection against noncoding sequences that have small deleterious consequences. Therefore, selection against the accumulation of noncoding sequences is most effective in species with large populations, so such species (such as bacteria or yeasts) have relatively little noncoding DNA compared with species with small populations (see Figure 24.9).

24.2 RECAP

By examining the relative rates of synonymous and nonsynonymous substitutions in genes across evolutionary history, biologists can distinguish the evolutionary mechanisms acting on individual genes. Neutral theory provides an explanation for the relatively constant rate of molecular change seen in many species.

- Describe how the ratio of synonymous to nonsynonymous substitutions can be used to determine whether a particular gene region is evolving neutrally, under positive selection, or under stabilizing selection. **See pp. 505–506 and Figure 24.6**
- Contrast two hypotheses for the wide diversity of genome sizes among different organisms. **See pp. 508–509**

We have examined some of the ways that biologists can use genomes to study the molecular mechanisms of evolution. But how do organisms gain new functions through time?

24.3 How Do Genomes Gain and Maintain Functions?

As we noted in the previous section, most multicellular organisms have many more genes than do most unicellular species. But multicellular organisms evolved from unicellular ancestors. Therefore, some mechanisms must exist that result in the increase of gene numbers within genomes over evolutionary time. There are two primary ways to accomplish this increase: genes can be transferred from other species, or genes can be duplicated within species.

Lateral gene transfer can result in the gain of new functions

In Chapter 22, we noted that the tree of life is usually visualized as a branching diagram, with each lineage dividing into two (or more) lineages through time, from one common ancestor to the millions of species that are alive today. Chapter 23 described how, in the process of speciation, ancestral lineages divide into descendant lineages, and it is those speciation events that the tree of life captures. However, there are also processes of **lateral gene transfer**, which allow individual genes, organelles, or fragments of genomes to move horizontally from one lineage to another. Some species may pick up fragments of DNA directly from the environment. Other genes may be picked up in a viral genome and then transferred to a new host when the virus becomes integrated in the new host’s genome. Hybridization between species also results in the transfer of large numbers of genes.

Lateral gene transfer can be highly advantageous to the species that incorporates novel genes from a distant relative. Genes that confer antibiotic resistance, for example, are com-

monly transferred among different species of bacteria. Lateral gene transfer is another way, in addition to mutation and recombination, that species can increase their genetic variability. Genetic variability then provides the raw material on which selection acts, resulting in evolution.

A phylogenetic tree constructed from a single laterally transferred genome fragment is likely to reflect only that transfer event, rather than the overall organismal phylogeny (see Section 26.3). Most biologists prefer to build trees from large samples of genes or their products, so that the underlying species tree (as well as any lateral gene transfer events) can be reconstructed. The depiction of lateral gene transfer events on the underlying species tree are known as *reticulations* on the phylogenetic tree.

The degree to which lateral gene transfer events occur in various parts of the tree of life is a matter of considerable current investigation and debate. Lateral gene transfer appears to be relatively uncommon among most eukaryote lineages, although the two major endosymbioses that gave rise to mitochondria and chloroplasts can be viewed as lateral transfers of entire bacteria genomes to the eukaryote lineage. Some groups of eukaryotes, most notably some plants, are subject to relatively high levels of hybridization among closely related species. Hybridization leads to the exchange of many genes among recently separated lineages of plants. The greatest degree of lateral transfer, however, appears to occur among species of bacteria. Many bacteria genes have been transferred repeatedly among lineages of bacteria, to the point that relationships among the bacteria species are often hard to decipher. Nonetheless, the broad relationships of the major groups of bacteria can still be determined (as we will discuss in Part Seven of this book). Lateral transfer of genes makes it difficult to identify the boundaries of bacteria species, which is one reason why fewer bacteria species have been named than are known to exist.

Most new functions arise following gene duplication

Gene duplication is yet another way in which genomes can acquire new functions. When a gene is duplicated, one copy of that gene is potentially freed from having to perform its original function. The identical copies of a duplicated gene can have any one of four different fates:

- Both copies of the gene may retain their original function (which can result in a change in the amount of gene product that is produced by the organism).
- Both copies of the gene may retain the ability to produce the original gene product, but the expression of the genes may diverge in different tissues or at different times of development.
- One copy of the gene may be incapacitated by the accumulation of deleterious substitutions and become a functionless pseudogene.
- One copy of the gene may retain its original function while the second copy accumulates enough substitutions that it can perform a different function.

How often do gene duplications arise, and which of these four outcomes is most likely? Investigators have found that rates of gene duplication are fast enough for a yeast or *Drosophila* population to acquire several hundred duplicate genes over the course of a million years. They have also found that most of the duplicated genes in these organisms are very young. Many extra genes are lost from a genome within 10 million years (which is rapid on an evolutionary time scale).

Many gene duplications affect only one or a few genes at a time, but entire genomes are often duplicated in polyploid organisms (including many plants). When all the genes are duplicated, there are massive opportunities for new functions to evolve. That is exactly what appears to have happened in the evolution of vertebrates. The genomes of the jawed vertebrates appear to have four diploid sets of many major genes, which leads biologists to believe that two genome-wide duplication events occurred in the ancestor of these species. These duplications have allowed considerable specialization of individual vertebrate genes, many of which are now highly tissue-specific in their expression. A good example is the duplication of sodium channel genes, which allowed the evolution of the electric organs of electric fishes described in the opening of this chapter.

Although many extra genes disappear rapidly, some duplication events lead to the evolution of genes with new functions. Several successive rounds of duplication and mutation may result in a **gene family**, a group of homologous genes with related functions, often arrayed in tandem along a chromosome. An example of this process is provided by the *globin gene family* (see Figure 17.10). The globins were among the first proteins to be sequenced and compared. Comparisons of their amino acid sequences strongly suggest that the different globins arose via gene duplications. These comparisons can also tell us how long the globins have been evolving separately, because differences among these proteins have accumulated with time.

Hemoglobin, a tetramer (four-subunit molecule) consisting of two α -globin and two β -globin polypeptide chains, carries oxygen in blood. Myoglobin, a monomer, is the primary O_2 storage protein in muscle. Myoglobin's affinity for O_2 is much higher than that of hemoglobin, but hemoglobin has evolved to be more diversified in its role. Hemoglobin binds O_2 in the lungs or gills, where the O_2 concentration is relatively high, transports it to deep body tissues, where the O_2 concentration is low, and releases it in those tissues. With its more complex tetrameric structure, hemoglobin is able to carry four molecules of O_2 , as well as hydrogen ions and carbon dioxide, in the blood.

To estimate the time of the globin gene duplication that gave rise to the α - and β -globin gene clusters, we can create a phylogenetic tree of the gene sequences that encode the various globins (Figure 24.10). The rate of molecular evolution of globin genes has been estimated from other studies, using the divergence times of groups of vertebrates that are well documented in the fossil record. These studies indicate an average rate of divergence for globin genes of about 1 nucleotide substitution every 2 million years. Applying this rate to the gene tree, the two globin gene clusters are estimated to have split about 450 million years ago.

24.10 A Globin Family Gene Tree This gene tree suggests that the α -globin and β -globin gene clusters diverged about 450 million years ago (open circle), soon after the origin of the vertebrates.

Some gene families evolve through concerted evolution

Although the members of the globin gene family have diversified in form and function, the members of many other gene families do not evolve independently of one another. For instance, almost all organisms have many copies (up to thousands) of the ribosomal RNA genes. *Ribosomal RNA* (rRNA) is the principal structural element of ribosomes and, as such, has a primary role in protein synthesis. Every living species needs to synthesize proteins, often in large amounts (especially during early development). Having many copies of the rRNA genes ensures that organisms can rapidly produce many ribosomes and thereby maintain a high rate of protein synthesis.

Like all portions of the genome, ribosomal RNA genes evolve, and differences accumulate in the rRNA genes of different species. But within any one species, the multiple copies of rRNA genes are very similar, both structurally and functionally. This similarity makes sense, because ideally every ribosome in a species should synthesize proteins in the same way. In other words, within a given species, the multiple copies of these rRNA genes are evolving in concert with one another, a phenomenon called **concerted evolution**.

How does concerted evolution occur? There must be one or more mechanisms to cause a substitution in one copy to spread to other copies in a species so that all of the copies remain similar. In fact, two different mechanisms appear to be responsi-

ble for concerted evolution. The first of these is *unequal crossing over*. When DNA is replicated during meiosis in a diploid species, the homologous chromosome pairs align and recombine by crossing over (see Section 11.4).

In the case of highly repeated genes, however, it is easy for genes to become displaced in alignment, since so many copies of the same genes are present in the repeats (**Figure 24.11A**). The end result is that one chromosome will gain extra copies of the repeat and the other chromosome will have fewer copies of the repeat. If a new substitution arises in one copy of the repeat, it can spread to new copies (or be eliminated) through unequal crossing over. Thus, over time, a novel substitution will either become fixed or lost entirely from the repeat. In either case, all the copies of the repeat will remain very similar to one another.

The second mechanism that produces concerted evolution is *biased gene conversion*. This mechanism can be much faster than unequal crossing over, and has been shown to be the primary mechanism for concerted evolution of rRNA genes. DNA strands break often, and are repaired by the DNA repair systems of cells (see Section 13.4). At many times during the cell cycle, the genes for ribosomal RNA are clustered close together. If damage occurs to one of the genes, a copy of the rRNA gene on another chromosome may be used to repair the damaged copy, and the sequence that is used as a template can thereby replace the original sequence (**Figure 24.11B**). In many cases, this repair system appears to be biased in favor of using particular sequences as templates for repair, and thus the favored sequence rapidly spreads across all copies of the gene. In this way, changes may appear in a single copy and then rapidly spread to all the other copies.

Regardless of the mechanism responsible, the net result of concerted evolution is that the copies of a highly repeated gene do not evolve independently of one another. Mutations still oc-

(A) Unequal crossing over

(B) Biased gene conversion

cur, but once they arise in one copy, they either spread rapidly across all the copies or are lost from the genome completely. This process allows the products of each copy to remain similar through time in both sequence and function.

24.3 RECAP

Gene duplication can lead to the evolution of new functions. Lateral gene transfer can result in the spread of genetic functions between distantly related species. Some highly repeated genes evolve in concert, which maintains uniform functionality.

- Explain the potential advantages of lateral gene transfer. **See pp. 509–510**
- What are four possible outcomes of gene duplication? **See p. 510**
- Describe the pattern of concerted evolution among highly repeated genes and the mechanisms that lead to concerted evolution. **See p. 511 and Figure 24.11**

We have seen how the principles and methods of molecular evolution have opened new vistas in evolutionary science. Now let's consider some of the practical applications of this field.

24.11 Concerted Evolution Two mechanisms can produce concerted evolution of highly repeated genes. (A) Unequal crossing over results in deletions and duplications of a repeated gene. (B) Biased gene conversion can rapidly spread a new variant across multiple copies of a repeated gene.

24.4 What Are Some Applications of Molecular Evolution?

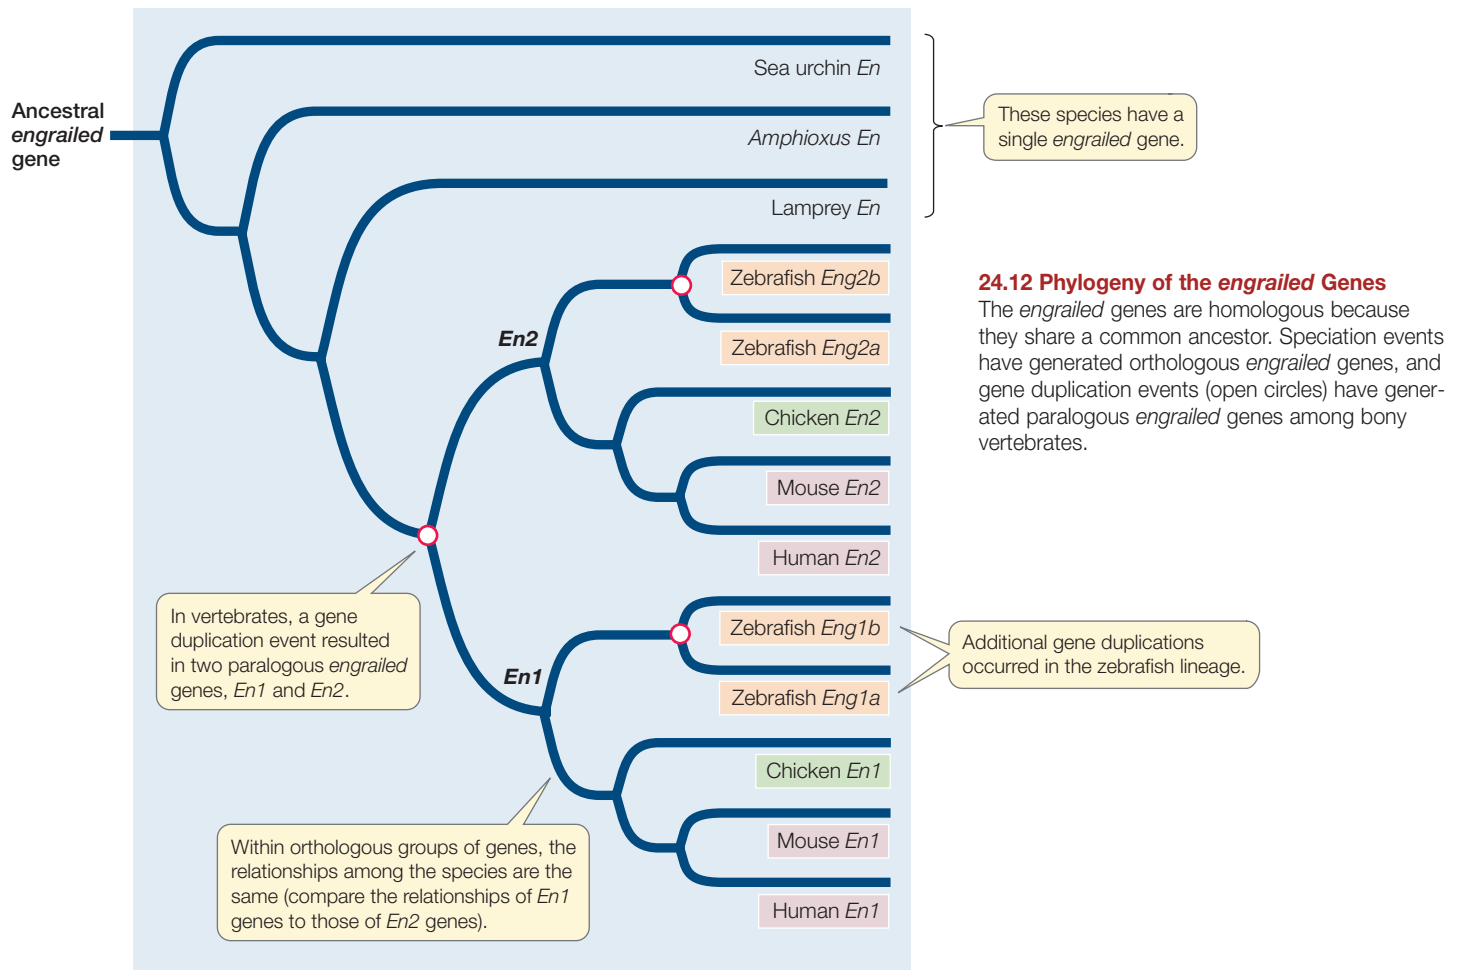

Our understanding of molecular biology has helped reveal how biological molecules function as well as how they diversify. Such knowledge allows scientists to create new molecules with novel functions in the laboratory, and to understand and treat disease.

Molecular sequence data are used to determine the evolutionary history of genes

A **gene tree** shows the evolutionary relationships of a single gene in different species or of the members of a gene family (as in Figure 24.10). The methods for constructing a gene tree are the same as those we described in Section 22.2 for building phylogenetic trees of species. The process involves identifying differences between genes and using those differences to reconstruct the evolutionary history of the genes. Gene trees are often used to infer phylogenetic trees of species, but the two types of trees are not necessarily equivalent. Processes such as gene duplication can give rise to differences between the phylogenetic trees of genes and species. From a gene tree, biologists can reconstruct the history and timing of gene duplication events and learn how gene diversification has resulted in the evolution of new protein functions.

All of the genes of a particular gene family have similar sequences because they have a common ancestry. As we discussed in Section 22.1, features that are similar as a result of common ancestry are referred to as *homologs* of one another. When discussing gene trees, however, we usually need to distinguish between two forms of homology. Genes found in different species, and whose divergence we can trace to the speciation events that gave rise to various species, are called **orthologs**. Genes in the same or different species that are related through gene duplication events are called **paralogs**. When we examine a gene tree, the questions we wish to address determine whether we should compare orthologous or paralogous genes. If we wish to reconstruct the evolutionary history of the species that contain the genes, then our comparison should be restricted to orthologs (because they will reflect the history of speciation events). If we are interested in the changes in function that have resulted from gene duplication events, however, then the appropriate comparison is among paralogs (because they will reflect the history of gene duplication events). If our focus is on the diversification of a gene family through both processes, then we will want to include both paralogs and orthologs in our analysis.

Figure 24.12 depicts a gene tree for the members of a gene family called *engrailed* (its members encode transcription factors

that regulate development). At least three gene duplications have occurred in this family, resulting in up to four different *engrailed* genes (*En*) in some vertebrate species (such as the zebrafish). All of the *engrailed* genes are homologs because they have a common ancestor. Gene duplication events have generated paralogous *engrailed* genes in some lineages of vertebrates. We could compare the orthologous sequences of the *En1* group of genes to reconstruct the history of the bony vertebrates (i.e., all the species in Figure 24.12 except the lamprey), or we could use the orthologous sequences of the *En2* group of genes and expect the same answer (because there is only one history of the underlying speciation events). All bony vertebrates have both groups of *engrailed* genes because the two groups arose from a gene duplication event in the common ancestor of bony vertebrates. If we wanted to focus on the diversification that occurred as a result of this duplication, then the appropriate comparison would be between the paralogous genes of the *En1* versus *En2* groups.

Gene evolution is used to study protein function

Earlier in this chapter we discussed the ways in which biologists can detect regions of genes that are under positive selection for change. What are the practical uses of this information? Consider the evolution of the family of gated sodium channel genes, which we introduced in the opening of this chapter. Sodium channels have many functions, including the control of nerve

impulses in the nervous system. Sodium channels can become blocked by various toxins, such as the tetrodotoxin that is present in puffer fishes and many other animals. A human who eats the tissues of a puffer fish that contain tetrodotoxin can become paralyzed and die, because the tetrodotoxin blocks sodium channels and prevents nerves and muscles from functioning.

Puffer fish themselves have sodium channels; so why doesn't the tetrodotoxin cause paralysis in a puffer fish? The sodium channels of puffer fish (and other animals that sequester tetrodotoxin) have evolved to become resistant to the toxin. Nucleotide substitutions in the puffer fish genome have resulted in changes to the proteins that make up sodium channels, and those changes prevent tetrodotoxin from binding to the sodium channel pore and blocking it. Several different substitutions that result in tetrodotoxin resistance have evolved in the various duplicated sodium channel genes of the many species of puffer fish.

Many other changes that have nothing to do with the evolution of tetrodotoxin resistance have occurred in these genes as well. Biologists who study the function of sodium channels can learn a great deal about how the channels work (and about neurological diseases that are caused by mutations in the sodium channel genes) by understanding which changes have been selected for tetrodotoxin resistance. They can do this by comparing the rates of synonymous and nonsynonymous substitutions across the genes in various lineages that have evolved tetrodo-

toxin resistance. In a similar manner, molecular evolutionary principles are used to understand function and diversification of function in many other proteins.

As biologists studied the relationship between selection, evolution, and function in macromolecules, they realized that molecular evolution could be used in a controlled laboratory environment to produce new molecules with novel and useful functions. Thus were born the applications of *in vitro* evolution.

In vitro evolution produces new molecules

Living organisms produce thousands of compounds that humans have found useful. The search for such naturally occurring compounds, which can be used for pharmaceutical, agricultural, or industrial purposes, has been termed *bioprospecting*. These compounds are the result of millions of years of molecular evolution across millions of species of living organisms. Yet biologists can imagine molecules that could have evolved but have not, lacking the right combination of selection pressures and opportunities.

For instance, we might like to have a molecule that binds a particular environmental contaminant so that it can be easily isolated and extracted from the environment. But if the environmental contaminant is synthetic (not produced naturally), then it is unlikely that any living organism would have evolved a molecule with the function we desire. This problem was the inspiration for the field of **in vitro evolution**, in which new molecules are produced in the laboratory to perform novel and useful functions.

The principles of *in vitro* evolution are based on the principles of molecular evolution that we have learned from the natural world. Consider the evolution of a new RNA molecule that was produced in the laboratory using the principles of mutation and selection. This molecule's intended function was to join two other RNA molecules (acting as a ribozyme with a function similar to that of the naturally occurring DNA ligase described in Section 13.3, but for RNA molecules). The process started with a large pool of random RNA sequences (10^{15} different sequences, each about 300 nucleotides long), which were then selected for any ligase activity (Figure 24.13). None were very effective ribozymes for ligase activity, but some were slightly better than others. The best of the ribozymes were selected and reverse-transcribed into cDNA (using the enzyme reverse transcriptase). The cDNA molecules were then amplified using the polymerase chain reaction (PCR; see Figure 13.22).

PCR amplification is not perfect, and it introduced many new mutations into the pool of sequences. These sequences were then transcribed back into RNA molecules using RNA polymerase, and the process was repeated. The ligase activity of the RNAs evolved quickly; after 10 rounds of *in vitro* evolution, it had increased by about 7 million times (see Figure 24.13). Similar techniques have since been used to create a wide variety of molecules with novel enzymatic and binding functions.

24.13 In Vitro Evolution Starting with a large pool of random RNA sequences, Bartel and Szostak produced a new ribozyme through rounds of mutation and selection for the ability to ligate RNA sequences.

Molecular evolution is used to study and combat diseases

Many of the most problematic human diseases are caused by living, evolving organisms that present a moving target for modern medicine. Recall the example of influenza described at the start of Chapter 21 and that of HIV described in Chapter 22. The control of these and many other human diseases depends on techniques that can track the evolution of pathogenic organisms through time.

During the past century, transportation advances have allowed humans to move around the world with unprecedented speed and increasing frequency. Unfortunately, this mobility has allowed pathogens to be transmitted among human populations at much higher rates, which has led to the global emergence of many “new” diseases. Most of these emerging diseases are caused by viruses, and virtually all new viral diseases have been identified by evolutionary comparison of their genomes with those of known viruses. In recent years, for example, ro-

dent-borne hantaviruses have been identified as the source of widespread respiratory illnesses, and the virus (and its host) that causes Sudden Acute Respiratory Syndrome (SARS) has been identified using evolutionary comparisons of genes. Studies of the origins, the timing of emergence, and the global diversity of many human pathogens depend on the principles of molecular evolution, as do the efforts to develop and use effective vaccines against these pathogens. For example, the techniques to develop polio vaccines, as well as the methods used to track their effectiveness in human populations, rely on molecular evolutionary approaches.

In the future, molecular evolution will become even more critical to the identification of human (and other) diseases. Once biologists have collected data on the genomes of enough organisms, it will be possible to identify an infection by sequencing a portion of the infecting organism's genome and comparing this sequence with other sequences on an evolutionary tree. At present, it is difficult to identify many common viral infections (those that cause "colds," for instance). As genomic databases and evolutionary trees increase, however, automated methods of sequencing and rapid phylogenetic comparison of the sequences will allow us to identify and treat a much wider array of human illnesses.

24.4 RECAP

Molecular evolutionary studies have provided biologists with new tools to understand the functions of macromolecules and how those functions can change through time. Molecular evolution is used to develop synthetic molecules for industrial and pharmaceutical uses and to identify and combat human diseases.

- Why might a biologist limit a particular investigation to orthologous (as opposed to paralogous) genes? **See pp. 512–513**
- Explain how gene evolution can be used to study protein function. **See pp. 513–514**
- Describe the process of in vitro evolution. **See p. 514 and Figure 24.13**

Now that we have discussed how organisms and biological molecules evolve, we are ready to consider the evolutionary history of the Earth. Chapter 25 describes the long-term evolutionary changes that have given rise to all of life's diversity.

CHAPTER SUMMARY

24.1 How Are Genomes Used to Study Evolution?

SEE WEB ACTIVITY 24.1

- The field of **molecular evolution** concerns relationships between the structures of genes and proteins and the functions of organisms.
- A **genome** is an organism's full set of genes and noncoding DNA. In eukaryotes, the genome includes genetic material in the nucleus of the cell as well as in mitochondria and chloroplasts (where present).
- Nucleotide substitutions may or may not result in amino acid replacements in the encoded proteins.
- The estimated number of substitutions between sequences can be calculated from a **similarity matrix** using models of sequence evolution that account for changes that cannot be observed directly. **Review Figure 24.1, WEB ACTIVITY 24.2**
- The concept of homology (similarity that results from common ancestry) extends down to the level of particular positions in nucleotide or amino acid sequences. **Sequence alignments** from different organisms allow us to compare the sequences and identify homologous positions. **Review Figure 24.3**

24.2 What Do Genomes Reveal about Evolutionary Processes?

- **Nonsynonymous substitutions** of nucleotides result in amino acid replacements in proteins, but **synonymous substitutions** do not. **Review Figure 24.5**
- Rates of synonymous substitution are typically higher than rates of nonsynonymous substitution in protein-coding genes (a result of stabilizing selection). **Review Figure 24.6**

- Much of the molecular change in nucleotide sequences is a result of **neutral evolution**. The rate of fixation of neutral mutations is independent of population size and is equal to the mutation rate.
- Positive selection for change in a protein-coding gene may be detected by a higher rate of nonsynonymous versus synonymous substitutions.
- Genome size evolves by the addition or deletion of genes and noncoding DNA. The total size of genomes varies much more widely across multicellular species than does the number of functional genes. **Review Figures 24.8 and 24.9**
- Even though many noncoding regions of the genome may not have direct functions, these regions can affect the phenotype of an organism by influencing gene expression.
- Functionless **pseudogenes** can serve as the raw material for the evolution of new genes.

24.3 How Do Genomes Gain and Maintain Functions?

- Lateral gene transfer can result in the rapid acquisition of new functions from distantly related species.
- **Gene duplications** can result in increased production of the gene's product, in pseudogenes, or in new gene functions. Several rounds of gene duplication can give rise to multiple genes with related functions, known as a **gene family**.
- Some highly repeated genes evolve by **concerted evolution**: multiple copies within an organism maintain high similarity, while the genes continue to diverge between species. **SEE ANIMATED TUTORIAL 24.1**

24.4 What Are Some Applications of Molecular Evolution?

SEE WEB ACTIVITY 24.3

- **Gene trees** describe the evolutionary history of particular genes or gene families.
- **Orthologs** are genes that are related through speciation events, whereas **paralogs** are genes that are related through gene duplication events. **Review Figure 24.12**
- Protein function can be studied by examining gene evolution. Detection of positive selection can be used to identify molecular changes that have resulted in functional changes.
- **In vitro evolution** is used to produce synthetic molecules with particular desired functions. **Review Figure 24.13**
- Many diseases are identified, studied, and combated through molecular evolutionary investigations.

SELF-QUIZ

- A higher rate of synonymous relative to nonsynonymous substitutions in a protein-coding gene is expected under
 - purifying selection.
 - positive selection.
 - neutral evolution.
 - concerted evolution.
 - none of the above
- Before nucleotide and amino acid sequences can be compared in an evolutionary framework, they must be aligned to account for
 - deletions and insertions.
 - selection and neutrality.
 - parallelisms and convergences.
 - gene families.
 - all of the above
- Models of nucleotide sequence evolution, developed by biologists to estimate sequence divergence, include parameters that account for
 - substitution rates between different nucleotides.
 - differences in substitution rates across different positions in a gene.
 - differences in nucleotide frequencies.
 - all of the above
 - none of the above
- The rate of fixation of neutral mutations is
 - independent of population size.
 - higher in small populations than in large populations.
 - higher in large populations than in small populations.
 - slower than the rate of fixation of deleterious mutations.
 - none of the above
- Genome size differs widely among different multicellular species of eukaryotes. What is the greatest contributing cause for these differences?
 - The number of protein-coding genes
 - The amount of noncoding DNA
 - The number of duplicated genes
 - The degree of concerted evolution
 - The amount of positive selection for change in protein-coding genes
- Which of the following is *not* true of concerted evolution?
 - Concerted evolution refers to the nonindependent evolution of some repeated genes within a species.
 - Unequal crossing over may produce concerted evolution.
 - Biased gene conversion may produce concerted evolution.
 - Ribosomal RNA genes are an example of a gene family that has undergone concerted evolution.
 - Concerted evolution results in divergence of members of a gene family within an organism.
- When a gene is duplicated, which of the following may occur?
 - Production of the gene's product may increase.
 - The two copies may become expressed in different tissues.
 - One copy of the gene may accumulate deleterious substitutions and become functionless.
 - The two copies may diverge and acquire different functions.
 - All of the above
- Paralogous genes are genes that trace back to a common
 - speciation event.
 - substitution event.
 - insertion event.
 - deletion event.
 - duplication event.
- Which of the following is true of in vitro evolution?
 - In vitro evolution refers to bioprospecting for naturally occurring macromolecules.
 - In vitro evolution can produce new molecular sequences not known from nature.
 - In vitro evolution can only produce new proteins.
 - In vitro evolution only selects for changes that were present in the starting pool of molecules, and does not introduce any new mutations.
 - All of the above
- Which of the following is true of the use of molecular evolutionary studies of human disease?
 - Molecular evolutionary studies are useful for identifying many diseases.
 - Molecular evolutionary studies are often used to determine the origin of emerging diseases.
 - Molecular evolutionary studies are important for developing vaccines against diseases.
 - Molecular evolutionary studies are used to track the effectiveness of polio vaccines in human populations.
 - All of the above

FOR DISCUSSION

1. Rates of evolutionary change differ among different molecules, and different species differ widely in generation times and population sizes. How does this variation limit how and in what ways we can use the concept of a molecular clock to help us answer questions about the evolution of both molecules and organisms?
2. One hypothesis proposed to explain the existence of large amounts of noncoding DNA is that the cost of maintaining that DNA is so small that natural selection is too weak to reduce it. How could you test this hypothesis against the hypothesis that genome size is functionally related to developmental rate?
3. If fossil evidence and molecular evidence disagree on the date of a major lineage split, which of the two kinds of evidence would you favor? Why?
4. Scientists can produce and release into the wild genetically modified mosquitoes that are unable to harbor and transmit malarial parasites. What ethical issues need to be discussed before such releases are permitted?

ADDITIONAL INVESTIGATION

Over evolutionary history, many groups of organisms that inhabit caves have lost the organs of sight. For instance, although surface-dwelling crayfishes have functional eyes, several crayfish species that are restricted to underground habitats lack eyes. Opsins are a group of light-sensitive proteins known to have an important function in vision (see Chapter 46), and opsin genes are expressed in eye tissues. Opsin genes are pres-

ent in the genomes of eyeless, cave-dwelling crayfish. Two alternative hypotheses are (1) the opsin genes are no longer experiencing purifying selection (because there is no longer selection for function in vision); or (2) the opsin genes are experiencing selection for a function other than vision. How would you investigate these alternatives using the sequences of the opsin genes in various species of crayfishes?

When hawk-sized dragonflies ruled the air

Almost anyone who has spent time around fresh water ponds is familiar with dragonflies. Their hovering flight, bright colors, and transparent wings stimulate our visual senses on bright summer afternoons as they fly about their business of devouring mosquitoes, mating, and laying their eggs. The largest dragonflies alive today have wingspans that can be covered by a human hand. Three hundred million years ago, however, dragonflies such as *Meganeuropsis permiana* had wingspans of more than 70 centimeters—well over 2 feet, matching or exceeding the wingspans of many modern birds of prey—and were the largest flying predators on Earth.

No flying insects alive today are anywhere near this size. But during the Carboniferous and Permian geological periods, between 350 and 250 million years ago, many groups of flying insects contained gigantic members. *Meganeuropsis* probably ate huge mayflies and other

giant flying insects that shared their home in the Permian swamps. These enormous insects were themselves eaten by giant amphibians.

None of the giant flying insects or amphibians of that time would be able to survive on Earth today. The oxygen concentrations in Earth's atmosphere were about 50 percent higher than they are now, and those high oxygen levels are thought to have been necessary to support giant insects and their huge amphibian predators.

Paleontologists have uncovered fossils of *Meganeuropsis permiana* in the rocks of Kansas. How do we know the age of these fossils, and how can we know how much oxygen that long-vanished atmosphere contained? The *stratigraphic* layering of the rocks allows us to tell their ages relative to each other, but it does not by itself indicate a given layer's absolute age.

One of the remarkable achievements of twentieth-century scientists was to develop sophisticated techniques that use the decay rates of various radioisotopes, changes in Earth's magnetic field, and the ratios of certain molecules to infer conditions and events in the remote past and to date them accurately. It is those methods that allow us to age the fossils of *Meganeuropsis* and to calculate the concentration of oxygen in Earth's atmosphere at the time.

The development of the science of biology is intimately linked to changing concepts of

Giant Dragonflies *Meganeuropsis permiana*, shown here in a reconstruction from fossils, dwarfed modern dragonflies (shown in the inset at the same scale) in size. Otherwise, however, the Permian giant was quite similar to modern dragonflies in general appearance.

Younger Rocks Lie on Top of Older Rocks In the Grand Canyon, the Colorado River cut through and exposed many strata of ancient rocks. The oldest rocks visible here formed about 540 million years ago. The youngest, at the top, are about 500 million years old. Knowing the ages of rock strata allows scientists to date the fossils found in each stratum.

time, especially of the age of Earth. About 150 years ago, geologists first provided solid evidence that Earth is ancient; before 1850, most people believed it was no more than a few thousand years old. For many more years, physicists continued to underestimate Earth's age, until an understanding of radioactive decay was developed. Today we know that Earth is about 4.5 billion years old and that life has existed on it for about 3.8 billion of those years. That means human civilizations have occupied Earth for less than 0.0003 percent of the history of life. Discovering what happened before humans were around is an ongoing and exciting area of science.

IN THIS CHAPTER we will examine how biologists assign dates to events in the distant evolutionary past, and how such dating allows us to review the major changes in physical conditions on Earth during the past 4 billion years. We will then look at how these changes in physical conditions have influenced the major patterns in the evolution of life, and describe how scientists organize our knowledge of biological diversity based on the relationships among species.

CHAPTER OUTLINE

- 25.1** How Do Scientists Date Ancient Events?
- 25.2** How Have Earth's Continents and Climates Changed over Time?
- 25.3** What Are the Major Events in Life's History?

25.1 How Do Scientists Date Ancient Events?

Many evolutionary changes happen rapidly enough to be studied directly and manipulated experimentally. Plant and animal breeding by agriculturalists and insects' evolution of resistance to pesticides are examples of rapid, short-term evolution. Other changes, such as the appearance of new species and evolutionary lineages, usually take place over much longer time frames.

To understand the long-term patterns of evolutionary change, we must think in time frames spanning many millions of years, and consider events and conditions very different from those we observe today. Earth of the distant past was so unlike the present that it seems like a foreign planet inhabited by strange organisms. The continents were not where they are today, and climates were sometimes dramatically different from those of today.

Fossils—the preserved remains of ancient organisms—can tell us a great deal about the body form, or *morphology*, of organisms that lived long ago, as well as how and where they lived. Fossils provide a direct record of evolution. But to understand patterns of evolutionary change, we must also understand how Earth has changed over time.

Earth's history is largely recorded in its rocks. We cannot tell the ages of rocks just by looking at them, but we can determine the ages of rocks relative to one another. The first person to formally recognize that this could be done was the seventeenth-century Danish physician Nicolaus Steno. Steno realized that in undisturbed **sedimentary rocks** (rocks formed by the accumulation of grains on the bottom of bodies of water), the oldest layers of rock, or **strata** (singular *stratum*), lie at the bottom; thus successively higher strata are progressively younger.

Geologists, particularly the eighteenth-century English scientist William Smith, subsequently combined Steno's insight with their observations of fossils contained in sedimentary rocks. They concluded that:

- Fossils of similar organisms are found in widely separated places on Earth.
- Certain fossils are always found in younger rocks, and certain other fossils in older rocks.
- Organisms found in higher, more recent strata are more similar to modern organisms than are those found in lower, more ancient strata.

These patterns revealed much about the relative ages of sedimentary rocks as well as patterns in the evolution of life. But the geologists still could not tell how old the rocks were. A method of dating rocks did not become available until after radioactivity was discovered at the beginning of the twentieth century.

Radioisotopes provide a way to date rocks

Radioactive isotopes of atoms (see Section 2.1) decay in a predictable pattern over long time periods. During each successive time interval, known as a **half-life**, half of the remaining radioactive material of the radioisotope decays to become a different, stable isotope (Figure 25.1A).

To use a radioisotope to date a past event, we must know or estimate the concentration of the isotope at the time of that event. In the case of carbon, the production of new carbon-14 (¹⁴C) in the upper atmosphere (by the reaction of neutrons with nitrogen-14) just balances the natural radioactive decay of ¹⁴C to ¹⁴N. Therefore, the ratio of ¹⁴C to its stable isotope, carbon-12 (¹²C), is relatively constant in living organisms and their environment. As soon as an organism dies, however, it ceases to exchange carbon compounds with its environment. Its decaying ¹⁴C is no longer replenished, and the ratio of ¹⁴C to ¹²C in its remains decreases through time. Paleontologists can use the ratio of ¹⁴C to ¹²C in fossil material to date fossils that are less than 50,000 years old (and thus the sedimentary rocks that contain those fossils). If fossils are older than that, so little ¹⁴C remains that the limits of detection using this particular isotope are reached.

Radioisotope	Half-life (years)	Decay product	Useful dating range (years)
Carbon-14 (¹⁴ C)	5,700	Nitrogen-14 (¹⁴ N)	100 – 50,000
Potassium-40 (⁴⁰ K)	1.3 billion	Argon-40 (⁴⁰ Ar)	10 million – 4.5 billion
Uranium-238 (²³⁸ U)	4.5 billion	Lead 206 (²⁰⁶ Pb)	10 million – 4.5 billion

25.1 Radioactive Isotopes Allow Us to Date Ancient Rocks The decay of radioactive “parent” atoms into stable “daughter” isotopes happens at a steady rate known as a half-life. (A) The graph demonstrates the principle of half-life using carbon-14 (¹⁴C) as an example. (B) Radioisotopes have different characteristic half-lives that allow us to measure how much time has elapsed since the rocks containing them were laid down.

TABLE 25.1				
Earth’s Geological History				
RELATIVE TIME SPAN	ERA	PERIOD	ONSET	MAJOR PHYSICAL CHANGES ON EARTH
Precambrian	Cenozoic	Quaternary	2.6 mya	Cold/dry climate; repeated glaciations
		Tertiary	65 mya	Continents near current positions; climate cools
	Mesozoic	Cretaceous	145 mya	Northern continents attached; Gondwana begins to drift apart; meteorite strikes Yucatán Peninsula
		Jurassic	200 mya	Two large continents form: Laurasia (north) and Gondwana (south); climate warm
		Triassic	251 mya	Pangaea begins to slowly drift apart; hot/humid climate
	Paleozoic	Permian	297 mya	Extensive lowland swamps; O ₂ levels 50% higher than present; by end of period continents aggregate to form Pangaea, and O ₂ levels begin to drop rapidly
		Carboniferous	359 mya	Climate cools; marked latitudinal climate gradients
		Devonian	416 mya	Continents collide at end of period; meteorite probably strikes Earth
		Silurian	444 mya	Sea levels rise; two large land masses emerge; hot/humid climate
		Ordovician	488 mya	Massive glaciation, sea level drops 50 meters
		Cambrian	542 mya	O ₂ levels approach current levels
Precambrian	Precambrian		900 mya	O ₂ level at >5% of current level
			1.5 bya	O ₂ level at >1% of current level
			3.8 bya	O ₂ first appears in atmosphere
			4.5 bya	

Note: mya, million years ago; bya, billion years ago.

Radioisotope dating methods have been expanded and refined

Sedimentary rocks are formed from materials that existed for varying lengths of time before being transported, sometimes over long distances, to the site of their deposition. Therefore, the inorganic isotopes in a sedimentary rock do not contain reliable information about the date of its formation. Dating rocks more ancient than 50,000 years requires estimating isotope concentrations in *igneous* rocks—rocks formed when molten material cools. To date older sedimentary rocks, geologists search for places where sedimentary rocks show igneous intrusions of volcanic ash or lava flows.

A preliminary estimate of the age of an igneous rock determines which isotope is used to date it (**Figure 25.1B**). The decay of potassium-40 (which has a half-life of 1.3 billion years) to argon-40 has been used to date many of the ancient events in the evolution of life. Fossils in the adjacent sedimentary rock that are similar to those in other rocks of known ages provide additional clues.

Radioisotope dating of rocks, combined with fossil analysis, is the most powerful method of determining geological age. But in places where sedimentary rocks do not contain suitable ig-

neous intrusions and few fossils are present, paleontologists turn to other methods.

One method, known as **paleomagnetic dating**, relates the ages of rocks to patterns in Earth's magnetism, which change over time. Earth's magnetic poles move and occasionally reverse themselves. Because both sedimentary and igneous rocks preserve a record of Earth's magnetic field at the time they were formed, paleomagnetism helps determine the ages of those rocks. Other dating methods use information about continental drift, sea level changes, and molecular clocks (the last of which is described in Section 22.3).

Using these methods, geologists divided the history of life into *eras*, which in turn are subdivided into *periods* (**Table 25.1**). The boundaries between these time frames are based on striking differences scientists have observed in the assemblages of fossil organisms contained in successive layers of rocks. Geologists defined and named these divisions before they were able to establish the ages of fossils, adding and refining the time scales as new methods for geological dating were developed.

25.1 RECAP

Fossils in sedimentary rocks enabled geologists to determine the relative ages of organisms, but absolute dating was not possible until the discovery of radioactivity. Geologists divide the history of life into eras and periods, based on assemblages of fossil organisms found in successive layers of rocks.

- What observations about fossils suggested to geologists that they could be used to determine the relative ages of rocks? **See p. 519**
- How is the rate of decay of radioisotopes used to estimate the absolute ages of rocks? **See p. 520 and Figure 25.1**

MAJOR EVENTS IN THE HISTORY OF LIFE

Humans evolve; many large mammals become extinct
Diversification of birds, mammals, flowering plants, and insects

Dinosaurs continue to diversify; mass extinction at end of period (≈76% of species disappear)

Diverse dinosaurs; radiation of ray-finned fishes; first fossils of flowering plants

Early dinosaurs; first mammals; marine invertebrates diversify; mass extinction at end of period (≈65% of species disappear)

Reptiles diversify; giant amphibians and flying insects present; mass extinction at end of period (≈96% of species disappear)

Extensive “fern” forests; first reptiles; insects diversify

Fishes diversify; first insects and amphibians; mass extinction at end of period (≈75% of species disappear)

Jawless fishes diversify; first ray-finned fishes; plants and animals colonize land

Mass extinction at end of period (≈75% of species disappear)

Rapid diversification of multicellular animals; diverse photosynthetic protists

Ediacaran fauna; earliest fossils of multicellular animals

Eukaryotes evolve

Origin of life; prokaryotes flourish

The scale at the left of Table 25.1 gives a relative sense of geological time, especially the vast expanse of the Precambrian era, during which early life evolved amid stupendous physical changes of Earth and its atmosphere. During the Precambrian to Cambrian transition, an “explosion” of new life forms took place as representatives of many of the major multicellular groups of life evolved. Earth continued to undergo massive physical changes that influenced the evolution of life, and these events and important milestones are listed in the table. In the next two sections we'll discuss the most important of these changes.

25.2 How Have Earth's Continents and Climates Changed over Time?

The globes and maps that adorn our walls, shelves, and books give an impression of a static Earth. It would be easy for us to assume that the continents have always been where they are, but we would be wrong. The idea that Earth's land masses have changed position over the millennia, and that they continue to do so, was first put forth in 1912 by the German meteorologist

25.2 Plate Tectonics and Continental Drift

The heat of Earth's core generates convection currents (arrows) in the magma that push the lithospheric plates, along with the land masses lying on them, together or apart. When lithospheric plates collide, one often slides under the other. The resulting seismic activity can create mountains and deep rift valleys (the latter known as trenches when they occur under ocean basins).

and geophysicist Alfred Wegener. His book *The Origin of Continents and Oceans* was initially met with skepticism and resistance. By the 1960s, however, physical evidence and increased understanding of the geophysics of **plate tectonics**—the study of movement of major land masses—had convinced virtually all geologists of the reality of Wegener's vision.

Earth's crust consists of several solid plates approximately 40 kilometers thick, which collectively make up the lithosphere. The lithospheric plates float on a fluid layer of molten rock, or magma (Figure 25.2). Heat produced by radioactive decay deep in Earth's core sets up convection currents in the fluid magma, which then rises and exerts tremendous pressure on the solid plates. When the pressure of the rising magma pushes plates apart, ocean basins may form between them. When plates are pushed together, they either move sideways past each other or one plate slides under the other, pushing up mountain ranges and carving deep rift valleys. When they occur under the water of ocean basins, rift valleys are known as trenches. The

movement of the lithospheric plates and the continents they contain is known as **continental drift**.

We now know that at times the drifting of the plates has brought continents together and at other times has pushed them apart (these movements are depicted in Figure 25.12). The positions and sizes of the continents influence oceanic circulation patterns, global climates, and sea levels. Major drops in sea level have usually been accompanied by massive extinctions—particularly of marine organisms, which could not survive the exposure of vast areas of the continental shelves and the disappearance of the shallow seas that covered them (Figure 25.3).

GO TO Animated Tutorial 25.1 • Evolution of the Continents

25.3 Sea Levels Have Changed Repeatedly Most mass extinctions of marine organisms (indicated by asterisks) have coincided with periods of low sea levels.

25.4 Stromatolites (A) A vertical section through a fossil stromatolite. (B) These rocklike structures are living stromatolites that thrive in the very salty waters of Shark Bay in western Australia. Layers of cyanobacteria are found in the uppermost parts of the structures.

Oxygen concentrations in Earth's atmosphere have changed over time

As the continents have moved over Earth's surface, the world has experienced other physical changes, including large increases and decreases in atmospheric oxygen. The atmosphere of early Earth probably contained little or no free oxygen gas (O_2). The increase in atmospheric O_2 came in two big steps more than a billion years apart. The first step occurred at least 2.4 billion years ago (bya), when certain bacteria evolved the ability to use water as the source of hydrogen ions for photosynthesis. By chemically splitting H_2O , these bacteria generated atmospheric O_2 as a waste product. They also made electrons available for reducing CO_2 to form organic compounds (see Section 10.3).

One group of O_2 -generating bacteria, the *cyanobacteria*, formed rocklike structures called

stromatolites, which are abundantly preserved in the fossil record. Cyanobacteria are still forming stromatolites today in a few very salty places on Earth (Figure 25.4). Cyanobacteria liberated enough O_2 to open the way for the evolution of oxidation reactions as the energy source for the synthesis of ATP (see Section 9.1).

The evolution of life thus irrevocably changed the physical nature of Earth. Those physical changes, in turn, influenced the evolution of life. When it first appeared in the atmosphere, O_2 was poisonous to the anaerobic prokaryotes that inhabited Earth at the time. Over millennia, however, prokaryotes that evolved the ability to metabolize O_2 not only survived but gained several advantages. Aerobic metabolism proceeds more rapidly and harvests energy more efficiently than anaerobic metabolism (see Section 9.4), and organisms with aerobic metabolism replaced anaerobes in most of Earth's environments.

An atmosphere rich in O_2 also made possible larger cells and more complex organisms. Small unicellular aquatic organisms can obtain enough O_2 by simple diffusion even when O_2 concentrations are very low. Larger unicellular organisms have lower surface area-to-volume ratios (see Figure 5.2); to obtain enough O_2 by simple diffusion, they must live in an environment with a relatively high oxygen concentration. Bacteria can thrive on 1 percent of the current atmospheric O_2 levels; eukaryotic cells require levels that are at least 2–3 percent of current concentrations. (For concentrations of dissolved O_2 in the oceans to reach these levels, much higher atmospheric concentrations were needed.)

Probably because it took many millions of years for Earth to develop an oxygenated atmosphere, only unicellular prokaryotes lived on Earth for more than 2 billion years. About 1.5 bya, atmospheric O_2 concentrations became high enough for large eukaryotic cells to flourish (Figure 25.5). Further increases in atmospheric O_2 levels 750 to 570 million years ago (mya) enabled several groups of multicellular organisms to evolve.

25.5 Larger Cells, Larger Organisms Need More Oxygen Changes in oxygen concentrations have strongly influenced, and been influenced by, the evolution of life. (Note that the horizontal axis of the graph is on a logarithmic scale.)

INVESTIGATING LIFE

25.6 Rising Oxygen Levels and Body Size in Insects

In this experiment, flies were raised under hyperbaric conditions (increased atmospheric pressure), thus increasing the partial pressure of O_2 in a manner that simulated the greater levels of atmospheric O_2 characteristic of the Carboniferous and Permian. Robert Dudley asked if flies raised in hyperbaric conditions would grow larger than their normal counterparts.

HYPOTHESIS Under increased atmospheric pressure, the increased partial pressure of O_2 will allow directional selection for increased body size in flying insects.

METHOD

1. Divide a population of fruit flies (*Drosophila melanogaster*) into two lines.
2. Raise one line (the control) at current atmospheric oxygen conditions. Raise the experimental line in hyperbaric conditions (increased partial pressure of O_2 , simulating increased atmospheric oxygen concentrations). Continue for 5 generations.
3. Raise the F_6 offspring of both lines under identical environmental conditions.
4. Weigh all the F_6 individuals and test for statistical differences in the average body mass of the flies in each population.

RESULTS

The average body mass of F_6 individuals of both sexes in the experimental line was significantly ($p < 0.0001$) greater than that of insects in the control line.

CONCLUSION In at least some flying insects, increased concentrations of oxygen could lead to a long-term evolutionary trend toward increased body size.

FURTHER INVESTIGATION: How would you confirm that the change in average body size is related to increased partial pressure of O_2 , and not to other aspects of overall increased atmospheric pressure?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

O_2 concentrations increased again during the Carboniferous and Permian periods because of the evolution of large vascular plants in the expansive lowland swamps that existed then (see

Table 25.1). These swamps resulted in extensive burial of plant debris from vascular plants, which led to the formation of Earth's vast coal deposits. As the buried organic material was not subject to oxidation, and the living plants were producing large quantities of O_2 , atmospheric O_2 increased to concentrations that have not been reached again in Earth's history (see Figure 25.5). As mentioned in the opening of this chapter, high concentrations of atmospheric O_2 allowed the evolution of giant flying insects and amphibians that could not survive in today's atmosphere. The drying of the lowland swamps at the end of the Permian reduced global organic burial, and also the production of atmospheric O_2 , so O_2 concentrations dropped rapidly. Over the past 200 million years, with the diversification of flowering plants, O_2 concentrations have again increased, but not to the levels that characterized the Carboniferous and Permian periods.

Biologists have conducted experiments that demonstrate the changing selective pressures that can accompany changes in O_2 levels. In experimental conditions, an increase in O_2 concentration can be simulated by increasing atmospheric pressure in a hyperbaric chamber. Increasing atmospheric pressure increases the *partial pressure of oxygen* (see Chapter 49) in a manner that simulates an increase in O_2 concentration at normal atmospheric pressure. When lines of fruit flies (*Drosophila*) are raised in artificial hyperbaric atmospheres (which have higher partial pressure of O_2), they quickly evolve larger body sizes over just a few generations (Figure 25.6). The current levels of atmospheric O_2 appear to constrain body size evolution of these flying insects; increases in O_2 appear to relax these constraints. This demonstrates that the *stabilizing selection* on body size at present O_2 concentrations can quickly switch to *directional selection* (see Section 21.3) for a change in body size in response to a change in O_2 levels. Directional selection over a period of millions of years would be sufficient to account for giant insects such as *Meganeuropsis*, described at the beginning of this chapter.

Many physical conditions on Earth have oscillated in response to the planet's internal processes, such as volcanic activity and continental drift. Extraterrestrial events, such as collisions with meteorites, have also left their mark. In some cases, as we saw earlier and will see again in this chapter, changing physical parameters caused **mass extinctions**, during which a large proportion of the species living at the time disappeared. After each mass extinction, the diversity of life rebounded, but recovery took millions of years.

Earth's climate has shifted between hot/humid and cold/dry conditions

Through much of its history, Earth's climate was considerably warmer than it is today, and temperatures decreased more gradually toward the poles. At other times, Earth was colder than it is today. Large areas were covered with glaciers near the end of the Precambrian and Ordovician, and during parts of the Carboniferous and Permian periods. These cold periods were separated by long periods of milder climates (Figure 25.7). Because we are living in one of the colder periods in Earth's history, it is difficult for us to imagine the mild climates that were found at high latitudes during much of the history of life. During the

25.7 Hot/Humid and Cold/Dry Conditions Have Alternated over Earth's History Throughout Earth's history, periods of cold climates and glaciations (white depressions) have been separated by long periods of milder climates.

Quaternary period there has been a series of glacial advances, interspersed with warmer interglacial intervals during which the glaciers retreated.

"Weather" refers to daily events, such as individual storms. "Climate" refers to long-term average expectations of the various seasons at a given location. Weather often changes rapidly; climates typically change slowly. Major climatic shifts have taken place over periods as short as 5,000 to 10,000 years, primarily as a result of changes in Earth's orbit around the sun. A few climatic shifts have been even more rapid. For example, during one Quaternary interglacial period, the ice-locked Antarctic Ocean became nearly ice-free in less than 100 years. Such rapid changes are usually caused by sudden shifts in ocean currents. Some climate changes have been so rapid that the extinctions caused by them appear to be nearly "instantaneous" in the fossil record.

We are currently living in a time of rapid climate change thought to be caused by a buildup of atmospheric CO_2 , primarily from the burning of fossil fuels. We are reversing the process of organic burial that occurred (especially) in the Carboniferous and Permian, but we are doing so over a few hundred years rather than the many millions of years over which these deposits accumulated. The current rate of increase of atmospheric CO_2 is unprecedented in Earth's history. A doubling of the atmospheric CO_2 concentration—which may happen during the current century—is expected to increase the average temperature of Earth, change rainfall patterns, melt glaciers and ice caps, and raise sea level. The possible consequences of such climate changes are discussed in Chapters 58 and 59.

Volcanoes have occasionally changed the history of life

Most volcanic eruptions produce only local or short-lived effects, but a few large volcanic eruptions have had major consequences for life. When Krakatoa erupted in Indonesia in 1883,

it ejected more than 25 cubic kilometers of ash and rock, as well as large quantities of sulphur dioxide gas (SO_2). The SO_2 was ejected into the stratosphere and then moved by high-level winds around the planet. This led to high concentrations of sulphurous acid (H_2SO_3) in high-level clouds, which meant less sunlight got through to Earth's surface. Global temperatures dropped by 1.2°C in the year following the eruption, and global weather patterns showed strong effects for another 5 years. This was all the result of a single volcanic eruption. The collision of continents during the Permian period (about 275 mya) formed a single, gigantic land mass (Pangaea) and caused many massive volcanic eruptions. These eruptions resulted in considerable blockage of sunlight, contributing to the glaciations of that time (see Figure 25.7). Massive volcanic eruptions occurred again as the continents drifted apart during the late Triassic and at the end of the Cretaceous.

Extraterrestrial events have triggered changes on Earth

At least 30 meteorites between the sizes of baseballs and soccer balls hit Earth each year. Collisions with large meteorites or comets are rare, but such collisions have probably been responsible for several mass extinctions. Several types of evidence tell us about these collisions. Their craters, and the dramatically disfigured rocks that resulted from their impact, are found in many places. Geologists have also discovered compounds in these rocks that contain helium and argon with isotope ratios characteristic of meteorites, which are very different from the ratios found elsewhere on Earth.

A meteorite caused or contributed to a mass extinction at the end of the Cretaceous period (about 65 mya). The first clue that a meteorite was responsible came from the abnormally high concentrations of the element iridium in a thin layer separating rocks deposited during the Cretaceous from those deposited during the Tertiary (Figure 25.8). Iridium is abundant in some meteorites, but it is exceedingly rare on Earth's surface. Scientists discovered a circular crater 180 kilometers in diameter buried beneath the northern coast of the Yucatán Peninsula of

25.8 Evidence of a Meteorite Impact The white layers of rock are Cretaceous in age; the layers at the upper left were deposited in the Tertiary. Between the two is a thin, dark layer of clay that contains large amounts of iridium, a metal common in some meteorites but rare on Earth. Its high concentration in sediments deposited about 65 million years ago suggests the impact of a large meteorite.

Mexico. When it collided with Earth, the meteorite released energy equivalent to that of 100 million megatons of high explosives, creating great tsunamis. A massive plume of debris swelled to a diameter of up to 200 kilometers, spread around Earth, and descended. The descending debris heated the atmosphere to several hundred degrees, ignited massive fires, and blocked the sun, preventing plants from photosynthesizing. The settling debris formed the iridium-rich layer. About a billion tons of soot, which has a composition that matches smoke from forest fires, was also deposited. Many fossil species (particularly dinosaurs) that are found in Cretaceous rocks are not found in the Tertiary rocks of the next layer.

25.2 RECAP

Conditions on Earth have changed dramatically over time. Changes in atmospheric concentrations of O_2 and in Earth's climate have had major effects on biological evolution. Continental drift, volcanic eruptions, and large meteorite strikes have contributed to climatic changes during Earth's history.

- Describe how increases in atmospheric concentrations of O_2 affected the evolution of multicellular organisms. **See pp. 523–524 and Figure 25.5**
- How have volcanic eruptions and meteorite strikes influenced the course of life's evolution? **See p. 525**

The many dramatic physical events of Earth's history have influenced the nature and timing of evolutionary changes among Earth's living organisms. We now will look more closely at some of the major events that characterize the history of life on Earth.

25.3 What Are the Major Events in Life's History?

Life first evolved on Earth about 3.8 bya. By about 1.5 bya, eukaryotic organisms had evolved (see Table 25.1). The fossil record of organisms that lived prior to 550 mya is fragmentary, but it is good enough to show that the total number of species and individuals increased dramatically in late Precambrian times. As discussed above, pre-Darwinian geologists divided geological history into eras and periods based on their distinct fossil assemblages. Biologists refer to the assemblage of all organisms of all kinds living at a particular time or place as a **biota**. All of the plants living at a particular time or place are its **flora**; all of the animals are its **fauna**. Table 25.1 describes some of the physical and biological changes, such as mass extinctions and dramatic increases in the diversity of major groups of organisms, associated with each unit of time.

About 300,000 species of fossil organisms have been described, and the number steadily grows. The number of named species, however, is only a tiny fraction of the species that have ever lived. We do not know how many species lived in the past, but we have ways of making reasonable estimates. Of the present-day biota, nearly 1.8 million species have been named. The actual number of living species is probably well over 10 million, and possibly much higher, because many species have not yet been discovered and described by biologists. So the number of described fossil species is only about 3 percent of the estimated minimum number of living species. Life has existed on Earth for about 3.8 billion years. Many species last only a few million years before undergoing speciation or going extinct; therefore, Earth's biota must have turned over many times during geological history. So the total number of species that have lived over evolutionary time must vastly exceed the number living today. Why have only about 300,000 of these tens of millions of species been described from fossils to date?

Several processes contribute to the paucity of fossils

Only a tiny fraction of organisms ever become fossils, and only a tiny fraction of fossils are ever discovered by paleontologists. Most organisms live and die in oxygen-rich environments in which they quickly decompose. They are not likely to become fossils unless they are transported by wind or water to sites that lack oxygen, where decomposition proceeds slowly or not at all. Furthermore, geological processes often transform rocks, destroying the fossils they contain, and many fossil-bearing rocks are deeply buried and inaccessible. Paleontologists have studied only a tiny fraction of the sites that contain fossils, but they find and describe many new ones every year.

The fossil record is most complete for marine animals that had hard skeletons (which resist decomposition). Among the nine major animal groups with hard-shelled members, approximately 200,000 species have been described from fossils—roughly twice the number of living marine species in these same groups. Paleontologists lean heavily on these groups in their interpretations of the evolution of life. Insects and spiders are also relatively well represented in the fossil record, because they are numerically abundant and have hard exoskeletons.

Solenopsis sp.

25.9 Insect Fossils Chunks of amber—fossilized tree resin—often contain insects that were preserved when they were trapped in the sticky resin. This fire ant fossil is some 30 million years old.

(**Figure 25.9**). The fossil record, though incomplete, is good enough to document clearly the factual history of the evolution of life.

By combining information about geological changes during Earth's history with evidence from the fossil record, scientists have composed portraits of what Earth and its inhabitants may have looked like at different times. We know in general where the continents were and how life changed over time, but many of the details are poorly known, especially for events in the more remote past.

Precambrian life was small and aquatic

For most of its history, life was confined to the oceans, and all organisms were small. Over the long ages of the **Precambrian era**—more than 3 billion years—the shallow seas slowly be-

gan to teem with life. For most of the Precambrian, life consisted of microscopic prokaryotes; eukaryotes evolved about two-thirds of the way through the era (**Figure 25.10**). Unicellular eukaryotes and small multicellular animals fed on floating photosynthetic microorganisms. Small floating organisms, known collectively as *plankton*, were strained from the water and eaten by slightly larger *filter-feeding* animals. Other animals ingested sediments on the seafloor and digested the remains of organisms within them. By the late Precambrian (630–542 mya), many kinds of multicellular soft-bodied animals had evolved. Some of them were very different from any animals living today, and may be members of groups that have no living descendants (**Figure 25.11**).

Life expanded rapidly during the Cambrian period

The Cambrian period (542–488 mya) marks the beginning of the Paleozoic era. The oxygen concentration in the Cambrian atmosphere was approaching its current level, and the land masses had come together to form several large continents. A geologically rapid diversification of life took place that is sometimes referred to as the **Cambrian explosion** (although in fact it began before the Cambrian, and the “explosion” took millions of years). Several of the major groups of animals that have species living today first evolved during the Cambrian. An overview of the continental and biotic shifts that characterized the Cambrian and subsequent periods is shown in **Figure 25.12** on the following pages.

For the most part, fossils tell us only about the hard parts of organisms, but in three known Cambrian fossil beds—the Burgess Shale in British Columbia, Sirius Passet in northern Greenland, and the Chengjiang site in southern China—the soft parts of many animals were preserved. Crustacean arthropods (crabs, shrimps, and their relatives) are the most diverse group

25.10 A Sense of Life's Time The top timeline shows the 4.5 billion year history of life on Earth. Most of this time is accounted for by the Precambrian, a 3.4 billion year era that saw the origin of life and the evolution of cells, photosynthesis, and multicellularity. The final 600 million years are expanded in the second timeline and detailed in Figure 25.12.

*Spriggina floundersi**Mawsonites spriggi**Dickinsonia costata*

25.11 Precambrian Life These fossils of soft-bodied invertebrates, excavated at Ediacara in southern Australia, were formed about 600 million years ago. Very different from later life forms, they illustrate the diversity of life at the end of the Precambrian era.

in the Chinese fauna; some of them were large carnivores. Multicellular diversity was largely or completely aquatic during the Cambrian. If there was life on land at this time, it was probably restricted to microbial organisms.

Many groups of organisms that arose during the Cambrian later diversified

Geologists divide the remainder of the Paleozoic era into the Ordovician, Silurian, Devonian, Carboniferous, and Permian periods. Each period is characterized by the diversification of specific groups of organisms. Mass extinctions marked the ends of the Ordovician, Devonian, and Permian.

THE ORDOVICIAN (488–444 MYA) During the Ordovician period, the continents, which were located primarily in the Southern Hemisphere, still lacked multicellular plants. Evolutionary radiation of marine organisms was spectacular during the early Ordovician, especially among animals, such as brachiopods and mollusks, that lived on the seafloor and filtered small prey from the water. At the end of the Ordovician, as massive glaciers formed over the southern continents, sea levels dropped about 50 meters and ocean temperatures dropped. About 75 percent of the animal species became extinct, probably because of these major environmental changes.

THE SILURIAN (444–416 MYA) During the Silurian period, the continents began to merge together. Marine life rebounded from the mass extinction at the end of the Ordovician. Animals able to swim in open water and feed above the ocean bottom appeared for the first time. Jawless fishes diversified, and the first ray-finned fishes evolved. The tropical sea was uninterrupted by land barriers, and most marine organisms were widely distributed. On land, the first vascular plants evolved late in the Silurian (about 420 mya). The first terrestrial arthropods—scorpions and millipedes—evolved at about the same time.

THE DEVONIAN (416–359 MYA) Rates of evolutionary change accelerated in many groups of organisms during the Devonian period. The major land masses continued to move slowly toward each other. In the oceans there were great evolutionary radiations of corals and of shelled, squidlike cephalopod mollusks. Fishes diversified as jawed forms replaced jawless ones and as heavy armor gave way to the less rigid outer coverings of modern fishes.

Terrestrial communities changed dramatically during the Devonian. Club mosses, horsetails, and tree ferns became common; some attained the size of large trees. Their roots accelerated the weathering of rocks, resulting in the development of the first forest soils. The ancestors of gymnosperms—the first plants to produce seeds—appeared in the Devonian. The first known fossils of centipedes, spiders, mites, and insects date to this period, and fishlike amphibians began to occupy the land.

A massive extinction of about 75 percent of all marine species marked the end of the Devonian. Paleontologists are uncertain about its cause, but two large meteorites that collided with Earth at that time (one in present-day Nevada and the other in western Australia) may have been responsible, or at least a contributing factor. The continued coalescence of the continents, with the corresponding reduction in continental shelves, may have also contributed to this mass extinction event.

THE CARBONIFEROUS (359–297 MYA) Large glaciers formed over high-latitude portions of the southern land masses during the Carboniferous period, but extensive swamp forests grew on the tropical continents. These forests were not made up of the kinds of trees we know today, but were dominated by giant tree ferns and horsetails with small leaves. Fossilized remains of those forests formed the coal we now mine for energy. In the seas,

25.12 A Brief History of Life on Earth The geologically rapid “explosion” of life during the Cambrian saw the rise of several animal groups that have representatives surviving today. The following three pages depict life’s history from the Cambrian forward. Movements of the major continents during the past half-billion years are shown in the maps of Earth, and associated biotas for each time period are depicted. The artists’ reconstructions are based on fossils such as those shown in the photographs.

Cambrian

Marrella splendens

Ottoia sp.

Anomalocaris canadensis (claw only)

Devonian

Codiocrinus schultzei

Phacops ferdinandi

Eridophyllum sp.

Orthoconic nautiloid

Extensive swamp forests produce coal; origin of amniotes; great increase in terrestrial animal diversity

Giant amphibians and flying insects; ray-finned fishes abundant in freshwater

On land, conifers become dominant plants; frogs and reptiles begin to diversify

Dinosaurs, pterosaurs, ray-finned fishes diversify; first mammals appear

First known flowering plant fossils

25.13 Evidence of Insect Diversification

The margins of this fossil fern leaf from the Carboniferous have been chewed by insects.

crinoids (sea lilies and feather stars) reached their greatest diversity, forming “meadows” on the seafloor.

The diversity of terrestrial animals increased greatly during the Carboniferous. Snails, scorpions, centipedes, and insects were abundant and diverse. Insects evolved wings, becoming the first animals to fly. Flight gave herbivorous insects easy access to tall plants; plant fossils from this period show evidence of chewing by insects (**Figure 25.13**). The terrestrial vertebrate lineage split, and amphibians became larger and better adapted to terrestrial existence, while the sister lineage led to the **amniotes**, vertebrates with well-protected eggs that can be laid in dry places.

THE PERMIAN (297–251 MYA) During the Permian period, the continents coalesced completely into the supercontinent **Pangaea**. Permian rocks contain representatives of many major groups of insects we know today. By the end of the period, the reptiles split from a second amniote lineage (which would lead to the mammals). Ray-finned fishes became common in the fresh waters of Pangaea.

Conditions for life deteriorated toward the end of the Permian. Massive volcanic eruptions resulted in outpourings of lava that covered large areas of Earth. The ash and gases produced by the volcanoes blocked sunlight and cooled the climate, resulting in the largest glaciers in Earth’s history. Atmospheric oxygen concentrations gradually dropped from about 30 to 15 percent. At such low concentrations, most animals would have been unable to survive at elevations above 500 meters; thus about half of the land area would have been uninhabitable at the end of the Permian. The combination of these changes resulted in the most drastic mass extinction event in Earth’s history. Scientists estimate that about 96 percent of all species became extinct at the end of the Permian.

Geographic differentiation increased during the Mesozoic era

The few organisms that survived the Permian mass extinction found themselves in a relatively empty world at the start of the

Mesozoic era (251 mya). As Pangaea slowly began to break apart, the oceans rose and once again flooded the continental shelves, forming huge, shallow inland seas. Atmospheric oxygen concentrations gradually rose. Life once again proliferated and diversified, but different groups of organisms came to the fore. The three groups of phytoplankton (floating photosynthetic organisms) that dominate today’s oceans—dinoflagellates, coccolithophores, and diatoms—became ecologically important at this time; their remains are the primary origin of the world’s oil deposits. Seed-bearing plants replaced the trees that had ruled the Permian forests.

The Mesozoic era is divided into three periods: the Triassic, Jurassic, and Cretaceous. The Triassic and Cretaceous were terminated by mass extinctions, probably caused by meteorite impacts.

THE TRIASSIC (251–200 MYA) Pangaea began to break apart during the Triassic period. Many invertebrate groups became more species-rich, and many burrowing animals evolved from groups living on the surfaces of seafloor sediments. On land, conifers and seed ferns were the dominant trees. The first frogs and turtles appeared. A great radiation of reptiles began, which eventually gave rise to crocodilians, dinosaurs, and birds. The end of the Triassic was marked by a mass extinction that eliminated about 65 percent of the species on Earth.

THE JURASSIC (200–145 MYA) During the Jurassic period, Pangaea became fully divided into two large continents: **Laurasia** drifted northward and **Gondwana** drifted south. Ray-finned fishes rapidly diversified in the oceans. The first lizards appeared, and flying reptiles (pterosaurs) evolved. Most of the large terrestrial predators and herbivores of the period were dinosaurs. Several groups of mammals made their first appearance, and the earliest known fossils of flowering plants are from late in this period.

THE CRETACEOUS (145–65 MYA) By the early Cretaceous period, Laurasia and Gondwana had begun to break apart into the con-

tinents we know today. A continuous sea encircled the tropics. Sea levels were high, and Earth was warm and humid. Life proliferated both on land and in the oceans. Marine invertebrates increased in diversity and in number of species. On land, the reptile radiation continued as dinosaurs diversified further and the first snakes appeared. Early in the Cretaceous, flowering plants began the radiation that led to their current dominance of the land. By the end of the period, many groups of mammals had evolved. Most early mammals were small, but one species recently discovered in China, *Repenomamus giganticus*, was large enough to capture and eat young dinosaurs.

As described in Section 25.2, another meteorite-caused mass extinction took place at the end of the Cretaceous (the impact site was near the present day Yucatán Peninsula of Mexico). In the seas, many planktonic organisms and bottom-dwelling invertebrates became extinct. On land, almost all animals larger than about 25 kilograms in body weight became extinct. Many species of insects died out, perhaps because the growth of their food plants was greatly reduced following the impact. Some species in northern North America and Eurasia survived in areas that were not subjected to the devastating fires that engulfed most low-latitude regions.

Modern biota evolved during the Cenozoic era

By the early Cenozoic era (65 mya), the positions of the continents resembled those of today, but Australia was still attached to Antarctica, and the Atlantic Ocean was much narrower. The Cenozoic was characterized by an extensive radiation of mammals, but other groups were also undergoing important changes.

Flowering plants diversified extensively and came to dominate world forests, except in the coolest regions, where the forests were composed primarily of gymnosperms. Mutations of two genes in one group of plants (the legumes) allowed them to use atmospheric nitrogen directly by forming symbioses with a few species of nitrogen-fixing bacteria (see Section 36.4). The evolution of this symbiosis between certain early Cenozoic plants and these specialized bacteria was the first “green revolution” and dramatically increased the amount of nitrogen available for terrestrial plant growth; the symbiosis remains fundamental to the ecological base of life as we know it today.

The Cenozoic era is divided into the Tertiary and the Quaternary periods. Because both the fossil record and our subsequent knowledge of evolutionary history become more extensive as we approach our own time, paleontologists have subdivided these two periods into *epochs* (Table 25.2).

THE TERTIARY (65–2.6 MYA) During the Tertiary period, Australia began its northward drift. By 20 mya it had nearly reached its current position. The early Tertiary was a hot and humid time, and the ranges of many plants shifted latitudinally. The tropics were probably too hot for rainforests and were clothed in low-lying vegetation instead. In the middle of the Tertiary, however, Earth’s climate became considerably cooler and drier. Many lineages of flowering plants evolved herbaceous (non-woody) forms, and grasslands spread over much of Earth.

TABLE 25.2		
Subdivisions of the Cenozoic Era		
PERIOD	EPOCH	ONSET (MYA)
Quaternary	Holocene ^a	0.01 (~10,000 years ago)
	Pleistocene	2.6
Tertiary	Pliocene	5.3
	Miocene	23
	Oligocene	34
	Eocene	55.8
	Paleocene	65

^aThe Holocene is also known as the Recent.

By the start of the Cenozoic era, invertebrate faunas had already come to resemble those of today. It is among the terrestrial vertebrates that evolutionary changes during the Tertiary were most rapid. Frogs, snakes, lizards, birds, and mammals all underwent extensive radiations during this period. Three waves of mammals dispersed from Asia to North America across one of the several land bridges that have intermittently connected the two continents during the past 55 million years. Rodents, marsupials, primates, and hoofed mammals appeared in North America for the first time.

THE QUATERNARY (2.6 MYA TO PRESENT) We are living in the Quaternary period. It is subdivided into two epochs, the Pleistocene and the Holocene (the Holocene also being known as the Recent).

The Pleistocene was a time of drastic cooling and climate fluctuations. During 4 major and about 20 minor “ice ages,” massive glaciers spread across the continents, and the ranges of animal and plant populations shifted toward the equator. The last of these glaciers retreated from temperate latitudes less than 15,000 years ago. Organisms are still adjusting to these changes. Many high-latitude ecological communities have occupied their current locations for no more than a few thousand years.

It was during the Pleistocene that divergence within one group of mammals, the primates, resulted in the evolution of the hominoid lineage. Subsequent hominoid radiation eventually led to the species *Homo sapiens*—modern humans (see Section 33.5). Many large bird and mammal species became extinct in Australia and in the Americas when *H. sapiens* arrived on those continents about 45,000 and 15,000 years ago, respectively. Many paleontologists believe these extinctions were probably the result of hunting and other influences of *Homo sapiens*.

The tree of life is used to reconstruct evolutionary events

The fossil record reveals broad patterns in life’s evolution. To reconstruct major events in the history of life, biologists also rely on the phylogenetic information in the tree of life (see Chapter 22 and the Tree of Life Appendix). We can use phylogeny (in combination with the paleontological record) to reconstruct the

timing of such major events as the acquisition of mitochondria in the ancestral eukaryotic cell, the several independent origins of multicellularity, and the movement of life onto dry land. We can also follow major changes in the genomes of organisms, and even reconstruct many gene sequences of species that are long extinct (see Chapter 24).

Changes to the physical environment on Earth have clearly influenced the great diversity in living organisms we see on the planet today. To study the evolution of that diversity, biologists examine the evolutionary relationships among species. Deciphering these relationships is an important step in understanding how life has diversified on Earth. Part Seven of this book explores the major groups of life and the different solutions that have evolved for major functions such as reproduction, energy acquisition, dispersal, and escape from predation.

25.3 RECAP

Life evolved in the Precambrian oceans. It diversified as atmospheric oxygen approached its current level and the continents came together to form several large land masses. Numerous climate changes and rearrangements of the continents, as well as meteorite impacts, contributed to five major mass extinctions.

- Why have so few of the multitudes of organisms that have existed over millennia become fossilized? [See pp. 526–527](#)
- What do we mean when we refer to the “Cambrian explosion”? [See p. 527](#)
- In what ways has continental drift affected the evolution of life on Earth? [See Figure 25.12](#)

CHAPTER SUMMARY

25.1 How Do Scientists Date Ancient Events?

- The relative ages of organisms can be determined by the dating of fossils and the **strata** of **sedimentary rocks** in which they are found.
- Paleontologists use a variety of radioisotopes with different **half-lives** to date events at different times in the remote past. [Review Figure 25.1](#)
- Geologists divide the history of life into eras and periods, based on major differences in the fossil assemblages found in successive layers of rocks. [Review Table 25.1](#)

25.2 How Have Earth's Continents and Climates Changed over Time?

- Earth's crust consists of solid lithospheric plates that float on fluid magma. **Continental drift** caused by convection currents in the magma moves these plates and the continents that lie on top of them. [Review Figure 25.2, ANIMATED TUTORIAL 25.1](#)
- Conditions on Earth have changed dramatically over time. Increases in atmospheric oxygen and changes in Earth's climate have greatly influenced the evolution of life on Earth. [Review Figures 25.5 and 25.7](#)
- Oxygen-generating cyanobacteria liberated enough O₂ to open the door to oxidation reactions in metabolic pathways. The aerobic prokaryotes were able to harvest more energy than anaerobic organisms and began to proliferate. Increases in atmospheric O₂ levels supported the evolution of large eukaryotic cells.

- Major physical events on Earth, such as the collision of continents that formed the supercontinent **Pangaea**, have affected Earth's surface, climate, and atmosphere. In addition, extraterrestrial events such as meteorite strikes created sudden and dramatic environmental shifts. All of these changes have affected the history of life.

25.3 What Are The Major Events in Life's History?

- Paleontologists use fossils and evidence of geological changes to determine what Earth and its **biota** may have looked like at different times.
- During most of its history, life was confined to the oceans. Multicellular life diversified extensively during the **Cambrian explosion**. [Review Figure 25.11](#)
- The periods of the Paleozoic era were each characterized by the diversification of specific groups of organisms. **Amniotes**—vertebrates whose eggs can be laid in dry places—first appeared during the Carboniferous period.
- During the Mesozoic era, distinct terrestrial biotas evolved on each continent.
- Five episodes of **mass extinction** punctuated the history of life in the Paleozoic and Mesozoic eras.
- Earth's **flora** has been dominated by flowering plants since the Cenozoic era.
- Phylogenetic trees help reconstruct the timing of evolutionary events and clarify relationships among modern species.

SEE WEB ACTIVITY 25.1 for a concept review of this chapter.

SELF-QUIZ

- Which of the following is *not* true of the giant flying dragonflies of the Carboniferous and Permian?
 - Some species grew to have wing spans as wide or wider than many modern birds of prey.
 - They were the largest flying predators of the time.
 - Such large flying insects could exist because of the higher concentrations of atmospheric oxygen compared to the present.
 - Their predators were giant reptiles.
 - Fossils of one large species, *Meganeurosia permiana*, have been found in the Permian rocks of Kansas.
- In undisturbed strata of sedimentary rock, the oldest rocks
 - lie at the top.
 - lie at the bottom.
 - are in the middle.
 - are distributed among the strata of younger rocks.
 - none of the above
- ^{14}C can be used to determine the ages of fossil organisms because
 - all organisms contain many carbon compounds.
 - ^{14}C has a regular rate of decay to ^{14}N .
 - the ratio of ^{14}C to ^{12}C in living organisms is always the same as that in the atmosphere.
 - the production of new ^{14}C in the atmosphere just balances the natural radioactive decay of ^{14}C .
 - all of the above
- The concentration of oxygen in the Earth's atmosphere
 - has increased steadily through time.
 - has decreased steadily through time.
 - has been both higher and lower in the past than at present.
 - was lower during most of the Permian than at present.
 - was at its highest levels in the Cambrian.
- The total of all species of organisms in a given region is known as the region's
 - biota.
 - flora.
 - fauna.
 - flora and fauna.
 - biogeography.
- The coal beds we now mine for energy are largely the remains of
 - plants that grew in swamps during the Carboniferous period.
 - algae that grew in marshes during the Devonian period.
 - giant insects and amphibians of the Permian period.
 - plants that grew in the oceans during the Carboniferous period.
 - none of the above
- The mass extinction at the end of the Ordovician period was probably caused by
 - the collision of Earth with a large meteorite.
 - massive volcanic eruptions.
 - massive glaciation on the southern continents and associated climatic changes.
 - the uniting of all continents to form Pangaea.
 - changes in Earth's orbit.
- The cause of the mass extinction at the end of the Mesozoic era probably was
 - continental drift.
 - the collision of Earth with a large meteorite.
 - changes in Earth's orbit.
 - massive glaciation.
 - changes in the salt concentration of the oceans.
- Which of the following times was marked by the largest mass extinction of life in the history of Earth?
 - The end of the Cretaceous
 - The end of the Devonian
 - The end of the Permian
 - The end of the Triassic
 - The end of the Silurian
- Paleontologists have subdivided the Cenozoic era into epochs because
 - Homo sapiens* evolved at the start of the Cenozoic.
 - the continents had achieved their present positions.
 - the number of species stopped increasing at this time.
 - our knowledge of the evolutionary events of the Cenozoic is more extensive than for other eras.
 - starting with the Cenozoic, the fossil record is no longer a necessary source of information about evolutionary relationships.

FOR DISCUSSION

- Some groups of organisms have evolved to contain large numbers of species; other groups have produced only a few species. Is it meaningful to consider the former groups more successful than the latter? What does the word "success" mean in evolution?
- Scientists date ancient events using a variety of methods, but nobody was present to witness or record those events. Accepting those dates requires us to understand the accuracy and appropriateness of indirect measurement techniques. What other basic scientific concepts are also based on the results of indirect measurement techniques?
- Why is it useful to be able to date past events absolutely as well as relatively?
- If we are living during one of the cooler periods in Earth's history, why should we be concerned about human activities that are thought to contribute to global climate warming?
- What conditions may have favored the evolution of multicellular groups of organisms near the end of the Precambrian?
- In what ways do endosymbiotic events (such as the origin of mitochondria and chloroplasts) complicate the classification of the major groups of life?

ADDITIONAL INVESTIGATION

The experiment in Figure 25.6 showed that body size of insects may evolve quickly following changes in atmospheric oxygen

concentrations. What other experiments could you devise to test the effects of changing atmospheric oxygen?

26

Bacteria and Archaea: The Prokaryotic Domains

Life on a strange planet

It must have been quite a shock when Thomas “Griff” Taylor’s Antarctic exploration team first spotted Blood Falls in 1911. The blood-red falls were certainly a surprise in the snowy, icy terrain. What could possibly cause a red waterfall in Antarctica?

A few million years ago, the Taylor Glacier (which now bears the explorer’s name) moved above a pool of salty water, trapping the pool under 400 meters of ice. The harsh environment in the resulting enclosed subglacial sea could hardly seem more hostile to life. It is extremely cold; there is no light and virtually no oxygen; and salt concentrations are several times higher than seawater. In short, it is not a place one might expect to find a diverse living ecosystem.

Some water is able to seep out of this subglacial sea. This water is stained a dark, rusty red, and it spills from the head of Taylor Glacier to form Blood Falls. Taylor specu-

lated that red algae might account for the red coloration, but in the 1960s geologist Robert Black discovered that the water’s color arises from iron oxides that come from the underlying bedrock. With the methods then available, biologists could not detect any living organisms in the cold, saline, iron-rich water.

A half-century later, biologists were better equipped to study microscopic life in strange places. By then it was also possible to amplify and sequence genes from single microbes, and to place these gene sequences into the framework of the tree of life to identify and classify the microbes. Microbiologist Jill Mikucki and her colleagues used these techniques on water samples from Blood Falls, and reported in 2009 that the falls contain an unusual ecosystem of at least 17 different species of bacteria. The bacteria survive by metabolizing minute amounts of organic matter trapped in the subglacial sea, using sulfate and iron ions as catalysts and electron acceptors.

The presence of living organisms in Blood Falls confirms that it is hard to find a place on or even near the surface of the Earth that does not contain populations of prokaryotes. There are prokaryotes in volcanic vents, in the clouds, in environments as acidic as battery acid or as alkaline as household ammonia. There are species that can survive below the freezing point and above the boiling point

A Splash of Color in a Frozen World of White Antarctica’s Blood Falls is the outflow of a subglacial sea that contains an unusual ecosystem of bacteria that rely on sulfate and iron ions for metabolism.

Prokaryotes Can Take the Heat Entire ecosystems of prokaryotes create the beauty of Morning Glory Pool, a hot spring in Yellowstone National Park. Cyanobacteria impart the “morning glory blue” color. Archaea live in the intensely hot regions of the pool’s interior.

of water. There are more prokaryotes living on and inside our bodies than we have human cells. The prokaryotes are masters of metabolic ingenuity, having developed more ways to obtain energy from the environment than the eukaryotes have. They have been around much longer than other organisms, too.

Prokaryotes are by far the most numerous organisms on Earth. Late in the twentieth century, it became apparent to microbiologists that all prokaryotes are not most closely related to one another. Two prokaryotic lineages diverged early in life’s evolution: Bacteria and Archaea. An early merging between members of these two groups is thought to have given rise to the eukaryotic lineage, which includes humans.

IN THIS CHAPTER we will discuss the distribution of prokaryotes and examine their remarkable metabolic diversity. We will describe the difficulties involved in determining evolutionary relationships among the prokaryotes and will survey the surprising diversity of organisms in each domain. We will discuss how prokaryotes can have enormous influence on their environments. Finally, we will discuss the evolutionary origin and diversity of viruses and their relationship to the rest of life.

CHAPTER OUTLINE

- 26.1** How Did the Living World Begin to Diversify?
- 26.2** What Are Some Keys to the Success of Prokaryotes?
- 26.3** How Can We Resolve Prokaryote Phylogeny?
- 26.4** What Are the Major Known Groups of Prokaryotes?
- 26.5** How Do Prokaryotes Affect Their Environments?
- 26.6** Where Do Viruses Fit into the Tree of Life?

26.1 How Did the Living World Begin to Diversify?

You may think that you have little in common with unicellular prokaryotes. But multicellular eukaryotes like yourself actually share many attributes with Bacteria and Archaea. For example, all three of you:

- conduct glycolysis
- use DNA as the genetic material that encodes proteins
- produce those proteins by transcription and translation using a similar genetic code
- replicate DNA semiconservatively
- have plasma membranes and ribosomes in abundance

These features support the conclusion that all living organisms are related to one another. If life had multiple origins, there would be little reason to expect all organisms to use overwhelmingly similar genetic codes or to share structures as unique as ribosomes. Furthermore, similarities in DNA sequences of universal genes (such as those that encode the structural components of ribosomes) confirm the monophyly of life.

Despite the commonalities found across all three domains, major differences have evolved as well. Let’s first distinguish between Eukarya and the two prokaryotic domains. Note that “domain” is a subjective term used for the largest groups of life. There is no objective definition of a domain, any more than there is of a kingdom or a family.

The three domains differ in significant ways

Prokaryotic cells differ from eukaryotic cells in three important ways:

- *Prokaryotic cells lack a cytoskeleton and a nucleus, so they do not divide by mitosis.* Instead, after replicating their DNA (see Figure 11.2), prokaryotic cells divide by their own method, *binary fission*.
- *The organization of the genetic material differs.* The DNA of the prokaryotic cell is not organized within a membrane-enclosed nucleus. DNA molecules in prokaryotes (both bacteria and archaea) are often circular. Many (but not all) prokaryotes have only one main chromosome and are effectively haploid, although many have additional smaller DNA molecules, called *plasmids*, as well (see Section 12.6).

TABLE 26.1
The Three Domains of Life on Earth

CHARACTERISTIC	BACTERIA	DOMAIN ARCHAEA	EUKARYA
Membrane-enclosed nucleus	Absent	Absent	Present
Membrane-enclosed organelles	Absent	Absent	Present
Peptidoglycan in cell wall	Present	Absent	Absent
Membrane lipids	Ester-linked	Ester-linked	Ester-linked
	Unbranched	Branched	Unbranched
Ribosomes ^a	70S	70S	80S
Initiator tRNA	Formylmethionine	Methionine	Methionine
Operons	Yes	Yes	No
Plasmids	Yes	Yes	Rare
RNA polymerases	One	One ^b	Three
Ribosomes sensitive to chloramphenicol and streptomycin	Yes	No	No
Ribosomes sensitive to diphtheria toxin	No	Yes	Yes

^a70S ribosomes are smaller than 80S ribosomes.

^bArchaeal RNA polymerase is similar to eukaryotic polymerases.

- Prokaryotes have none of the membrane-enclosed cytoplasmic organelles—mitochondria, Golgi apparatus, and others—that are found in most eukaryotes. However, the cytoplasm of a prokaryotic cell may contain a variety of infoldings of the plasma membrane and photosynthetic membrane systems not found in eukaryotes.

A glance at **Table 26.1** will show you that there are also major differences (most of which cannot be seen even under an electron microscope) between the two prokaryotic domains. In some ways archaea are more like eukaryotes; in other ways they are more like bacteria. (Note that we use lowercase when referring to the members of these domains and uppercase when referring to the domains themselves.) The structures of prokaryotic and eukaryotic cells are compared in Chapter 5. The basic unit of an *archaeon* (the term for a single archaeal organism) or *bacterium* (a single bacterial organism) is the prokaryotic cell. Each single-celled organism contains a full complement of genetic and protein-synthesizing systems, including DNA, RNA, and all the enzymes needed to transcribe and translate the genetic information into proteins. The prokaryotic cell also contains at least one system for generating the ATP it needs.

Genetic studies clearly indicate that all three domains had a single common ancestor. For a major portion of their genome, eukaryotes share a more recent common ancestor with Archaea than they do with Bacteria (**Figure 26.1**). However, the mitochondria of eukaryotes (as well as the chloroplasts of photosynthetic eukaryotes, such as plants) originated through the endosymbiosis of a bacterium, as described in Section 5.5. Some biologists prefer to view the origin of eukaryotes as a fusion of two equal

partners (one ancestor that was related to modern archaea, and another that was more closely related to modern bacteria). Others view the divergence of the early eukaryotes from the archaea as a separate and earlier event than the later endosymbiosis of the bacterium (the origin of mitochondria). In either case, some genes of eukaryotes are more closely related to those of archaea, while others are more closely related to those of bacteria. The tree of life therefore contains some merging of lineages, as well as the predominant diverging of lineages.

The common ancestor of all three domains had DNA as its genetic material, and its machinery for transcription and translation produced RNAs and proteins, respectively. This ancestor probably had a circular chromosome.

Three shapes are particularly common among the bacteria: spheres, rods, and curved or helical forms (**Figure 26.2**). A spherical bacterium is called a *coccus* (plural *cocci*). Cocci may live singly or may associate in two- or three-dimensional arrays

26.1 The Three Domains of the Living World All three domains share a common prokaryotic ancestor.

26.2 Bacterial Cell Shapes This composite, colorized micrograph shows the three common types of bacterial morphology. Spherical cells are called cocci; the acid-producing cocci shown here in green are a species of *Enterococcus* from the mammalian gut. The rod-shaped bacilli (orange) are represented by *Escherichia coli*, also a resident of the gut. *Leptospira interrogans* is a helical (spiral) bacterium and a human pathogen.

as chains, plates, blocks, or clusters of cells. A rod-shaped bacterium is called a *bacillus* (plural *bacilli*). The spiral form (like a corkscrew), or *helix* (plural *helices*), is the third main bacterial shape. Bacilli and helices may be single, form chains, or gather in regular clusters. Among the other bacterial shapes are long filaments and branched filaments.

Less is known about the shapes of archaea because many of these organisms have never been seen. Many archaea are known only from samples of DNA from the environment, as we describe in Section 26.4. However, the morphology of some species is known, including cocci, bacilli, and even triangular and square-shaped species; the latter grow on surfaces, arranged like sheets of postage stamps.

Archaea, Bacteria, and Eukarya are all products of billions of years of mutation, natural selection, and genetic drift, and they are all well adapted to present-day environments. None is “primitive.” Their last common ancestor probably lived 2 to 3 billion years ago. The earliest prokaryotic fossils date back at least 3.5 billion years, and they indicate that there was considerable diversity among the prokaryotes even during the earliest days of life.

26.1 RECAP

Bacteria and archaea are highly divergent from each other and are only distantly related on the tree of life. Eukaryotes received ancient evolutionary contributions from both of these prokaryotic lineages.

- What are the principal differences between the prokaryotes and the eukaryotes? **See pp. 537–538 and Table 26.1**
- Why don’t we group Bacteria and Archaea together in a single domain? **See p. 538 and Table 26.1**

The prokaryotes were alone on Earth for a very long time, adapting to new environments and to changes in existing environments. They have survived to this day, in massive numbers and incredible diversity, and they are found everywhere.

26.2 What Are Some Keys to the Success of Prokaryotes?

If success is measured by numbers of individuals, the prokaryotes are the most successful organisms on Earth. Individual bacteria and archaea in the oceans number more than 3×10^{28} . This stunning number is perhaps 100 million times as great as the number of stars in the visible universe. In fact, the bacteria living in your intestinal tract outnumber all the humans who have ever lived.

Prokaryotes are unicellular organisms, although many form multicellular colonies that contain many individual cells. These multicellular associations are not cases of true multicellular organisms, however, because each individual cell is fully viable and independent. These associations arise as cells adhere to one another after reproducing by binary fission. Associations in the form of chains are called **filaments**. Some filaments become enclosed in delicate tubular sheaths.

Prokaryotes generally form complex communities

Prokaryotic cells and their associations do not usually live in isolation. Rather, they live in communities of many different species of organisms, often including microscopic eukaryotes. (Microscopic organisms are often collectively referred to as *microbes*.) Some microbial communities form layers in sediments, and others form clumps a meter or more in diameter. While some microbial communities are harmful to humans, others provide important services. They help us digest our food, break down municipal waste, and recycle organic matter in the environment.

Many microbial communities tend to form dense **biofilms**. Upon contacting a solid surface, the cells secrete a gel-like sticky polysaccharide matrix that then traps other cells (**Figure 26.3**). Once this biofilm forms, it is difficult to kill the cells. Pathogenic (disease-causing) bacteria are difficult for the immune system—and modern medicine—to combat once they form a biofilm. For example, the film may be impermeable to antibiotics. Worse, some drugs stimulate the bacteria in a biofilm to lay down more matrix, making the film even more impermeable.

Biofilms form on contact lenses, on artificial joint replacements, and on just about any available surface. They foul metal pipes and cause corrosion, a major problem in steam-driven electricity generation plants. The stain on our teeth that we call dental plaque is also a biofilm. Fossil stromatolites—large, rocky structures made up of alternating layers of fossilized microbial biofilm and calcium carbonate—are the oldest remnants of early life on

26.3 Forming a Biofilm (A) Free-swimming bacteria and archaea readily attach themselves to surfaces and form films stabilized and protected by a surrounding matrix. Once the population size is large enough, the developing biofilm can send chemical signals that attract other microorganisms. (B) Scanning electron micrograph reveals a biofilm of plaque on a used toothbrush bristle. The matrix of dental plaque consists of proteins from both bacterial secretions and saliva.

Earth (see Figure 25.4). Stromatolites still form today in some parts of the world.

Biofilms are the subject of much current research. For example, some biologists are studying the chemical signals that bacteria in biofilms use to communicate with one another. By blocking the signals that lead to the production of the matrix polysaccharides, researchers may be able to prevent biofilms from forming.

A team of bioengineers and chemical engineers recently devised a sophisticated technique that enables them to monitor biofilm development in extremely small populations of bacteria, cell by cell. They developed a tiny chip housing six separate growth chambers, or “microchemostats” (Figure 26.4). The techniques of *microfluidics* use microscopic tubes and computer-controlled valves to direct fluid flow through complex “plumbing circuits” in the growth chambers.

TOOLS FOR INVESTIGATING LIFE

26.4 The Microchemostat

Using techniques from microfluidic engineering, biologists can monitor the dynamics of extremely small bacterial populations. The photograph shows six microchemostats on a chip. Each of the six is equipped with input ports for growth and flushing media, and a number of output ports (diagram). Tiny valves, controlled by a computer, direct flow. Samples are removed through the output ports and are analyzed to record changes in the bacterial population.

Prokaryotes have distinctive cell walls

Many prokaryotes have a thick and relatively stiff cell wall. It is quite different from the cell walls of land plants and algae, which contain cellulose and other polysaccharides, and from those of fungi, which contain chitin. The cell walls of almost all bacteria contain **peptidoglycan** (a cross-linked polymer of amino sugars), which produces a meshlike structure around the cell. Archaeal cell walls are of differing types, but most contain significant amounts of protein. One group of archaea has *pseudopeptidoglycan* in its cell wall; as you can probably guess from the prefix *pseudo*, pseudopeptidoglycan is similar to, but distinctly different from, the peptidoglycan of bacteria. The monomers making up pseudopeptidoglycan differ from and are differently linked than those of peptidoglycan. Peptidoglycan is a substance unique to bacteria; its absence from the

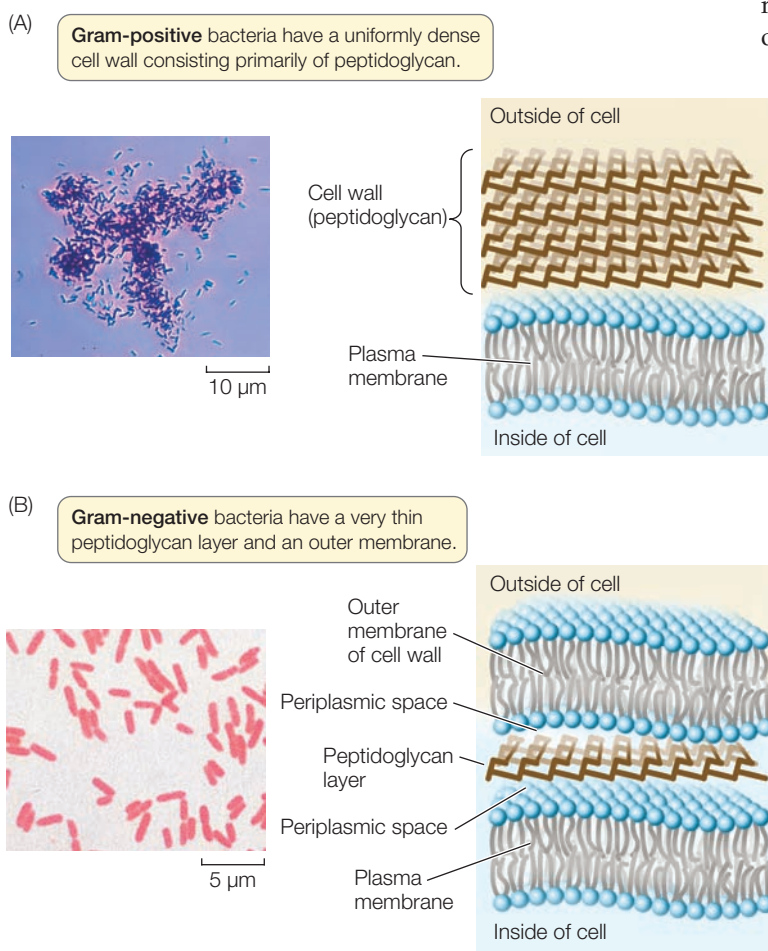

walls of archaea is a key difference between the two prokaryotic domains.

To appreciate the complexity of some bacterial cell walls, consider the reactions of bacteria to a simple staining process. A test called the **Gram stain** separates most types of bacteria into two distinct groups, Gram-positive and Gram-negative. A smear of cells on a microscope slide is soaked in a violet dye and treated with iodine; it is then washed with alcohol and counterstained with a red dye (safranin). **Gram-positive bacteria** retain the violet dye and appear blue to purple (**Figure 26.5A**). The alcohol washes the violet stain out of Gram-negative cells; these cells then pick up the safranin counterstain, so **Gram-negative bacteria** appear pink to red (**Figure 26.5B**).

For most bacteria, the Gram-staining results are determined by the chemical structure of the cell wall. A Gram-negative cell wall usually has a thin peptidoglycan layer, and outside the peptidoglycan layer the cell is surrounded by a second, outer membrane quite distinct in chemical makeup from the plasma membrane (see **Figure 26.5B**). Between the inner (plasma) and outer membranes of Gram-negative bacteria is a *periplasmic space*. This space contains proteins that are important in digesting some materials, transporting others, and detecting chemical gradients in the environment.

A Gram-positive cell wall usually has about five times as much peptidoglycan as a Gram-negative wall. This thick peptidoglycan layer is a meshwork that may serve some of the same purposes as the periplasmic space of the Gram-negative cell wall.

The consequences of the different features of prokaryotic cell walls are numerous and relate to the disease-causing characteristics of some bacteria. Indeed, the cell wall is a favorite target in medical combat against pathogenic bacteria because it has no counterpart in eukaryotic cells. Antibiotics such as penicillin and ampicillin, as well as other agents that specifically interfere with the synthesis of peptidoglycan-containing cell walls, tend to have little, if any, effect on the cells of humans and other eukaryotes.

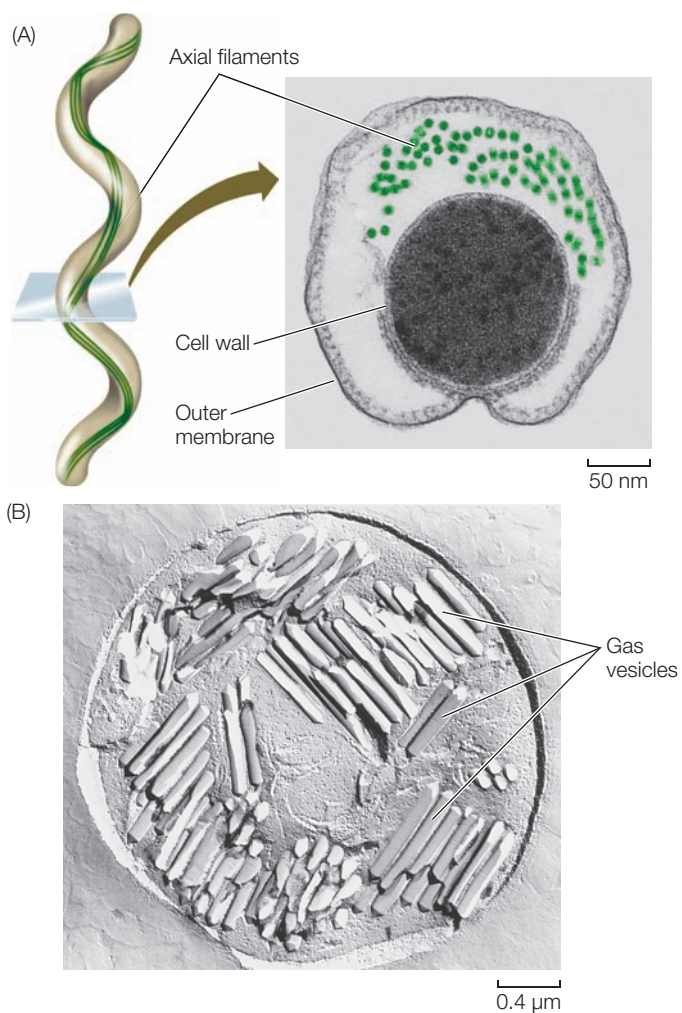

26.5 The Gram Stain and the Bacterial Cell Wall When treated with Gram stain, the cell walls of different bacteria react in one of two ways. (A) Gram-positive bacteria have a thick peptidoglycan cell wall that retains the violet dye and appears deep blue or purple. (B) Gram-negative bacteria have a thin peptidoglycan layer that does not retain the violet dye but picks up the counterstain and appears pink to red.

Prokaryotes have distinctive modes of locomotion

Although many prokaryotes cannot move, others are *motile*. These organisms move by one of several means. Some helical bacteria, called *spirochetes*, use a corkscrew-like motion made possible by modified flagella, called *axial filaments*, running along the axis of the cell beneath the outer membrane (**Figure 26.6A**). Many cyanobacteria and a few other groups of bacteria use various poorly understood gliding mechanisms, including rolling. Various aquatic prokaryotes, including some cyanobacteria, can move slowly up and down in the water by adjusting the amount of gas in *gas vesicles* (**Figure 26.6B**). By far the most common type of locomotion in prokaryotes, however, is that driven by flagella.

Prokaryotic **flagella** are slender filaments that extend singly or in tufts from one or both ends of the cell or are distributed all around it (**Figure 26.7**). A prokaryotic flagellum consists of a single fibril made of the protein *fla*-

26.6 Structures Associated with Prokaryote Motility (A) A spirochete from the gut of a termite, seen in cross section, shows the axial filaments used to produce a corkscrew-like motion. (B) Gas vesicles in a cyanobacterium, visualized by the freeze-fracture technique.

gellin, projecting from the cell surface, plus a hook and basal body responsible for motion (see Figure 5.5). In contrast, the flagellum of eukaryotes is enclosed by the plasma membrane and usually contains a circle of nine pairs of microtubules surrounding two central microtubules, all containing the protein *tubulin*, along with many other associated proteins. The prokaryotic flagellum rotates about its base, much like a propeller, rather than beating in a whiplike manner, as a eukaryotic flagellum or cilium does.

Prokaryotes reproduce asexually, but genetic recombination can occur

Prokaryotes reproduce by binary fission, an asexual process (see Figure 11.2). Recall, however, that there are also processes—transformation, conjugation, and transduction—that allow the exchange of genetic information between some prokaryotes without reproduction occurring. So prokaryotes can exchange and recombine their DNA with other individuals (this is sex in

26.7 Some Prokaryotes Use Flagella for Locomotion Multiple flagella propel this *Salmonella* bacillus.

the genetic sense of the word), but this genetic exchange is not directly linked to reproduction as it is in most eukaryotes.

If conditions are favorable, some prokaryotes can multiply very rapidly. The shortest known prokaryote generation times are about 10 minutes, although these rapid rates of replication usually are not maintained for long. Under less optimal conditions, generation times often extend to many hours or even several days. Bacteria living deep in Earth's crust may suspend their growth for more than a century without dividing, then multiply for a few days before once again suspending growth.

Prokaryotes can communicate

Prokaryotes can send and receive signals from one another and from other organisms. One communication channel they employ is chemical. Another is physical, with light as the medium.

Bacteria release chemical substances that are sensed by other bacteria of the same species. They can announce their availability for conjugation, for example, by means of such signals. They can also monitor the density of their population. As the density of bacteria in a particular region increases, the concentration of a chemical signal builds up. When the bacteria sense that their population has become sufficiently dense, they can commence activities that smaller densities could not manage, such as forming a biofilm (see Figure 26.3). This density-sensing technique is called **quorum sensing**.

Like fireflies and many other organisms, some bacteria can emit light by a process called **bioluminescence**. A complex, enzyme-catalyzed reaction requiring ATP causes the emission of light but not heat. Often such bacteria luminesce only when a quorum has been sensed. The bioluminescent spots present in some deep-sea fishes are produced by colonies of biolumines-

26.8 Bioluminescent Bacteria Seen from Space In this satellite photo, legions of bioluminescent *Vibrio harveyi* form a glowing patch thousands of square kilometers in area in the Indian Ocean, off the Horn of Africa. Compare their blue glow with the white light of cities in eastern Africa and the Middle East.

cent bacteria. On land, some soil-dwelling bioluminescent bacteria produce eerily glowing patches of ground at night.

How is bioluminescence useful to a prokaryote? One fairly well understood case is that of some bacteria of the genus *Vibrio*. These bacteria can live freely, but they truly thrive inside the guts of fish. Inside the fish, they may attach to food particles and then can be expelled as waste along with particulate matter. Reproducing on the particles, a bacteria population increases until a glowing particle attracts another fish, which ingests the bacteria along with the particle—giving the bacteria a new home and food source for a while. In this case, *Vibrio* are both communicating with another species and enhancing their own nutritional status. In the Indian Ocean off the eastern coast of Africa, *Vibrio* sometimes concentrate over such a large area (several thousand square kilometers) that their bioluminescence is visible from space (**Figure 26.8**).

Prokaryotes have amazingly diverse metabolic pathways

Bacteria and archaea outdo the eukaryotes in terms of metabolic diversity. Although much more diverse in size and shape, eukaryotes draw on fewer metabolic mechanisms for their energy needs. In fact, much of the eukaryotes' energy metabolism is carried out in organelles—mitochondria and chloro-

plasts—that are endosymbiotic descendants of bacteria, as described in Section 5.5.

The long evolutionary history of bacteria and archaea, during which they have had time to explore a wide variety of habitats, has led to the extraordinary diversity of their metabolic “lifestyles”—their use or nonuse of oxygen, their energy sources, their sources of carbon atoms, and the materials they release as waste products.

ANAEROBIC VERSUS AEROBIC METABOLISM Some prokaryotes can live only by anaerobic metabolism because molecular oxygen is poisonous to them. These oxygen-sensitive organisms are called **obligate anaerobes**. Other prokaryotes can shift their metabolism between anaerobic and aerobic modes (see Chapter 9) and thus are called **facultative anaerobes**. Many facultative anaerobes alternate between anaerobic metabolism (such as fermentation) and cellular respiration as conditions dictate. **Aerotolerant anaerobes** cannot conduct cellular respiration but are not damaged by oxygen when it is present. By definition, an anaerobe does not use oxygen as an electron acceptor for its respiration.

At the other extreme from the obligate anaerobes, some prokaryotes are **obligate aerobes**, unable to survive for extended periods in the *absence* of oxygen. They require oxygen for cellular respiration.

NUTRITIONAL CATEGORIES All living organisms face the same nutritional challenges: they must synthesize energy-rich compounds such as ATP to power their life-sustaining metabolic reactions, and they must obtain carbon atoms to build their own organic molecules. Biologists recognize four broad nutritional categories of organisms: photoautotrophs, photoheterotrophs, chemolithotrophs, and chemoheterotrophs. Prokaryotes are represented in all four groups (**Table 26.2**).

Photoautotrophs perform photosynthesis. They use light as their energy source and carbon dioxide (CO₂) as their carbon source. Like green plants and other photosynthetic eukaryotes, the cyanobacteria, a group of photoautotrophic bacteria, use chlorophyll *a* as their key photosynthetic pigment and produce

NUTRITIONAL CATEGORY	ENERGY SOURCE	CARBON SOURCE
Photoautotrophs (found in all three domains)	Light	Carbon dioxide
Photoheterotrophs (some bacteria)	Light	Organic compounds
Chemolithotrophs (some bacteria, many archaea)	Inorganic substances	Carbon dioxide
Chemoheterotrophs (found in all three domains)	Organic compounds	Organic compounds

oxygen gas (O_2) as a by-product of noncyclic electron transport (see Section 10.1).

There are other photosynthetic groups among the bacteria, but these use *bacteriochlorophyll* as their key photosynthetic pigment, and they do not release O_2 . Indeed, some of these photosynthesizers produce particles of pure sulfur, because hydrogen sulfide (H_2S) rather than H_2O is their electron donor for photophosphorylation (see Section 10.2). Bacteriochlorophyll molecules absorb light of longer wavelengths than the chlorophyll molecules used by all other photosynthesizing organisms. As a result, bacteria using this pigment can grow in water under fairly dense layers of algae, using light of wavelengths that are not absorbed by the algae (**Figure 26.9**).

Photoheterotrophs use light as their energy source but must obtain their carbon atoms from organic compounds made by other organisms. Their “food” consists of organic compounds such as carbohydrates, fatty acids, and alcohols. For example, compounds released from plant roots (as in rice paddies) or from decomposing photosynthetic bacteria in hot springs are taken up by photoheterotrophs and metabolized to form building blocks for other compounds; sunlight provides the necessary ATP through photophosphorylation. The purple nonsulfur bacteria, among others, are photoheterotrophs.

Chemolithotrophs (also called chemoautotrophs) obtain their energy by oxidizing inorganic substances, and they use some of that energy to fix CO_2 . Some chemolithotrophs use reactions identical to those of the typical photosynthetic cycle, but others use alternative pathways to fix CO_2 . Some bacteria oxidize ammonia or nitrite ions to form nitrate ions. Others oxidize hydrogen gas, hydrogen sulfide, sulfur, and other materials. Many archaea are chemolithotrophs.

Deep-sea hydrothermal vent ecosystems are dependent on chemolithotrophic prokaryotes that are incorporated into large communities of crabs, mollusks, and giant worms, all living at a depth of 2,500 meters—below any hint of sunlight. These bacteria obtain energy by oxidizing hydrogen sulfide and other substances released in the near-boiling water flowing from volcanic vents in the ocean floor.

Finally, **chemoheterotrophs** obtain both energy and carbon atoms from one or more complex organic compounds that have been synthesized by other organisms. Most known bacteria and archaea are chemoheterotrophs—as are all animals and fungi and many protists.

NITROGEN AND SULFUR METABOLISM Key metabolic reactions in many prokaryotes involve nitrogen or sulfur. For example, some bacteria carry out respiratory electron transport without using oxygen as an electron acceptor. These organisms use oxidized inorganic ions such as nitrate, nitrite, or sulfate as electron acceptors. Examples include the **denitrifiers**, bacteria that release nitrogen to the atmosphere as nitrogen gas (N_2). These normally aerobic bacteria, mostly species of the genera *Bacillus* and *Pseudomonas*, use nitrate (NO_3^-) as an electron acceptor in place of oxygen if they are kept under anaerobic conditions:

Nitrogen fixers convert atmospheric nitrogen gas into a chemical form (ammonia) usable by the nitrogen fixers themselves as well as by other organisms, especially land plants:

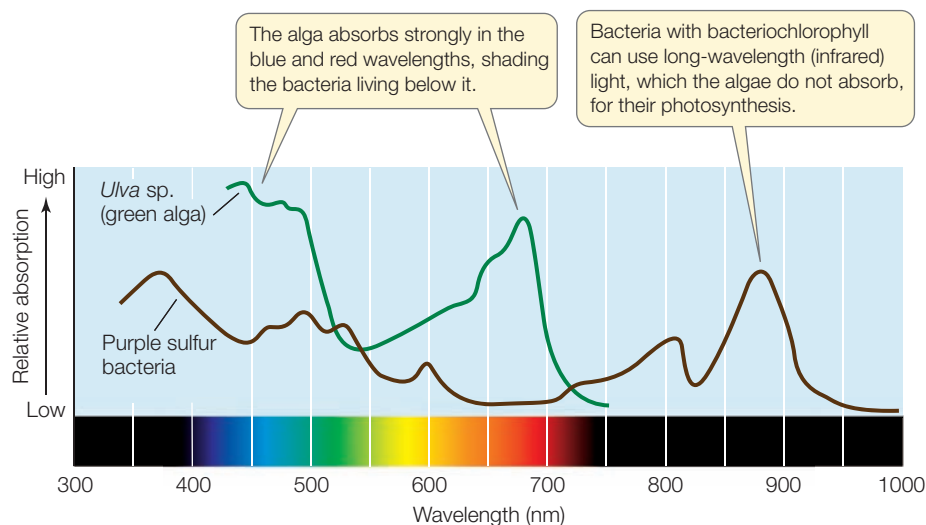

All organisms require nitrogen in order to build proteins, nucleic acids, and other important compounds. Nitrogen fixation is thus vital to life as we know it. This all-important biochemical process is carried out by a wide variety of archaea and bacteria (including cyanobacteria) but by no other organisms, so we depend on these prokaryotes for our very existence. We describe the details of nitrogen fixation in Chapter 36.

Ammonia is oxidized to nitrate in soil and in seawater by chemolithotrophic bacteria called **nitrifiers**. Bacteria of two genera, *Nitrosomonas* and *Nitrosococcus*, convert ammonia to nitrite ions (NO_2^-), and *Nitrobacter* oxidizes nitrite to nitrate (NO_3^-).

What do the nitrifiers get out of these reactions? Their metabolism is powered by the energy released by the oxidation of ammonia or nitrite. For example, by passing the electrons from nitrite through an electron transport chain (see Section 9.3),

Nitrobacter can make ATP, and using some of this ATP, can also make NADH. With this ATP and NADH, the bacterium can convert CO_2 and H_2O to glucose.

26.9 Bacteriochlorophyll Absorbs Long-Wavelength Light

The chlorophyll in *Ulva*, a green alga, absorbs no light of wavelengths longer than 750 nm. Purple sulfur bacteria, which contain bacteriochlorophyll, can conduct photosynthesis using longer wavelengths.

26.2 RECAP

Prokaryotes have established themselves everywhere on Earth. They may form communities called biofilms that coat materials with a gel-like matrix. Prokaryotes have distinctive cell walls and modes of locomotion, communication, reproduction, and nutrition.

- How do biofilms form and why are they of special interest to researchers? **See pp. 539–540 and Figure 26.3**
- Describe bacterial cell wall architecture. **See p. 541 and Figure 26.5**
- How are the four nutritional categories of prokaryotes distinguished? **See pp. 543–544 and Table 26.2**
- Explain why nitrogen metabolism in the prokaryotes is vital to other organisms. **See p. 544**

We noted earlier that only recently have scientists appreciated the huge distinctions between Bacteria and Archaea. How do researchers approach the classification of organisms they can't even see?

26.3 How Can We Resolve Prokaryote Phylogeny?

As detailed in Chapter 22, classification schemes serve three primary purposes: to identify organisms, to reveal evolutionary relationships, and to provide universal names. Classifying bacteria and archaea is of particular importance to humans because scientists and medical technologists must be able to identify bacteria quickly and accurately; when the bacteria are pathogenic, lives may depend on it. In addition, many emerging biotechnologies (see Chapter 18) depend on a thorough knowledge of prokaryote biochemistry, and understanding an organism's phylogeny allows biologists to make predictions about the distribution of biochemical processes across the wide diversity of prokaryotes.

The small size of prokaryotes has hindered our study of their phylogeny

Until about 300 years ago, nobody had even *seen* an individual prokaryote; these organisms remained invisible to humans until the invention of the first simple microscope. Prokaryotes are so small that even the best light microscopes don't reveal much about them. It took the advanced microscopic equipment and techniques of the twentieth century (see Figure 5.3) to open up the microbial world.

Until recently, taxonomists based prokaryote classification on observable phenotypic characters such as shape, color, motility, nutritional requirements, antibiotic sensitivity, and reaction to the Gram stain. When biologists learned how to grow bacteria in pure culture on nutrient media, they learned a great deal about the genetics, nutrition, and metabolism of those species that could be cultured. However, these species represent prob-

ably less than 1 percent of living prokaryote species. Furthermore, this work provided little insight into how prokaryotic organisms evolved—a question of great interest to microbiologists and evolutionary biologists. Only recently have systematists developed the appropriate tools to produce classification schemes that make sense in evolutionary terms.

The nucleotide sequences of prokaryotes reveal their evolutionary relationships

Analyses of nucleotide sequences of ribosomal RNA (rRNA) genes provided the first comprehensive evidence of evolutionary relationships among prokaryotes. For several reasons, rRNA is particularly useful for evolutionary studies of living organisms:

- rRNA is evolutionarily ancient, as it was found in the common ancestor of life.
- No free-living organism lacks rRNA, so rRNA genes can be compared throughout the tree of life.
- rRNA plays a critical role in translation in all organisms, so *lateral transfer* of rRNA genes among distantly related species is unlikely.
- rRNA has evolved slowly enough that gene sequences can be aligned and analyzed among even distantly related species.

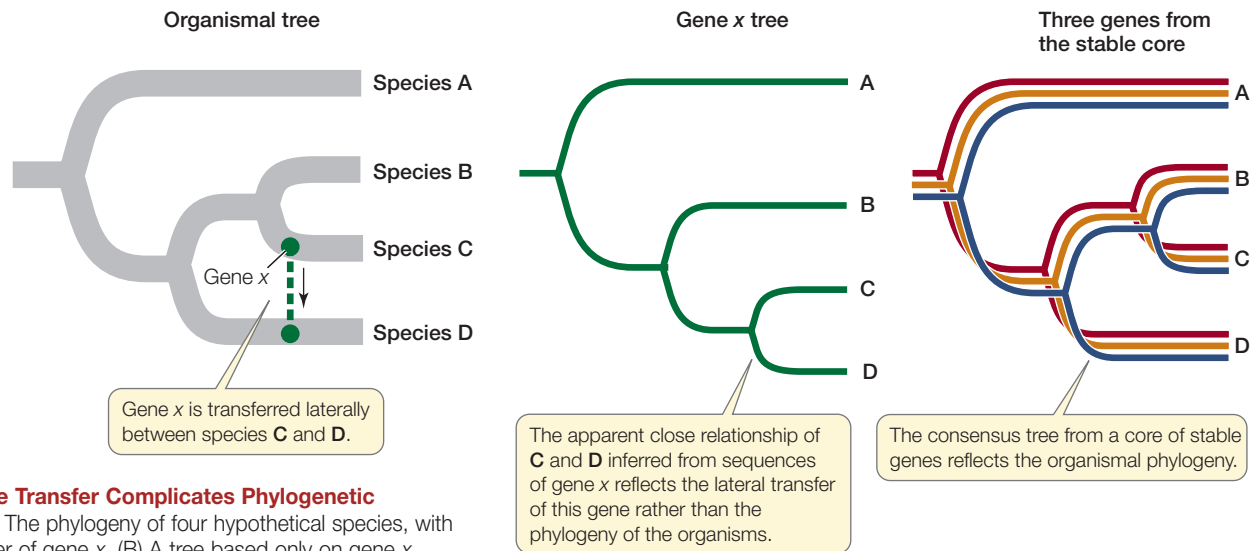

Comparisons of rRNA genes from a great many organisms have revealed the probable phylogenetic relationships from throughout the tree of life. Databases such as GenBank contain rRNA gene sequences from hundreds of thousands of species—more than any other gene sequences.

Although these data are helpful, it is clear that even distantly related prokaryotes sometimes exchange genetic material. In some groups of prokaryotes, analyses of multiple gene sequences have suggested several different phylogenetic patterns. How could such differences among different gene sequences arise?

Lateral gene transfer can lead to discordant gene trees

As noted earlier, prokaryotes reproduce by binary fission. If we could follow these divisions back through evolutionary time, we would be tracing the path of the complete tree of life for bacteria and archaea. This underlying tree of relationships, represented in highly abbreviated form in Appendix A, is called the *organismal* (or *species*) *tree*. Because whole genomes are replicated during asexual binary fission divisions, we expect phylogenetic trees constructed from most gene sequences to reflect these same relationships (see Chapter 22).

From early in evolution to the present day, however, some genes have been moving “sideways” from one prokaryotic species to another, a phenomenon known as **lateral gene transfer**. Mechanisms of lateral gene transfer include transfer by plasmids and viruses and uptake of DNA from the environment by transformation. Lateral gene transfers are well documented, especially among closely related species; some have been documented even across the three primary domains of life.

26.10 Lateral Gene Transfer Complicates Phylogenetic Relationships

(A) The phylogeny of four hypothetical species, with a lateral gene transfer of gene *x*. (B) A tree based only on gene *x* shows the phylogeny of the laterally transferred gene, rather than the organismal phylogeny. (C) In many cases, a “stable core” of prokaryote genes can be used to reconstruct the organismal phylogeny of prokaryotes.

Consider, for example, the genome of *Thermotoga maritima*, a bacterium that can survive extremely high temperatures. In comparing the 1,869 gene sequences of *T. maritima* against sequences for the same proteins in other species, investigators found that some of this bacterium’s genes have their closest relationships not with those of other bacterial species, but with the genes of archaeal species that live in similar environments.

When genes involved in lateral transfer events are sequenced and analyzed phylogenetically, the resulting individual gene trees will not match the organismal phylogeny in every respect (Figure 26.10). Individual gene trees will vary because the history of lateral gene transfer events is different for each gene. Biologists reconstruct the underlying organismal phylogeny by comparing multiple genes (to produce a *consensus tree*), or by concentrating on genes that are unlikely to be involved in lateral gene transfer events. For example, genes that are involved in fundamental cell processes (such as the rRNA genes discussed above) are unlikely to be replaced by the same genes from other species, since functional, locally adapted copies of these genes are already present.

What kinds of genes are most likely to be involved in lateral gene transfer? Genes that result in a new, adaptive function that will convey higher fitness to a recipient species are most likely to be transferred repeatedly among species. For example, genes that produce antibiotic resistance are often transferred on plasmids among many bacterial species, especially under the strong selective conditions of antibiotic medication by humans. This selection for antibiotic resistance is why informed physicians are now more careful in prescribing antibiotics. Improper or frequent use of antibiotics can lead to selection for resistant strains of bacteria, which are then much harder to treat effectively.

It is debatable whether lateral gene transfer has seriously complicated our attempts to resolve the tree of prokaryotic life.

Recent work suggests that it has not—while it complicates studies in some individual species, it need not present problems at higher levels. It is now possible to make nucleotide sequence comparisons involving entire genomes, and these studies are revealing a *stable core* of crucial genes that are uncomplicated by lateral gene transfer. Gene trees based on this stable core more accurately reveal relationships of the organismal phylogeny (see Figure 26.10). The problem remains, however, that only a very small proportion of the prokaryotic world has been described and studied.

The great majority of prokaryote species have never been studied

Most prokaryotes have defied all attempts to grow them in pure culture, causing biologists to wonder how many species, and possibly even important clades, we might be missing. A window onto this problem was opened with the introduction of a new way to look at nucleic acid sequences. Unable to work with the whole genome of a single species, biologists instead examine sequences in individual genes collected from a random sample of the environment.

Norman Pace of the University of Colorado isolated individual rRNA gene sequences from extracts of environmental samples such as soil and seawater. Comparing such sequences with previously known ones revealed an extraordinary number of new sequences, implying that they came from previously unrecognized species. Biologists have described only about 10,000 species of bacteria and only a few hundred species of archaea (see Figure 1.10). The results of Pace’s and similar studies suggest that there may be millions, perhaps hundreds of millions, of prokaryote species on Earth. Other biologists put the estimate much lower, and argue that the high dispersal ability of many bacterial species greatly reduces local endemism (geographically restricted species). Only the magnitude of these estimates differ, however; all sides agree that we have just begun to uncover Earth’s bacterial and archaeal diversity.

26.3 RECAP

The study of prokaryote phylogeny and diversity has been inhibited by the organisms' small size, our inability to grow some of them in pure culture, and lateral gene transfer. However, nucleotide sequences of essential genes are providing a much clearer picture of bacterial and archaeal evolutionary relationships.

- How did biologists classify bacteria before it became possible to determine nucleotide sequences? **See p. 545**
- Explain why nucleotide sequences of rRNA genes are useful for evolutionary studies. **See p. 545**
- How does lateral gene transfer complicate evolutionary studies? **See p. 545–546 and Figure 26.10**

With the advent of sequencing techniques, biologists have made rapid progress in understanding the phylogeny of prokaryotes. In the next section, we identify the characteristics and life history of the major groups.

26.4 What Are the Major Known Groups of Prokaryotes?

Here we use a widely accepted classification scheme that has considerable support from nucleotide sequence data. More than a dozen major clades have been proposed under this scheme, just a few of which we discuss here. We pay the closest attention to six groups that have received the most study: the spirochetes, chlamydias, high-GC Gram-positives, cyanobacteria, low-GC Gram-positives, and proteobacteria (**Figure 26.11**). First, however, a few words about the origins of the prokaryotes are in order.

Several of the earliest branching lineages of bacteria and archaea are **thermophiles** (Greek, “heat-lovers”). This observation is in line with the hypothesis that the first living organisms were thermophiles, given that most environments on early Earth were much hotter than those of today. While additional evidence continues to support this hypothesis, some researchers believe that the various thermophilic groups evolved more recently than did the lineages leading to the spirochetes and chlamydias.

Spirochetes move by means of axial filaments

Spirochetes are Gram-negative, motile, chemoheterotrophic bacteria characterized by unique structures called axial filaments, which are modified flagella running through the periplasmic space (see Figure 26.6A). The cell body is a long cylinder coiled into a helix (**Figure 26.12**). The axial filaments begin at either end of the cell and overlap in the middle. Protein motors connect the axial filaments to the cell wall, enabling rotation of these structures as they do in other prokaryotic flagella. Many spirochetes live in humans as parasites; a few are pathogens, including those that cause syphilis and Lyme disease. Others live free in mud or water.

26.11 Two Domains: A Brief Overview This abridged summary classification of the domains Bacteria and Archaea shows their relationships to each other and to Eukarya. The relationships among the many clades of bacteria, not all of which are listed here, are incompletely resolved at this time.

Treponema pallidum

200 nm

26.12 A Spirochete This corkscrew-shaped bacterium causes syphilis in humans.

Chlamydias are extremely small parasites

Chlamydias are among the smallest bacteria (0.2–1.5 μm in diameter). They can live only as parasites in the cells of other organisms. It was once believed that this obligate parasitism resulted from an inability of chlamydias to produce ATP—that chlamydias were “energy parasites.” However, genome sequencing from the end of the twentieth century indicates that chlamydias have the genetic capability to produce at least some ATP. They can augment this capacity by using an enzyme called a translocase, which allows them to take up ATP from the cytoplasm of their host in exchange for ADP from their own cells.

These tiny, Gram-negative cocci are unique prokaryotes because of their complex life cycle, which involves two different forms of cells, *elementary bodies* and *reticulate bodies* (Figure 26.13). In humans, various strains of chlamydias cause eye infections (especially trachoma), sexually transmitted diseases, and some forms of pneumonia.

Some high-GC Gram-positives are valuable sources of antibiotics

High-GC Gram-positives, also known as *actinobacteria*, derive their name from the relatively high ratio of G-C to A-T nucleotide base pairs in their DNA. These bacteria develop an elaborately branched system of filaments (Figure 26.14) and can resemble the filamentous growth habit of fungi, albeit at a reduced scale. Some high-GC Gram-positives reproduce by forming chains of spores at the tips of the filaments. In species that do not form spores, the branched, filamentous growth ceases, and the structure breaks up into typical cocci or bacilli, which then reproduce by binary fission.

26.13 Chlamydias Change Form during their Life Cycle

Elementary bodies and reticulate bodies are the two major phases of the chlamydia life cycle.

26.14 Filaments of a High-GC Gram-Positive The branching filaments seen in this scanning electron micrograph are typical of this medically important bacterial group.

The high-GC Gram-positives include several medically important bacteria. *Mycobacterium tuberculosis* causes tuberculosis, which kills 3 million people each year. Genetic data suggest that this bacterium arose 3 million years ago in East Africa, making it the oldest known human bacterial affliction. *Streptomyces* produce streptomycin as well as hundreds of other antibiotics. We derive most of our antibiotics from members of the high-GC Gram-positives.

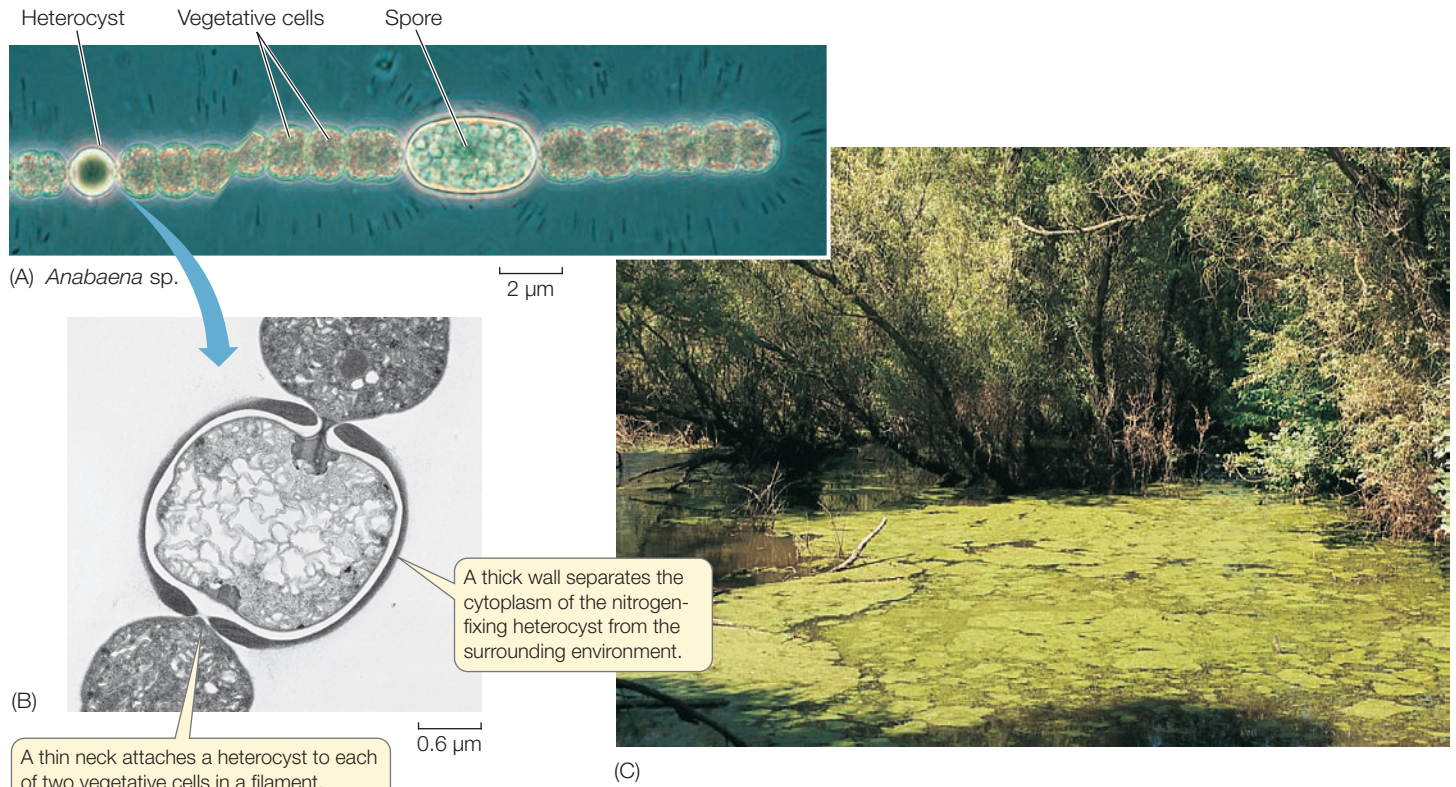

Cyanobacteria are important photoautotrophs

Cyanobacteria, sometimes called *blue-green bacteria* because of their pigmentation, are photoautotrophs that require only water, nitrogen gas, oxygen, a few mineral elements, light, and carbon dioxide to survive. They use chlorophyll *a* for photosynthesis and release oxygen gas; many species also fix nitrogen. Their photosynthesis was the basis of the “oxygen revolution” that transformed Earth’s atmosphere (see Section 25.3).

Cyanobacteria carry out the same type of photosynthesis that is characteristic of eukaryotic photosynthesizers. They contain elaborate and highly organized internal membrane systems called *photosynthetic lamellae*. The chloroplasts of photosynthetic eukaryotes are derived from an endosymbiotic cyanobacterium.

Cyanobacteria may live free as single cells or associate in colonies. Depending on the species and on growth conditions, colonies may range from flat sheets one cell thick to filaments to spherical balls of cells.

Some filamentous colonies of cyanobacteria differentiate into three cell types: vegetative cells, spores, and heterocysts (Figure 26.15). **Vegetative cells** photosynthesize, **spores** are resting stages that can survive harsh environmental conditions and eventually develop into new filaments, and **heterocysts** are cells specialized for nitrogen fixation. All of the known cyanobacteria with heterocysts fix nitrogen. Heterocysts also have a role in reproduction: when filaments break apart to reproduce, the heterocyst may serve as a breaking point.

26.15 Cyanobacteria (A) *Anabaena* is a genus of cyanobacteria that form filamentous colonies containing three cell types. (B) Heterocysts are specialized for nitrogen fixation and serve as a breaking point when filaments reproduce. (C) Cyanobacteria appear in enormous numbers in some environments. This California pond has experienced eutrophication: phosphorus and other nutrients generated by human activity have accumulated, feeding an immense green mat (commonly referred to as “pond scum”) that is made up of several species of free-living cyanobacteria.

The low-GC Gram-positives include the smallest cellular organisms

As their name suggests, the **low-GC Gram-positives** have a lower ratio of G-C to A-T nucleotide base pairs than do the high-GC Gram-positives. Some of the low-GC Gram-positives are in fact Gram-negative, and some have no cell wall at all. Despite these differences among the various species, phylogenetic analyses of DNA sequences support the monophyly of this clade.

Some low-GC Gram-positives can produce heat-resistant resting structures called **endospores** (Figure 26.16). When a key nutrient such as nitrogen or carbon becomes scarce, the bacterium replicates its DNA and encapsulates one copy, along with some of its cytoplasm, in a tough cell wall heavily thickened with peptidoglycan and surrounded by a spore coat. The parent cell then breaks down, releasing the endospore. Endospore production is not a reproductive process; the endospore merely replaces the parent cell. The endospore, however, can survive harsh environmental conditions that would kill the parent cell, such as high or low temperatures or drought, because it is *dormant*—its normal activity is suspended. Later, if it encounters favorable conditions, the endospore becomes metabolically active and divides, forming new cells that are like the parent cells.

Some endospores can be reactivated after more than 1,000 years of dormancy. There are even credible claims of reactivation of *Bacillus* endospores after millions of years. Members of this endospore-forming group of low-GC Gram-positives include the many species of *Clostridium* and *Bacillus*.

Dormant endospores of *Bacillus anthracis* are the source of an *exotoxin* (see page 555) that causes anthrax. The spores germinate when they sense specific molecules (macrophages; see Chapter 42) in the cytoplasm of mammalian blood cells. However, endospores of other, nonpathogenic *Bacillus* species do not germinate.

26.16 A Structure for Waiting Out Bad Times This low-GC Gram-positive bacterium, which can cause severe colitis in humans, produces endospores as resistant resting structures.

Staphylococcus aureus

1 μ m

26.17 Low-GC Gram-Positives “Grape clusters” are the usual arrangement of staphylococci.

nate in this environment. *B. anthracis* has been used as a bioterrorism agent because large quantities of its endospores are relatively easy to transport and spread among human populations, where they may be inhaled or ingested.

The genus *Staphylococcus*—the **staphylococci**—includes low-GC Gram-positives that are abundant on the human body surface; they are responsible for boils and many other skin problems (**Figure 26.17**). *Staphylococcus aureus* is the best-known human pathogen in this genus; it is found in 20 to 40 percent of normal adults (and in 50 to 70 percent of hospitalized adults). In addition to skin diseases, it can cause respiratory, intestinal, and wound infections.

Another interesting group of low-GC Gram-positives, the **mycoplasmas**, lack cell walls, although some have a stiffening material outside the plasma membrane. The mycoplasmas include the smallest cellular creatures known (**Figure 26.18**)—even smaller than chlamydias. The smallest mycoplasmas capable of multiplying by fission have a diameter of about 0.2 μ m. They are small in another crucial sense as well: they have less than half as much DNA as most other prokaryotes. It has been speculated that the amount of DNA in a mycoplasma, which codes for fewer than 500 proteins, may be the minimum amount required to encode the essential properties of a living cell.

The proteobacteria are a large and diverse group

By far the largest group of bacteria, in terms of number of described species, is the **proteobacteria**. The proteobacteria include many species of Gram-negative, bacteriochlorophyll-containing, sulfur-using photoautotrophs—as well as dramatically diverse bacteria that bear no phenotypic resemblance to the photoautotrophic species. Genetic and morphological evidence indicates that the mitochondria of eukaryotes were derived from a proteobacterium by endosymbiosis (see Section 27.2).

No characteristic demonstrates the diversity of the proteobacteria more clearly than their metabolic pathways (**Figure 26.19**). There are five groups of proteobacteria: alpha, beta, gamma, delta, and epsilon. The common ancestor of all the pro-

Mycoplasma gallisepticum

0.4 μ m

26.18 The Tiniest Cells Containing only about one-fifth as much DNA as *E. coli*, mycoplasmas are the smallest known bacteria.

teobacteria was a photoautotroph. Early in evolution, two groups of proteobacteria lost their ability to photosynthesize and have been chemotrophs ever since. The other three groups still have photoautotrophic members, but in each group some evolutionary lines have abandoned photoautotrophy and taken up other modes of nutrition. There are chemolithotrophs and chemoheterotrophs in all three groups. Why? One possibility is that each of the trends shown in Figure 26.19 was an evolution-

26.19 Modes of Nutrition in the Proteobacteria The common ancestor of all proteobacteria was probably a photoautotroph. As they encountered new environments, the delta and epsilon proteobacteria lost the ability to photosynthesize. In the other three groups, some evolutionary lineages became chemolithotrophs or chemoheterotrophs.

ary response to selective pressures encountered as these bacteria colonized new habitats that presented new challenges and opportunities. Lateral gene transfer may have played a role in these responses.

Among the proteobacteria are some nitrogen-fixing genera, such as *Rhizobium* (see Figure 36.9), and other bacteria that contribute to the global nitrogen and sulfur cycles. *Escherichia coli*, one of the most studied organisms on Earth, is a proteobacterium. So, too, are many of the most famous human pathogens, such as *Yersinia pestis* (which causes bubonic plague), *Vibrio cholerae* (cholera), and *Salmonella typhimurium* (gastrointestinal disease).

Although fungi cause most plant diseases, and viruses cause others, about 200 known plant diseases are of bacterial origin. *Crown gall*, with its characteristic tumors (Figure 26.20), is one of the most striking. The causal agent of crown gall is *Agrobacterium tumefaciens*, a proteobacterium that harbors a plasmid used in recombinant DNA studies as a vehicle for inserting genes into new plant hosts (see Section 18.2).

We have discussed six clades of bacteria in some detail. Other bacterial clades are well known, and there are probably dozens more waiting to be discovered. This estimate is conservative because so few bacteria have been cultured and studied in the laboratory.

Archaea differ in several important ways from bacteria

The separation of Archaea from Bacteria and Eukarya was originally based on phylogenetic relationships determined from sequences of rRNA genes. This conclusion was supported when biologists sequenced the first archaeal genome. It consisted of 1,738 genes, more than half of which were unlike any genes ever found in the other two domains. Archaea are well known for living in extreme habitats such as those with high salinity (salt content), low oxygen concentrations, high temperatures, or high or low pH (Figure 26.21). However, many archaea are not extremeophiles but live in moderate habitats; they are common in

26.20 Crown Gall A crown gall, the type of tumor shown here growing on the stem of a bushy shrub, is caused by the proteobacterium *Agrobacterium tumefaciens*.

INVESTIGATING LIFE

26.21 What Is the Highest Temperature Compatible with Life?

Can any organism thrive at temperatures above 120°C? This is the temperature used for sterilization, known to destroy all previously described organisms. Kazem Kashefi and Derek Lovley isolated an unidentified prokaryote from water samples taken near a hydrothermal vent and found it survived and even grew at 121°C. The organism was dubbed “Strain 121,” and its gene sequencing results indicate that it is an archaeal species.

HYPOTHESIS Some prokaryotes survive and even multiply at temperatures above the 120°C threshold of sterilization.

METHOD

1. Seal samples of unidentified, iron-reducing, thermal vent prokaryotes in tubes with a medium containing Fe^{3+} as an electron acceptor. Control tubes contain Fe^{3+} but no organisms.
2. Hold both tubes in a sterilizer at 121°C for 10 hours. If the iron-reducing organisms are metabolically active, they will reduce the Fe^{3+} to Fe^{2+} (as magnetite, which can be detected with a magnet).
3. Isolate any surviving organisms and test for growth at various temperatures.

RESULTS

The iron-containing solids were attracted to a magnet only in those tubes that contained living cells.

Cells multiplied most rapidly at about 105°C but divided about once a day even at 121°C.

CONCLUSION Some prokaryotic organisms can survive and grow at temperatures above the previously defined sterilization limit.

FURTHER INVESTIGATION: Note that Strain 121 did not grow during a 2-hour exposure to 130°C, but it did not die, either. How would you demonstrate that it was still alive?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

soil, for example. Perhaps the largest number of archaea live in the ocean depths.

One current classification scheme divides Archaea into two principal groups, **Euryarchaeota** and **Crenarchaeota**. Less is known about two more recently discovered groups, **Korarchaeota** and **Nanoarchaeota**. In fact, we know relatively little about the phylogeny of archaea, in part because the study of archaea is still in its early stages.

Two characteristics shared by all archaea are the absence of peptidoglycan in their cell walls and the presence of lipids of distinctive composition in their cell membranes (see Table 26.1). The unusual lipids in the membranes of archaea are found in all archaea and in no bacteria or eukaryotes. Most bacterial and eukaryotic membrane lipids contain unbranched long-chain fatty acids connected to glycerol molecules by *ester linkages*:

In contrast, some archaeal membrane lipids contain long-chain hydrocarbons connected to glycerol molecules by *ether linkages*:

These ether linkages are a synapomorphy of archaea. In addition, the long-chain hydrocarbons of archaea are branched. One class of these lipids, with hydrocarbon chains 40 carbon atoms in length, contains glycerol at *both* ends of the hydrocarbons (**Figure 26.22**). This *lipid monolayer* structure, unique to archaea, still fits in a biological membrane because the lipids are twice as long as the typical lipids in the bilayers of other membranes. Lipid monolayers and bilayers are both found among the archaea. The effects, if any, of these structural features on membrane performance are unknown. In spite of this striking difference in their membrane lipids, the membranes seen in all three domains have similar overall structures, dimensions, and functions.

26.22 Membrane Architecture in Archaea The long-chain hydrocarbons of many archaeal membranes have glycerol molecules at both ends, so that the membranes consist of a lipid monolayer. In contrast, the membranes of other archaea, bacteria, and eukaryotes consist of a lipid bilayer.

Most Crenarchaeota live in hot and/or acidic places

Most known Crenarchaeota are either thermophilic (heat loving), acidophilic (acid loving), or both. Members of the genus *Sulfolobus* live in hot sulfur springs at temperatures of 70°C to 75°C. They become metabolically inactive at 55°C (131°F). Hot sulfur springs are also extremely acidic. *Sulfolobus* grows best in the range from pH 2 to pH 3, but some members of this genus readily tolerate pH values as low as 0.9. Most acidophilic thermophiles maintain an internal pH of 5.5 to 7 (close to neutral) in spite of their acidic environment. These and other thermophiles thrive where very few other organisms can even survive. The archaea living in the volcanic vent shown in the opening of this chapter are examples of such thermophiles.

Euryarchaeota are found in surprising places

Some species of Euryarchaeota share the property of producing methane (CH₄) by reducing carbon dioxide. All of these methanogens are obligate anaerobes, and methane production is the key step in their energy metabolism. Comparison of rRNA gene sequences has revealed a close evolutionary relationship among these methanogenic species, which were previously assigned to several different bacterial groups.

Methanogens release approximately 2 billion tons of methane gas into Earth's atmosphere each year, accounting for 80 to 90 percent of the methane in the atmosphere, including the methane produced in some mammalian digestive systems. Approximately a third of this methane comes from methanogens living in the guts of grazing herbivores such as cattle, sheep, and deer, and another large fraction comes from the methanogens that live in the guts of termites and cockroaches. Methane is increasing in Earth's atmosphere by about 1 percent per year and contributes to the greenhouse effect. Part of the increase is due to increases in cattle and rice farming and the methanogens associated with both.

One methanogen, *Methanopyrus*, lives on the ocean bottom near hot hydrothermal vents. *Methanopyrus* can survive and grow at 122°C. It grows best at 98°C and not at all at temperatures below 84°C.

Another group of Euryarchaeota, the **extreme halophiles** (salt lovers), lives exclusively in very salty environments, such as the water of Blood Falls described in the opening of this chapter. Because they contain pink carotenoid pigments, halophiles are sometimes easy to see (**Figure 26.23**). Halophiles grow in the Dead Sea and in brines of all types: the reddish pink spots that can occur on pickled fish are colonies of halophilic archaea. Few other organisms can live in the saltiest of the homes that the extreme halophiles occupy; most would "dry" to death, losing too much water to the hypertonic environment. Extreme halophiles have been found in lakes with pH values as high as 11.5—the most alkaline environment inhabited by living organisms, and almost as alkaline as household ammonia.

Some of the extreme halophiles have a unique system for trapping light energy and using it to form ATP—without using any form of chlorophyll—when oxygen is in short supply. They use the pigment *retinal* (also found in the vertebrate eye) com-

26.23 Extreme Halophiles Commercial seawater evaporating ponds (these are in San Francisco Bay) are home to salt-loving archaea, easily visible here because of their carotenoid pigments.

bined with a protein to form a light-absorbing molecule called *bacteriorhodopsin*, and they form ATP by a chemiosmotic mechanism of the kind described in Figure 9.9.

Another member of the Euryarchaeota, *Thermoplasma*, has no cell wall. It is thermophilic and acidophilic, its metabolism is aerobic, and it lives in coal deposits. It has the smallest genome among the archaea, and among the smallest (along with the mycoplasmas) of any free-living organism—1,100,000 base pairs.

26.24 A Nanoarchaeote Growing in Mixed Culture with a Crenarchaeote *Nanoarchaeum equitans* (red), discovered living near deep-ocean hydrothermal vents, is the only representative of the nanoarchaeote group so far discovered. This tiny organism lives attached to cells of the crenarchaeote *Ignicoccus* (green). For this confocal laser micrograph, the two species were visually differentiated by fluorescent dye “tags” that are specific to their separate gene sequences.

Korarchaeota and Nanoarchaeota are less well known

The Korarchaeota are known only by evidence derived from DNA isolated directly from hot springs. No korarchaeote has been successfully grown in pure culture.

Another distinctive archaeal lineage has been discovered at a deep-sea hydrothermal vent off the coast of Iceland. It is the first representative of a group christened Nanoarchaeota because of their minute size. This organism lives attached to cells of *Ignicoccus*, a crenarchaeote. Because of their association, the two species can be grown together in culture (Figure 26.24).

26.4 RECAP

Bacteria and Archaea are highly diverse groups that survive in almost every imaginable habitat on Earth. Many can survive and even thrive in habitats where no eukaryotes can live, including extremely hot, acidic, or alkaline conditions.

- Can you explain how metabolic diversity could have become so great in the proteobacteria? **See pp. 550–551 and Figure 26.19**
- What makes the membranes of archaea unique? **See p. 552 and Figure 26.22**

Because prokaryotes have so many different metabolic and nutritional capabilities, and because they can live in so many environments, it is reasonable to expect that they affect their environments in many ways. As we are about to see, prokaryotes directly affect humans—in ways both beneficial and harmful.

26.5 How Do Prokaryotes Affect Their Environments?

Prokaryotes live in and exploit all kinds of environments and are part of all ecosystems. In this section we examine the roles of prokaryotes that live in soils, in water, and even in other organisms, where they may exist in a neutral, beneficial, or parasitic relationship with their host’s tissues. The roles of some prokaryotes living in extreme environments have yet to be determined.

Remember that in spite of our frequent mention of prokaryotes as human pathogens, only a small minority of the known prokaryotic species are pathogenic. Many more prokaryotes play positive roles in our lives and in the biosphere. We make direct use of many bacteria and a few archaea in such diverse applications as cheese production, sewage treatment, and the industrial production of an amazing variety of antibiotics, vitamins, organic solvents, and other chemicals.

Prokaryotes are important players in element cycling

Many prokaryotes are decomposers—organisms that metabolize organic compounds in dead organisms and other organic material and return the products to the environment as inorganic substances. Prokaryotes, along with fungi, return tremen-

dous quantities of organic carbon to the atmosphere as carbon dioxide, thus carrying out a key step in the carbon cycle. Prokaryotic decomposers also return inorganic nitrogen and sulfur to the environment.

Animals depend on plants and other photosynthetic organisms for their food, directly or indirectly. But plants depend on other organisms—prokaryotes—for their own nutrition. The extent and diversity of life on Earth would not be possible without nitrogen fixation by prokaryotes. Nitrifiers are crucial to the biosphere because they convert the products of nitrogen fixation into nitrate ions, the form of nitrogen most easily used by many plants (see Figure 36.11). Plants, in turn, are the source of nitrogen compounds for animals and fungi. Denitrifiers also play a key role in keeping the nitrogen cycle going. Without denitrifiers, which convert nitrate ions back into nitrogen gas, all forms of nitrogen would leach from the soil and end up in lakes and oceans, making life on land impossible. Other prokaryotes—both bacteria and archaea—contribute to a similar cycle of sulfur.

In the ancient past, the cyanobacteria had an equally dramatic effect on life: their photosynthesis generated oxygen, converting Earth's atmosphere from an anaerobic to an aerobic environment (see Section 25.3). A major result was the wholesale loss of obligate anaerobic species that could not tolerate the oxygen generated by the cyanobacteria. Only those anaerobes that adapted to aerobic conditions or colonized environments that remained anaerobic survived. However, this transformation to aerobic environments made possible the evolution of cellular respiration and the subsequent explosion of eukaryotic life.

Prokaryotes live on and in other organisms

Prokaryotes work together with eukaryotes in many ways. As we have seen, mitochondria and chloroplasts are descended from what were once free-living bacteria. Much later in evolutionary history, some plants became associated with bacteria to form cooperative nitrogen-fixing nodules on their roots (see Figure 36.9).

Many animals harbor a variety of bacteria and archaea in their digestive tracts. Cattle depend on prokaryotes to perform important steps in digestion. Like most animals, cattle cannot produce cellulase, the enzyme needed to start the digestion of the cellulose that makes up the bulk of their plant food. However, bacteria living in a special section of the gut, called the rumen, produce enough cellulase to process the daily diet for the cattle.

Humans use some of the metabolic products—especially vitamins B₁₂ and K—of bacteria living in our large intestine. These and other bacteria and archaea line our intestines with a dense biofilm that is in intimate contact with the mucosal lining of the gut. This biofilm facilitates nutrient transfer from the intestine into the body and induces immunity to the gut contents. The biofilm in the gut is a major part of an “organ” consisting of prokaryotes that is essential to our health. Its makeup varies from time to time and from region to region of the intestinal tract, and it has a complex ecology that scientists have just begun to explore in detail—including the possibility that the species composition of an individual's prokaryote gut fauna may contribute to obesity (or the resistance to it).

We are heavily populated inside and out by bacteria. A 2009 study of bacteria that live on human skin identified more than 1,000 species living on the outside of our bodies, and many of these are thought to be critical to maintaining the skin's health. Although only a small percentage of bacterial species are agents of disease, popular notions of bacteria as “germs” and fear of the consequences of infection arouse our curiosity about those few.

A small minority of bacteria are pathogens

The late nineteenth century was a productive era in the history of medicine—a time when bacteriologists, chemists, and physicians proved that many diseases are caused by microbial agents. During this time the German physician Robert Koch laid down a set of four rules for establishing that a particular microorganism causes a particular disease:

- The microorganism is always found in individuals with the disease.
- The microorganism can be taken from the host and grown in pure culture.
- A sample of the culture produces the same disease when injected into a new, healthy host.
- The newly infected host yields a new, pure culture of microorganisms identical to those obtained in the second step.

These rules, called **Koch's postulates**, were very important in a time when it was not widely understood that microorganisms cause disease. Although medical science today has more powerful diagnostic tools, the postulates remain useful on occasion. For example, physicians were taken aback in the 1990s when stomach ulcers—long accepted and treated as the result of excess stomach acid—were shown by Koch's postulates to be caused by the bacterium *Helicobacter pylori* (see Figure 51.14).

Only a tiny percentage of all prokaryotes are pathogens, and of those that are known, all are in the domain Bacteria. For an organism to be a successful pathogen, it must:

- arrive at the body surface of a potential host;
- enter the host's body;
- evade the host's defenses;
- multiply inside the host; and finally
- infect a new host.

Failure to successfully complete any of these steps ends the reproductive career of a pathogenic organism. However, in spite of the many defenses available to potential hosts (see Chapter 42), some bacteria are very successful pathogens.

For the host, the consequences of a bacterial infection depend on several factors. One is the **invasiveness** of the pathogen—its ability to multiply in the host's body. Another is its **toxigenicity**—its ability to produce toxins, chemical substances that are harmful to the host's tissues. *Corynebacterium diphtheriae*, the agent that causes diphtheria, has low invasiveness and multiplies only in the throat, but its toxigenicity is so great that the entire body is affected. In contrast, *Bacillus anthracis*, which causes anthrax (a disease primarily of cattle and sheep, but

which is also sometimes fatal in humans), has low toxigenicity but is so invasive that the entire bloodstream ultimately teems with the bacteria.

There are two general types of bacterial toxins: exotoxins and endotoxins. **Endotoxins** are released when certain Gram-negative bacteria grow or lyse (burst). Endotoxins are lipopolysaccharides (complexes consisting of a polysaccharide and a lipid component) that form part of the outer bacterial membrane. Endotoxins are rarely fatal; they normally cause fever, vomiting, and diarrhea. Among the endotoxin producers are some strains of the gamma-proteobacteria *Salmonella* and *Escherichia*.

Exotoxins are usually soluble proteins released by living, multiplying bacteria, and they may travel throughout the host's body. They are highly toxic—often fatal—to the host, but they do not produce fevers. Human diseases induced by bacterial exotoxins include tetanus (*Clostridium tetani*), cholera (*Vibrio cholerae*), and bubonic plague (*Yersinia pestis*). Anthrax results from three exotoxins produced by *Bacillus anthracis*. Botulism is caused by exotoxins produced by *Clostridium botulinum* that are among the most poisonous ever discovered. The lethal dose of the botulinum A exotoxin for humans is about one-millionth of a gram (1 µg). Nonetheless, much smaller doses of this exotoxin, marketed under various trade names, are used to treat muscle spasms and also for cosmetic purposes (temporary wrinkle reduction in skin).

Pathogenic bacteria are often surprisingly difficult to combat, even with today's arsenal of antibiotics. One source of this difficulty is the ability of prokaryotes to form biofilms.

26.5 RECAP

Prokaryotes play key roles in the cycling of Earth's elements. Many prokaryotes are beneficial and even necessary to other forms of life; others are pathogens.

- Describe the roles of bacteria in the nitrogen cycle.
See p. 554
- What are some of the challenges facing a pathogen?
See p. 554

Before moving on to discuss the diversity of eukaryotic life, it is appropriate to consider how viruses are related to the rest of life. Although they are not cellular, viruses are numerically among the most abundant organisms on Earth. Their effects on other organisms are enormous. Where did viruses come from, and how do they fit into the tree of life? Biologists are still working to answer these questions.

26.6 Where Do Viruses Fit into the Tree of Life?

Some biologists do not think of viruses as living organisms, primarily because they are not cellular and must depend on cellular organisms for basic life functions such as replication and metabolism. But viruses are derived from the cells of other living

organisms. They use the same essential forms of genetic storage and transmission as do cellular organisms. Viruses infect all cellular forms of life, including bacteria, archaea, and eukaryotes. They replicate, mutate, evolve, and interact with other organisms, often causing serious diseases when they infect their hosts. They are also numerically among the most abundant organisms on the planet. And, finally, viruses clearly evolve independently of other organisms, so it is almost impossible not to treat them as a part of life.

Several factors make virus phylogeny difficult to resolve. The tiny size of many viral genomes restricts the phylogenetic analyses that can be conducted to relate viruses to cellular organisms. The rapid mutational rate, which results in rapid evolution of viral genomes, tends to cloud evolutionary relationships across long periods of time. There are no known viral fossils (viruses are too small and delicate to fossilize), so the paleontological record offers no clues as to viral origins. Finally, viruses are highly diverse (see Figure 26.25), and several lines of evidence support the hypothesis that viruses have evolved repeatedly within each of the major groups of life.

Many RNA viruses probably represent escaped genomic components

Although viruses are now obligate parasites of cellular species, they may once have been cellular components involved in basic cellular functions—that is, they may be “escaped” components of cellular life that now evolve independently of their hosts.

NEGATIVE-SENSE SINGLE-STRANDED RNA VIRUSES A case in point is a class of viruses whose genome is composed of single-stranded RNA that is the complement (negative-sense) of the mRNA needed for protein translation. Many of these negative-sense single-stranded RNA viruses have only a few genes, including an RNA-dependent RNA polymerase that allows them to make mRNA from their negative-sense RNA genome. Modern cellular organisms cannot generate mRNA in this manner (at least in the absence of viral infections), but scientists speculate that single-stranded RNA genomes may have been common in the distant past, before DNA became the primary molecule for genetic information storage.

A self-replicating RNA polymerase gene that begins to replicate independently of a cellular genome could conceivably acquire a few additional protein-coding genes through recombination with its host's DNA. If one or more of these genes were to foster the development of a protein coat, the virus might then survive outside the host and infect new hosts. It is believed that this scenario has been repeated many times independently across the tree of life, given that many of the negative-sense single-stranded RNA viruses that infect organisms from bacteria to humans are not closely related to one another. In other words, negative-sense single-stranded RNA viruses do not represent a distinct taxonomic group, but exemplify a particular process of cellular escape that probably happened many different times.

Examples of familiar negative-sense single-stranded RNA viruses include the viruses that cause measles, mumps, rabies, and influenza (**Figure 26.25A**).

A negative-sense single-stranded RNA virus: Influenza virus H5N1, the “bird flu” virus. Surface view.

A positive-sense single-stranded RNA virus: Hepatitis C virus, the cause of a human liver disease. Surface view.

An RNA retrovirus: One of the human immunodeficiency viruses (HIV) that causes AIDS. Cutaway view.

A double-stranded DNA virus: One of the many herpes viruses (Herpesviridae). Different herpes viruses are responsible for many human infections, including chicken pox, shingles, cold sores, and genital herpes (HSV1/2). Surface view.

A double-stranded DNA virus: Bacteriophage T4. Viruses that infect bacteria are referred to as bacteriophage (or simply phage). T4 attaches leglike fibers to the outside of its host cell and injects its DNA into the cytoplasm through its “tail” (pink structure in this rendition).

A double-stranded DNA mimivirus: This *Acanthamoeba polyphaga* mimivirus (APMV) has the largest diameter of all known viruses and a genome larger than some prokaryote genomes. Cutaway view.

26.25 Viruses Are Diverse Relatively small genomes and rapid evolutionary rates make it difficult to reconstruct phylogenetic relationships among some classes of viruses. Instead, viruses are classified largely by general characteristics of their genomes. The images here are computer artists’ reconstructions based on cryoelectron micrographs.

POSITIVE-SENSE SINGLE-STRANDED RNA VIRUSES The genome of another type of single-stranded RNA viruses is composed of positive-sense RNA. Positive-sense genomes are already set for translation; unlike in negative-sense RNA, no replication of the genome into the complement strand is needed before protein translation can take place. Positive-sense single-stranded RNA viruses are the most abundant and diverse class of viruses (**Figure 26.25B**). Most of the viruses that cause diseases in crop plants are in this group. When they infect plants, these viruses kill patches of cells in the leaves or stems of the plants, leaving

live cells amid a patchwork of discolored dead plant tissue (giving them the name of *mosaic* or *mottle viruses*; **Figure 26.26**). Other viruses in this group infect bacteria, fungi, and animals. Human diseases caused by positive-sense single-stranded RNA viruses include polio, hepatitis C, and the common cold. As is true of the other functionally defined groups of viruses, these viruses appear to have evolved multiple times across the tree of life from different groups of cellular ancestors.

RNA RETROVIRUSES The RNA retroviruses are best known as the group that includes the human immunodeficiency viruses (HIV; **Figure 26.25C**). Like the previous two categories of viruses, RNA retroviruses have genomes composed of single-stranded RNA and likely evolved as escaped cellular components.

26.26 Mosaic Viruses Are a Problem for Agriculture Mosaic or “mottle” viruses are the most abundant and diverse class of viruses. This leaf is from an apple tree infected with mosaic virus.

Retroviruses are so named because they regenerate themselves by reverse transcription. When the retroviruses enter the nucleus of their vertebrate host, viral reverse transcriptase produces cDNA from the viral RNA genome and then replicates the single-stranded cDNA to produce double-stranded DNA. Another virally encoded enzyme called integrase catalyzes the integration of the new piece of double-stranded viral DNA into the host’s genome. The viral genome is then replicated along with the host cell’s DNA; the integrated retroviral DNA is known as a *provirus*. Many components of cellular species (such as retrotransposons; see Section 17.3) resemble components of retroviruses.

Retroviruses are only known to infect vertebrates, although genomic elements that resemble portions of these viruses are a component of the genomes of a wide variety of organisms including bacteria, plants, and many animals. Several retroviruses are associated with the development of various forms of cancer, as cells infected with these viruses are likely to undergo uncontrolled replication.

DOUBLE-STRANDED RNA VIRUSES Double-stranded RNA viruses may have evolved repeatedly from single-stranded RNA ancestors—or perhaps vice versa. These viruses, which are not closely related to one another, infect organisms from throughout the tree of life. For example, many important plant diseases are caused by double-stranded RNA viruses, whereas other viruses of this type cause many cases of infant diarrhea in humans.

Some DNA viruses may have evolved from reduced cellular organisms

Another class of viruses is composed of those that have a double-stranded DNA genome (**Figure 26.25D–F**). This group is also almost certainly polyphyletic (with many independent origins). Many of the common phage that infect bacteria (*bacteriophage*) are double-stranded DNA viruses, as are the viruses that cause smallpox and herpes in humans.

Some biologists think that at least some of the DNA viruses may represent highly reduced parasitic organisms that have lost their cellular structure as well as their ability to survive as free-living species. For example, some of the largest DNA viruses are the mimiviruses (see **Figure 26.25F**), which have a genome in excess of a million base pairs of DNA. This is double the genome size of some parasitic bacteria such as *Mycoplasma genitalium*. Phylogenetic analyses of these DNA viruses suggest that they have evolved repeatedly from cellular organisms. Furthermore, recombination among different viruses may have allowed the exchange of various genetic modules, further complicating the history and origins of viruses.

26.6 RECAP

Viruses are highly diverse and appear to have evolved independently from many different groups of cellular organisms from throughout the tree of life. Some viruses appear to have evolved from escaped components of cellular organisms, whereas other viruses may have evolved from parasitic cellular ancestors.

- What are some the reasons that it is difficult to place viruses precisely within the phylogeny of cellular organisms? **See p. 555**
- Explain the two main hypotheses of viral origins. **See p. 555–557**

It appears that the enormous diversity of viruses is, at least in part, a result of their multiple origins from many different cellular organisms. Some may have arisen as escaped genetic components, while others may represent reduced and specialized parasites. Some appear to be derived from bacterial species, others to be derived from eukaryotic organisms. It may be best to view viruses as spinoffs from the various branches on the tree of life—sometimes evolving independently of cellular genomes, sometimes recombining with them. One way to think of viruses is as the “bark” on the tree of life: certainly an important component all across the tree, but not quite like the main branches.

CHAPTER SUMMARY

26.1 How Did the Living World Begin to Diversify?

- Two of life's three domains, Bacteria and Archaea, are prokaryotic. They are distinguished from Eukarya in several ways, including their lack of membrane-enclosed organelles. **Review Table 26.1**
- Eukaryotes are related to both Archaea and Bacteria, and appear to have formed through a merging of members of these two lineages. The last common ancestor of all three domains probably lived 2 to 3 billion years ago. **Review Figure 26.1, ANIMATED TUTORIAL 26.1**
- Prokaryotes may be single or may form chains or clusters. The three most common bacterial morphologies are **cocci** (spheres), **bacilli** (rods), and **helices** (spirals). **Review Figure 26.2**
- The cells of some bacteria aggregate, forming **filaments** and other structures.

26.2 What Are Some Keys to the Success of Prokaryotes?

- Prokaryotes are the most numerous organisms on Earth. They occur in an enormous variety of habitats, including inside other organisms and deep in Earth's crust.
- Prokaryotes form complex communities, some of which become dense films called **biofilms**. **Review Figure 26.3**
- Most prokaryotes have cell walls containing molecules important in transport, digestion, and sensing the environment. Almost all bacterial cell walls contain **peptidoglycan**. The cell walls of archaea lack peptidoglycan and instead include pseudopeptidoglycan or proteins. **Review Figure 26.5, WEB ACTIVITY 26.1**
- Bacteria can be placed into two groups by the **Gram stain**. **Gram-negative bacteria** have a periplasmic space between the inner (plasma) and outer membranes. In **Gram-positive bacteria**, the cell wall usually has about five times as much peptidoglycan as a Gram-negative wall.
- Prokaryotes move by a variety of means, including axial filaments, gas vesicles, and **flagella**. **Review Figures 26.6 and 26.7**
- Prokaryotes reproduce asexually but may undergo genetic recombination. Reproduction and genetic recombination are not directly linked in prokaryotes.
- Prokaryote metabolism is very diverse. Some prokaryotes are anaerobic, others are aerobic, and yet others can shift between these modes. Prokaryotes are classified as **photoautotrophs**, **photoheterotrophs**, **chemolithotrophs**, or **chemoheterotrophs**. **Review Table 26.2**
- The metabolic pathways of some prokaryotes involve sulfur or nitrogen. **Nitrogen fixers** convert nitrogen gas into a form organisms can metabolize.

26.3 How Can We Resolve Prokaryote Phylogeny?

- Early attempts to classify prokaryotes were hampered by the organisms' small size and difficulties growing them in pure culture. Phylogenetic classification of prokaryotes is now based on nucleotide sequences of rRNA and other slowly evolving genes.

- Although **lateral gene transfer** has occurred throughout prokaryotic evolutionary history, elucidation of prokaryote phylogeny is still possible. **Review Figure 26.10**
- Only a tiny percentage of all prokaryote species have been described.

26.4 What Are the Major Known Groups of Prokaryotes?

- Several major taxonomic groups of prokaryotes have been recognized. The members of a prokaryote clade often differ profoundly from one another. **Review Figures 26.11 and 26.19**
- Of the major taxonomic groups of Bacteria, the **proteobacteria** embrace the largest number of species. Other important groups include the **cyanobacteria**, **spirochetes**, **chlamydias**, and **low-GC Gram-positives**. Some **high-GC Gram positives** produce important antibiotics.
- The low-GC Gram-positives include the **mycoplasmas**, which are among the smallest cellular organisms ever discovered.
- Ether linkages in the branched long-chain hydrocarbons of cell membranes are a synapomorphy of archaea.
- The best-studied groups of Archaea are **Euryarchaeota** and **Crenarchaeota**. Some species of Euryarchaeota are methanogens; extreme halophiles are also found among the Euryarchaeota. Most known Crenarchaeota are both thermophilic and acidophilic.

26.5 How Do Prokaryotes Affect their Environments?

- Prokaryotes play key roles in the cycling of elements such as nitrogen, oxygen, sulfur, and carbon. One such role is as decomposers of dead organisms.
- Nitrogen-fixing bacteria fix the nitrogen needed by all other organisms. **Nitrifiers** convert that nitrogen into forms that can be used by plants, and **denitrifiers** ensure that nitrogen is returned to the atmosphere.
- Oxygen production by early photosynthetic cyanobacteria reconfigured Earth's atmosphere, which made aerobic forms of life possible.
- Prokaryotes inhabiting the guts of many animals help them digest their food.
- **Koch's postulates** establish the criteria by which an organism may be classified as a pathogen. Relatively few bacteria—and no archaea—are known to be pathogens.

26.6 Where Do Viruses Fit Into the Tree of Life?

- Viruses have evolved many times from many different groups of cellular organisms. They do not represent a single taxonomic group.
- Some viruses are probably derived from escaped genetic elements of cellular species; others are thought to have evolved as highly reduced parasites.
- Viruses are categorized by the nature of their genomes. **Review Figure 26.25**

SELF-QUIZ

- Most prokaryotes
 - are agents of disease.
 - lack ribosomes.
 - evolved from the most ancient eukaryotes.
 - lack a cell wall.
 - are chemoheterotrophs.
- The division of the living world into three domains
 - is based on the number of cells in organisms of each group.
 - is based mostly on the major morphological differences between archaea and bacteria.
 - emphasizes the greater importance of eukaryotes.
 - was proposed by the early microscopists.
 - is based on phylogenetic relationships determined from nucleotide sequences of rRNA and other genes.
- Which statement about archaeal genomes is *true*?
 - They are typically organized in a circular chromosome, like bacterial genomes.
 - They include no rRNA genes.
 - They are always much smaller than bacterial genomes.
 - They are housed in the nucleus of the archaeal cell.
 - No archaeal genome has yet been sequenced.
- Which statement about nitrogen metabolism is *not* true?
 - Certain prokaryotes reduce atmospheric N_2 to ammonia.
 - Some nitrifiers are soil bacteria.
 - Denitrifiers are obligate anaerobes.
 - Nitrifiers obtain energy by oxidizing ammonia and nitrite.
 - Without nitrifiers, terrestrial organisms would lack a nitrogen supply.
- All photosynthetic bacteria
 - use chlorophyll *a* as their photosynthetic pigment.
 - use bacteriochlorophyll as their photosynthetic pigment.
 - release oxygen gas.
 - produce particles of sulfur.
 - are photoautotrophs.
- Gram-negative bacteria
 - appear blue to purple following Gram staining.
 - appear pink to red following Gram staining.
 - are all either bacilli or cocci.
 - contain no peptidoglycan in their cell walls.
 - are all photosynthetic.
- Endospores
 - are produced by viruses.
 - are reproductive structures.
 - are very delicate and easily killed.
 - are resting structures.
 - lack cell walls.
- Chlamydias
 - are among the smallest archaea.
 - live on the surface of human skin.
 - are never pathogenic to humans.
 - live only as parasites in the cells of other organisms.
 - have a very simple life cycle.
- Archaea
 - have cytoskeletons.
 - have distinctive lipids in their plasma membranes.
 - survive only at moderate temperatures and near neutrality.
 - all produce methane.
 - have substantial amounts of peptidoglycan in their cell walls.
- Genetic evidence suggests that viruses
 - are most closely related to Bacteria.
 - are most closely related to Archaea.
 - are most closely related to Eukarya.
 - have evolved multiple times from many different cellular species.
 - evolved from the fusion of a bacterial and an archaeal species.

FOR DISCUSSION

- Why do systematic biologists find rRNA sequence data more useful than data on metabolism or cell structure for classifying prokaryotes?
- How can lateral gene transfer mislead studies about prokaryote phylogeny? How could this issue be addressed?
- Differentiate among the members of the following sets of related terms:
 - prokaryotic/eukaryotic
 - obligate anaerobe/facultative anaerobe/obligate aerobe
 - photoautotroph/photoheterotroph/chemolithotroph/chemoheterotroph
 - Gram-positive/Gram-negative
- Why are the endospores of low-GC Gram-positives not considered to be reproductive structures?
- Originally, the cyanobacteria were called “blue-green algae” and were not grouped with the bacteria. Suggest several reasons for this (abandoned) tendency to separate the cyanobacteria from the bacteria. Why are the cyanobacteria now grouped with the other bacteria?
- The high-GC Gram-positives are of great commercial interest. Why?
- Thermophiles are of great interest to molecular biologists and biochemists. Why? What practical concerns might motivate that interest?
- How can biologists discuss the Korarchaeota when they have never seen one?
- Do you consider viruses to be living organisms? Why or why not?

ADDITIONAL INVESTIGATION

Kashefi and Lovley (see Figure 26.21) were able to grow an unnamed archaeal species at temperatures above 120°C only because they used Fe^{3+} as an electron acceptor—no other electron acceptor

they tried allowed growth. How might you explore the same or other high-temperature environments for other hyperthermophilic organisms not detected by Kashefi and Lovley using Fe^{3+} ?

27

The Origin and Diversification of Eukaryotes

How a microbial eukaryote may have changed the course of science

Charles Darwin suffered throughout his adult life from a debilitating illness that was never conclusively diagnosed. Whatever the cause of this illness, it seems to have contributed to the determination with which Darwin pursued his studies. In his autobiography, Darwin wrote that his “chief enjoyment and sole employment throughout life has been scientific work; and the excitement from such work makes me for the time forget, or drives quite away, my daily discomfort.” To Darwin, science was a pleasure that provided a distraction from his pain.

One hypothesis is that Darwin suffered from Chagas’ disease. Caused by the trypanosome *Trypanosoma cruzi*, one of many microbial eukaryotes, this disease currently affects 16 to 18 million people, primarily in Central and South America. The trypanosome is transmitted to people

by trypanosome-infected assassin bugs, which bite to suck blood from their victims and then often defecate near the wound. When people crush the insect or scratch its bite, they can become infected with the trypanosome, which is present in the assassin bug’s feces. That Darwin may have been infected in this way is suggested by a journal entry he made during his voyage around the world on the HMS *Beagle*. On March 25, 1835, while visiting Argentina, Darwin wrote:

At night I experienced an attack (for it deserves no less a name) of the Benchuca ... the great black bug of the Pampas. It is most disgusting to feel soft wingless insects, about an inch long, crawling over one's body. Before sucking they are quite thin but afterwards they become round and bloated with blood, and in this state they are easily crushed.

Darwin’s entry describes the experience of being bitten by one of the assassin bugs that carry *Trypanosoma cruzi*, so clearly Darwin had the opportunity to become infected. In fact, he even experimented with the insects to learn more about their habits. “[I]f a finger was presented, the bold insect would immediately protrude its sucker, make a charge, and if allowed, draw blood,” he wrote in his journal.

There is neither a vaccine nor any effective drug treatment for Chagas’

An Assassin with a Deadly Cargo

This member of the insect genus *Rhodnius* is an “assassin bug,” one of several species that transmits *Trypanosoma cruzi*, the causative agent of Chagas’ disease in humans.

Thugs in a Huddle Sometimes trypanosomes, like these *Leishmania major*, form clusters held together by a tangle of mucilage secreted around their flagella; nobody is sure yet why they behave this way.

disease, which kills more than 40,000 people a year. Other trypanosome species cause other debilitating diseases, including leishmaniasis (60,000 deaths/year) and African sleeping sickness (50,000 deaths/year). Since the infective organism in each of these diseases is a eukaryote like us, most of the drugs that are toxic to the trypanosomes are often toxic to humans as well. Although the treatment of bacterial diseases often capitalizes on the many differences between prokaryotes and eukaryotes in order to target only the bacteria, the diseases caused by microbial eukaryotes usually are, like Chagas' disease, much more difficult to treat.

IN THIS CHAPTER we describe the origin and early diversification of the eukaryotes and the complexity achieved by some single cells. We then explore some of the diversity of microbial eukaryote body forms and adaptations and present the developing current view of the evolutionary relationships among the major eukaryote groups.

CHAPTER OUTLINE

- 27.1** How Did the Eukaryotic Cell Arise?
- 27.2** What Features Account for Protist Diversity?
- 27.3** How Do Protists Affect the World Around Them?
- 27.4** How Do Protists Reproduce?
- 27.5** What Are the Evolutionary Relationships among Eukaryotes?

27.1 How Did the Eukaryotic Cell Arise?

Many members of the domain Eukarya are familiar to us. We have no problem recognizing trees, mushrooms, and insects as plants, fungi, and animals, respectively. However, a dazzling assortment of other eukaryotes—mostly microscopic organisms—do not fit into any of these three groups. Eukaryotes that are not plants, animals, or fungi have traditionally been “dropped” into the category **protists**. Phylogenetic analyses, however, are clear and consistent in showing that many of the groups that fall under the rubric of “protists” in fact are not closely related to one another, but are *paraphyletic* (see Figure 22.14). Thus the word “protist” does not describe a formal taxonomic group, but is a convenience term—a shorthand way of saying “all the eukaryotes that are not plants, animals, or fungi.”

The diversity of protists is reflected in both morphology and phylogeny

In terms of their evolutionary relationships, as well as in many aspects of their biology, protists are more diverse than any of the three better known eukaryote groups. Some protists are motile, while others do not move; some are photosynthetic, others heterotrophic; most are unicellular, but some are multicellular (**Table 27.1**). Most are microscopic, but a few are huge: giant kelps, for example, can grow to be longer than a football field. We refer to the unicellular species of protists as *microbial eukaryotes*, but you should keep in mind that there are large, multicellular protists as well.

The phylogeny of the major eukaryote lineages remains a subject of research and debate. Some groups of protists are closely related to animals and fungi, whereas others are closely related to the land plants, and still others are only distantly related to any of these familiar eukaryotes (**Figure 27.1**).

Cellular features support the monophyly of eukaryotes

Eukaryotic cells differ in many ways from prokaryotic cells, and these unique characters of eukaryotes lead us to conclude that eukaryotes are monophyletic. In other words, there was a single eukaryotic ancestor which diversified into the many different lineages of protists, as well as plants, animals, and fungi. Given the nature of evolutionary processes, the many synapomorphies of eukaryotes undoubtedly did not arise simultaneously. We can make some reasonable inferences about the most important events that led to the evolution of a new cell type, bearing in mind that the global environment underwent an

27.1 Major Eukaryote Groups in an Evolutionary Context This tree shows a current hypothesis for the evolutionary relationships among major groups of eukaryotes. The dashed lines indicate clades for which the evidence is weak or disputed. The root of the tree is uncertain.

TABLE 27.1

Major Eukaryote Clades

CLADE	ATTRIBUTES	EXAMPLE (GENUS)
Chromalveolates		
Haptophytes	Unicellular, often with calcium carbonate scales	<i>Emiliania</i>
Alveolates	Sac-like structures beneath plasma membrane	
Apicomplexans	Apical complex for penetration of host	<i>Plasmodium</i>
Dinoflagellates	Pigments give golden-brown color	<i>Gonyaulax</i>
Ciliates	Cilia; two types of nuclei	<i>Paramecium</i>
Stramenopiles	Hairy and smooth flagella	
Brown algae	Multicellular; marine; photosynthetic	<i>Macrocystis</i>
Diatoms	Unicellular; photosynthetic; two-part cell walls	<i>Thalassiosira</i>
Oomycetes	Mostly coenocytic; heterotrophic	<i>Saprolegnia</i>
Plantae		
Glaucophytes	Peptidoglycan in chloroplasts	<i>Cyanophora</i>
Red algae	No flagella; chlorophyll <i>a</i> and <i>c</i> ; phycoerythrin	<i>Chondrus</i>
Chlorophytes	Chlorophyll <i>a</i> and <i>b</i>	<i>Ulva</i>
*Land plants (Chs. 28–29)	Chlorophyll <i>a</i> and <i>b</i> ; protected embryo	<i>Ginkgo</i>
Charophytes	Chlorophyll <i>a</i> and <i>b</i> ; mitotic spindle oriented as in land plants	<i>Chara</i>
Excavates		
Diplomonads	No mitochondria; two nuclei; flagella	<i>Giardia</i>
Parabasalids	No mitochondria; flagella and undulating membrane	<i>Trichomonas</i>
Heteroloboseans	Can transform between amoeboid and flagellate stages	<i>Naegleria</i>
Euglenids	Flagella; spiral strips of protein support cell surface	<i>Euglena</i>
Kinetoplastids	Kinetoplast within mitochondrion	<i>Trypanosoma</i>
Rhizaria		
Cercozoans	Threadlike pseudopods	<i>Cercomonas</i>
Foraminiferans	Long, branched pseudopods; calcium carbonate shells	<i>Globigerina</i>
Radiolarians	Glassy endoskeleton; thin, stiff pseudopods	<i>Astrolithium</i>
Unikonts		
Opisthokonts	Single, posterior flagellum	
*Fungi (Ch. 30)	Heterotrophs that feed by absorption	<i>Penicillium</i>
Choanoflagellates	Resemble sponge cells; heterotrophic; with flagella	<i>Choanoeca</i>
*Animals (Chs. 31–33)	Heterotrophs that feed by ingestion	<i>Drosophila</i>
Amoebozoans	Amoebas with lobe-shaped pseudopods	
Loboseans	Feed individually	<i>Amoeba</i>
Plasmodial slime molds	Form coenocytic feeding bodies	<i>Physarum</i>
Cellular slime molds	Cells retain their identity in pseudoplasmodium	<i>Dictyostelium</i>

*Clades marked with an asterisk are made up of multicellular organisms and are discussed in the chapters indicated. All other groups listed are treated here as *protists*.

enormous change—from low to high availability of free oxygen—during the course of these events (see Section 25.3). Keep in mind, however, that these inferences, although reasonable and grounded, are still conjectural; the hypothesis we pursue

here is one of a few that biologists are currently considering. We describe here a prominent theory on the origin of the eukaryotic cell as a framework for thinking about the challenging question of eukaryotic origins.

The modern eukaryotic cell arose in several steps

Several events preceded the origin of the modern eukaryotic cell:

- The origin of a flexible cell surface
- The origin of a cytoskeleton
- The origin of a nuclear envelope, which enclosed a genome organized into chromosomes
- The appearance of *digestive vacuoles*
- The acquisition of certain organelles via *endosymbiosis*

RAMIFICATIONS OF A FLEXIBLE CELL SURFACE

Many fossil prokaryotes look like rods, and we presume that these ancient organisms, like most present-day prokaryotic cells, had firm cell walls. The first step toward the eukaryotic condition was the loss of the cell wall by an ancestral prokaryotic cell. This wall-less condition is present in some present-day bacteria, although many others have developed new types of cell walls. Let's consider the possibilities open to a flexible cell without a wall.

First, think of cell size. As a cell grows larger, its surface area-to-volume ratio decreases (see Figure 5.2). Unless the surface area can be increased, the cell volume will reach an upper limit. If the cell's surface is flexible, it can fold inward and elaborate itself, creating more surface area for gas and nutrient exchange (Figure 27.2).

With a surface flexible enough to allow infolding, the cell can exchange materials with its environment rapidly enough to sustain a larger volume and more rapid metabolism (Figure 27.2, steps 1–2). Furthermore, a flexible surface can pinch off bits of the environment, bringing them into the cell by endocytosis.

CHANGES IN CELL STRUCTURE AND FUNCTION

Other early steps in the evolution of the eukaryotic cell are likely to have included three advances: the formation of ribosome-studded internal membranes, some of which surrounded the DNA; the appearance of a cytoskeleton; and the evolution of digestive vacuoles (Figure 27.2, steps 3–7).

27.2 From Prokaryotic Cell to Eukaryotic Cell The loss of the rigid prokaryotic cell wall allowed the plasma membrane to fold inward and create more surface area. One possible evolutionary sequence, which includes the formation of a cytoskeleton and the enclosure of genetic material into the nucleus, is shown here.

A cytoskeleton composed of microfilaments and microtubules would support the cell and allow it to manage changes in shape, to distribute daughter chromosomes, and to move materials from one part of the now much larger cell to other parts. The presence of microtubules in the cytoskeleton could have evolved in some cells to give rise to the characteristic eukaryotic flagellum. The origin of the cytoskeleton is becoming clearer, as homologs of the genes that encode many cytoskeletal proteins have been found in modern prokaryotes.

The DNA of a prokaryotic cell is attached to a site on its plasma membrane. If that region of the plasma membrane were to fold into the cell, the first step would be taken toward the evolution of a *nucleus*, a primary feature of the eukaryotic cell.

From an intermediate kind of cell, the next step was probably *phagocytosis*—the ability to engulf and digest other cells. The cytoskeleton and nuclear envelope appeared early in the eukaryote lineage. Early eukaryotes may also have had an associated endoplasmic reticulum and Golgi apparatus, and perhaps one or more flagella of the eukaryotic type.

ENDOSYMBIOSIS AND ORGANELLES At the same time the processes outlined above were taking place, cyanobacteria were generating oxygen gas as a product of photosynthesis. The increasing O₂ levels in the atmosphere had disastrous consequences because most organisms of the time (archaea and bacteria) were unable to tolerate the newly oxidizing environment. But some prokaryotes managed to cope with these changes, and—fortunately for us—so did some of the new phagocytic eukaryotes.

At about this time, endosymbiosis might have come into play (Figure 27.2, steps 8–9). Recall that the theory of endosymbiosis proposes that certain organelles are the descendants of prokaryotes engulfed, but not digested, by ancient eukaryotic cells (see Section 5.5). One crucial endosymbiotic event in the history of the Eukarya was the incorporation of a proteobacterium that evolved into the mitochondrion. Initially, the new organelle's primary function was probably to detoxify O₂ by reducing it to water. Later, this reduction became coupled with the formation of ATP in cellular respiration (see Chapter 9). Upon completion of this step, the essential modern eukaryotic cell was complete.

Some important eukaryotes are the result of yet another endosymbiotic step, the incorporation of a prokaryote related to today's cyanobacteria, which became the chloroplast.

Chloroplasts are a study in endosymbiosis

Eukaryotes in several different groups possess chloroplasts, and groups with chloroplasts appear in several distantly related clades. Some of these groups differ in the photosynthetic pigments their chloroplasts contain. And we'll see that not all

chloroplasts have a pair of surrounding membranes—in some microbial eukaryotes, they are surrounded by *three or more* membranes. We now view these observations in terms of a remarkable series of endosymbioses, supported by extensive evidence from electron microscopy and nucleic acid sequence comparisons.

All chloroplasts trace their ancestry back to the engulfment of one cyanobacterium by a larger eukaryotic cell (**Figure 27.3A**).

27.3 Endosymbiotic Events in the "Family Tree" of Chloroplasts

(A) A single instance of primary endosymbiosis ultimately gave rise to all of today's chloroplasts. A eukaryotic cell engulfed a cyanobacterium but did not digest it. (B) Secondary endosymbiosis—the uptake and retention of a chloroplast-containing cell by another eukaryotic cell—took place several times, independent of each other.

This event, the step that gave rise to the photosynthetic eukaryotes, is known as **primary endosymbiosis**. The cyanobacterium, a Gram-negative bacterium, had both an inner and outer membrane. Thus the original chloroplasts had two surrounding membranes—the inner and outer membranes of the cyanobacterium. Remnants of the peptidoglycan-containing wall of the bacterium are present in the form of a bit of peptidoglycan between the chloroplast membranes of *glaucomphytes*, the first microbial eukaryote group to branch off following primary endosymbiosis of the cyanobacterium.

Primary endosymbiosis gave rise to the chloroplasts of the “green algae” (including *chlorophytes* and *charophytes*) and the *red algae*. Studies of phylogeny indicate that each of these distinct lineages trace back to a single primary endosymbiosis. The photosynthetic land plants arose later from a green algal ancestor. The red algal chloroplast retains certain pigments of the original cyanobacterial endosymbiont that are absent in green algal chloroplasts.

Almost all remaining photosynthetic eukaryotes are the result of additional rounds of endosymbiosis. For example, the photosynthetic *euglenids* derived their chloroplasts from **secondary endosymbiosis** (Figure 27.3B). Their ancestor took up a unicellular chlorophyte, retaining the endosymbiont’s chloroplast and eventually losing the rest of the constituents of the chlorophyte. This history explains why the photosynthetic euglenids have the same photosynthetic pigments as the chlorophytes and land plants. It also accounts for the third membrane of the euglenoid chloroplast, which is derived from the euglenid’s plasma membrane (as a result of endocytosis). An additional round of endosymbiosis (**tertiary endosymbiosis**) occurred when a dinoflagellate apparently lost its chloroplast and took up a haptophyte (itself the result of secondary endosymbiosis).

GO TO Animated Tutorial 27.1 • Family Tree of Chloroplasts

Lateral gene transfer accounts for the presence of some prokaryotic genes in eukaryotes

Several uncertainties remain about the origins of eukaryotic cells. Lateral gene transfer (see Section 26.4 and Figure 26.10) complicates the study of eukaryote origins, just as it complicates the study of relationships among prokaryotes. Lateral gene transfer accounts for the increasing numbers of genes of bacterial origin that are being found in eukaryotes by ongoing genetic analyses.

An endosymbiotic origin of mitochondria and chloroplasts accounts for the presence of bacterial genes encoding enzymes for energy metabolism (respiration and photosynthesis) in eukaryotes, but it does not explain the presence of some other bacterial genes. The eukaryotic genome clearly is a mixture of genes with different origins. A recent suggestion is that Eukarya might have arisen from the mutualistic fusion of a Gram-negative bacterium and an archaean.

Many interesting ideas about eukaryotic origins await additional data and analysis. We can expect that these questions and others will eventually yield to additional research.

27.1 RECAP

The modern eukaryotic cell likely arose from an ancestral prokaryote in several steps, including endosymbiosis. Primary endosymbiosis involves the engulfment of a bacterium by another free-living organism; the endosymbiosis of a bacterium probably gave rise to mitochondria, whereas the chloroplasts of photosynthesizing eukaryotes are thought to have originated in the endosymbiosis of a cyanobacterium.

- Explain why protists are described as paraphyletic rather than monophyletic. **See p. 561, Table 27.1, and Figure 27.1**
- Why was the development of a flexible cell surface a key event in eukaryotic cell history? **See p. 564**
- Identify some of the probable events involved in the evolution of the eukaryotic cell from a prokaryotic cell. **See pp. 564–565 and Figure 27.2**
- What is the difference between primary and secondary endosymbiosis? **See p. 566 and Figure 27.3**

Having considered some of the known and suspected steps that led from the prokaryotic to the eukaryotic condition, let’s now see what use the early eukaryotes made of their new features.

27.2 What Features Account for Protist Diversity?

The eukaryotic cell possesses some very useful features (detailed in Chapter 5). The cytoskeleton allows for various means of locomotion and also manages the controlled movement of cellular constituents (notably the mitotic and meiotic chromosomes). The specialized organelles of eukaryotes support a variety of activities. Given these tools, eukaryotes have been able to explore many environments and have exploited a variety of nutrient sources.

Protists occupy many different niches

Most protists are aquatic. Some live in marine environments, others in fresh water, and still others in the body fluids of host organisms. Many aquatic protists are plankton: free-floating aquatic organisms. The *slime molds* inhabit damp soil, animal feces, and the moist, decaying bark of rotting trees. Other microbial protists also live in soil water, and some of them contribute to the global nitrogen cycle by preying on soil bacteria and recycling their nitrogen compounds into nitrates.

Many metabolic lifestyles are found among the protists. Some protists are photosynthetic autotrophs, some are heterotrophs, and some switch with ease between the autotrophic and heterotrophic modes of nutrition. Some of the heterotrophs ingest their food; others, including many parasites, absorb nutrients from their environment.

27.4 An Amoeba in Motion Its flowing pseudopods are constantly changing shape as this “chaos amoeba” moves and feeds.

Two general terms are sometimes used to designate two broad categories of protists: the *protozoans* and *algae*. These are convenience terms used to describe categories of distantly related species that have some similar attributes. The term *protozoans* refers to various groups of protists, formerly classified as animals, that often survive by ingesting other species. Likewise, the term *algae* (singular *alga*) refers to several groups of photosynthetic protists. Neither of these terms designate formal taxonomic groups, however.

Protists have diverse means of locomotion

Although a few protist groups consist entirely of nonmotile organisms, most groups include organisms that move by amoeboid motion, by ciliary action, or by means of flagella. Each of these types of motion is based on activities of the cytoskeleton.

In *amoeboid motion*, the cell forms **pseudopods** (“false feet”) which are extensions of its constantly changing cell shape. Cells such as the one shown in **Figure 27.4** simply extend a pseudopod and then flow into it. Regions of the cytoplasm alternate between a more liquid state and a stiffer state,

and a network of cytoskeletal microfilaments squeezes the more liquid cytoplasm forward.

The proteins of the eukaryotic cytoskeleton form microtubules which allowed the evolution of different means of locomotion. *Cilia* are tiny, hairlike organelles that beat in a coordinated fashion to move the cell forward or backward. Some ciliated organisms can change direction rapidly in response to their environment. A eukaryotic flagellum moves like a whip; some flagella *push* the cell forward, others *pull* the cell forward. Cilia and eukaryotic flagella are identical in cross section, with a “9 + 2” arrangement of microtubules (see Figure 5.20); they differ only in length.

Protists employ vacuoles in several ways

Most unicellular organisms are microscopic. As noted above, an important reason that cells are small is that they need enough membrane surface area in relation to their volume to support the exchange of materials required for their existence. Some relatively large unicellular eukaryotes minimize this problem by having membrane-enclosed vacuoles of various types that increase their effective surface area.

Organisms living in fresh water are hypertonic to their environment (see Section 6.3). Many freshwater protists such as *Paramecium* address this problem by means of specialized vacuoles that excrete the excess water they constantly take in by osmosis. Members of several groups have such **contractile vacuoles**. The excess water collects in the contractile vacuoles, which then expel the water from the cell (**Figure 27.5**).

A **digestive vacuole** is a second important type of vacuole found in *Paramecium* and many other protists. These organisms engulf solid food by endocytosis, forming a vacuole within which the food is digested. Smaller vesicles containing digested food pinch away from the digestive vacuole and enter the cy-

27.5 Contractile Vacuoles Bail Out Excess Water Contractile vacuoles remove the water that constantly enters freshwater protists by osmosis.

INVESTIGATING LIFE

27.6 The Role of Vacuoles in Ciliate Digestion

An experiment with the ciliate protist *Paramecium* demonstrates the function of food vacuoles. Given that an acidic environment is known to aid digestion in many organisms, does this microbial eukaryote use acid to obtain nutrients?

HYPOTHESIS The food vacuoles of *Paramecium* produce an acidic environment that allows the organism to digest food particles.

- METHOD**
1. Feed *Paramecium* yeast cells stained with Congo red, a dye that is red at neutral or basic pH but turns green at acidic pH.
 2. Under a light microscope, observe the formation and degradation of food vacuoles within the *Paramecium*. Note time and sequence of color (i.e., acid level) changes.

RESULTS

CONCLUSION Acidification of food vacuoles assists digestion in this ciliate protist.

FURTHER INVESTIGATION: How might you determine whether the acid level changes in *Paramecium*'s food vacuoles are the result of enzymes?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

yourBioPortal.com

GO TO Animated Tutorial 27.2 • Food Vacuoles Handle Digestion and Excretion

toplasm. These tiny vesicles provide a large surface area across which the products of digestion may be absorbed by the rest of the cell (Figure 27.6).

The cell surfaces of protists are diverse

A few protists, such as the amoeba in Figure 27.4, are surrounded by only a plasma membrane, but most have stiffer surfaces that maintain the structural integrity of the cell. Many have cell walls, which are often complex in structure, outside the plasma membrane. Other protists that lack cell walls have a variety of ways of strengthening their surfaces.

Paramecium has proteins in its cell surface—known as a *pellicle* in this genus (see Figure 27.18)—that make it flexible but resilient. Other groups have external “shells,” which the organism either produces itself or makes from bits of sand and thickenings immediately beneath the plasma membrane, as some amoebas do (Figure 27.7A). The complex cell walls of diatoms are glassy, based on silica (silicon dioxide; Figure 27.7B). Biologists recently measured, at a microscopic scale, the forces

27.7 Cell Surfaces among Microbial Eukaryotes (A) This testate amoeba has built a lightbulb-shaped shell, or test, by gluing sand grains together. Its pseudopods extend through the single aperture in the test (compare with Figure 27.4). (B) Scanning electron micrography reveals the intricate patterning of the silica-dense cell walls of this diatom. These spectacular unicellular, photosynthetic eukaryotes dominate the aquatic phytoplankton community (see also Figure 27.19).

needed to break single, living diatoms, and discovered that the glassy cell walls are exceptionally strong. Evolution of these walls by natural selection may have given diatoms an enhanced defense against predators, and thus an edge over competitors.

27.2 RECAP

Protists are diverse in their habitat, nutrition, locomotion, and body form. Some protists move by use of pseudopods, cilia, or flagella. Protists may have cell walls or external coverings that provide structural support and protection.

- Can you explain the roles of the cytoskeleton in the locomotion of protists? **See p. 567**
- Do you understand the operation of contractile and food vacuoles in *Paramecium*? **See p. 567 and Figures 27.5 and 27.6**

The diversity of body form, habitat, nutrition, and locomotion found among the protists reflects the diversity of avenues pursued during the early evolution of eukaryotes. Protists have an enormous effect on biotic and physical environments.

27.3 How Do Protists Affect the World Around Them?

Protists are extremely diverse, and their effects on other organisms and on the physical environment are almost as diverse. Some protists are food for marine animals, while others poison the sea; some are packaged as nutritional supplements, and some are pathogens; the remains of some form the sands of many modern beaches, and others are a major source of today's ever more expensive crude oil. Many protists are constituents

of the plankton. Photosynthetic members of the plankton are called **phytoplankton**.

A single eukaryote clade, the *diatoms*, is responsible for about a fifth of all photosynthetic carbon fixation on Earth—about the same amount of photosynthesis performed by all of Earth's rainforests. These spectacular unicellular organisms (see Figures 27.7B and Figure 27.19) are the predominant members of the phytoplankton, but other protist clades also include important phytoplanktonic species that contribute heavily to global photosynthesis. Like green plants on land, the phytoplankton serve as a gateway for energy from the sun into the living world; in other words, they are *primary producers*. In turn, they are eaten by heterotrophs, including animals and many other protists. Those consumers are, in turn, eaten by other consumers. Most aquatic heterotrophs (with the exception of some species existing in the deep ocean) depend on the photosynthesis performed by phytoplankton.

Some protists are endosymbionts

As we have described, endosymbiosis is the condition in which two organisms live together, one inside the other. Endosymbiosis is common among the microbial protists, many of which live within the cells of animals. Members of the *dinoflagellates* are common symbionts in both animals and in other protists; most but not all dinoflagellate endosymbiont species are photosynthetic. Some dinoflagellates live endosymbiotically in the cells of corals, contributing products of their photosynthesis to the partnership. The importance to the coral is demonstrated when the dinoflagellates die as a result of changing environmental conditions, a phenomenon known as coral bleaching (**Figure 27.8A**); the coral is ultimately damaged or destroyed when its nutrient supply is reduced.

Many *radiolarians* also harbor photosynthetic endosymbionts (**Figure 27.8B**). As a result, the radiolarians, which are not photosynthetic themselves, appear greenish or golden, depending on the type of endosymbiont they contain. This arrangement is often mutually beneficial: the radiolarian can make use of the organic

Bleaching occurs when the photosynthetic dinoflagellates living endosymbiotically within this coral die.

27.8 Dinoflagellate Endosymbionts are Photosynthesizers

(A) Some corals lose their chief nutritional source when their photosynthetic endosymbionts die, often as a result of changing environmental conditions such as warming water. (B) Dinoflagellates live endosymbiotically inside a radiolarian (another protist), providing organic nutrients for the radiolarian and imparting the golden brown pigmentation seen at the center of its glassy skeleton.

(A)

(B)

nutrients produced by its photosynthetic guest, and the guest may in turn make use of metabolites made by the host or receive physical protection. In some cases, the guest is exploited for its photosynthetic products while receiving little or no benefit itself.

Some microbial protists are deadly

The best-known pathogenic microbial protists are members of the genus *Plasmodium*, a highly specialized group of *apicomplexans* that spend part of their life cycle as parasites in human red blood cells, where they are the cause of malaria (**Figure 27.9**). In terms of the number of people affected, malaria is one of the world's three most serious infectious diseases; it kills about 880,000 people each year, out of 250 million infected individuals. On average, someone dies from malaria every 36 seconds—usually in sub-Saharan Africa, although malaria occurs in more than 100 countries.

Female mosquitoes of the genus *Anopheles* transmit *Plasmodium* to humans. The parasite enters the human circulatory system when an infected *Anopheles* mosquito penetrates the human skin in search of blood. The parasites find their way to cells in

27.9 Life Cycle of the Malarial Parasite (A) Like many parasitic species, the apicomplexan *Plasmodium falciparum* has a complex life cycle, part of which is spent in mosquitoes of the genus *Anopheles* and part in humans. The sexual phase (gamete fusion) of this life cycle takes place in the insect, and the zygote is the only diploid stage. (B) Encysted *Plasmodium* zygotes (artificially colored blue) cover the stomach wall of a mosquito. Invasive sporozoites will hatch from the cysts and be transmitted to a human, in whom the parasite causes malaria.

27.10 Chromalveolates Can Bloom in the Oceans (A) By reproducing in astronomical numbers, the dinoflagellate *Gonyaulax tamarensis* can cause toxic red tides, such as this one along the coast of Baja California. (B) Massive blooms of this coccolithophore, a tiny haptophyte, can reduce the amount of sunlight able to penetrate to the waters below.

the liver and the lymphatic system, change their form, multiply, and reenter the bloodstream, attacking red blood cells.

The parasites multiply inside the red blood cells, which then burst, releasing new swarms of parasites. If another *Anopheles* bites the victim, the mosquito takes in *Plasmodium* cells along with blood. Some of the ingested cells are gametes that formed in human cells. The gametes unite in the mosquito, forming zygotes that lodge in the mosquito's gut, divide several times, and move into its salivary glands, from which they can be passed on to another human host. Thus *Plasmodium* is an extracellular parasite in the mosquito vector and an intracellular parasite in the human host.

Plasmodium has proved to be a singularly difficult pathogen to attack. The complex *Plasmodium* life cycle is best broken by the removal of stagnant water, in which mosquitoes breed. Using insecticides to reduce the *Anopheles* population can be effective, but the benefits must be weighed against the ecological, economic, and health risks posed by the insecticides themselves.

The genomes of one malarial parasite, *Plasmodium falciparum*, and one of the mosquitoes that transmits malaria, *Anopheles gambiae*, have been sequenced. These advances should lead to a better understanding of the biology of malaria and to the development of drugs, vaccines, or other means of dealing with this pathogen or its insect vectors. The opening story of Chapter 30 describes a novel weapon against malaria: mosquito netting containing fungi that attack mosquitoes.

Some *kinetoplastids* are human pathogens, such as the trypanosomes discussed at the opening of this chapter. Recall that

trypanosomes cause sleeping sickness, leishmaniasis, and Chagas' disease. The genomes of all three of the trypanosomes responsible for these diseases have now been sequenced.

Some *chromalveolates*, including diatoms, dinoflagellates, and haptophytes, reproduce in enormous numbers in warm and somewhat stagnant waters. The result can be a "red tide," so called because of the reddish color of the sea that results from the dinoflagellates' pigments (**Figure 27.10A**). During a dinoflagellate red tide, the concentration of cells may reach 60 million per liter of ocean water. Some red tide species produce a potent nerve toxin that can kill tons of fish. The genus *Gonyaulax* produces a toxin that can accumulate in shellfish in amounts that, although not fatal to the shellfish, may kill a person who eats the shellfish.

The haptophyte *Emiliania huxleyi* is one of the smallest unicellular protists, but it can form tremendous blooms in ocean waters. This *coccolithophore* ("sphere of stone") has an armored coating that makes the surface water more reflective (**Figure 27.10B**). This reflectivity cools the deeper layers of water below the bloom by reducing the amount of sunlight that penetrates. At the same time, it is possible that *E. huxleyi* contributes to global warming, because its metabolism increases the amount of dissolved CO₂ in ocean waters.

We continue to rely on the products of ancient marine protists

Diatoms are often lovely to look at, but their importance to us goes far beyond aesthetics. They store oil as an energy reserve and to help them float at the correct depth in the ocean. Over millions of years, diatoms have died and sunk to the ocean floor, ultimately undergoing chemical changes and becoming a major source of petroleum and natural gas, two of our most important energy supplies and political concerns.

Other marine protists have also contributed to today's world. Some *foraminiferans*, for example, secrete shells of calcium carbonate. After they reproduce (by mitosis and cytokinesis), the daughter cells abandon the parent shell and make new shells of their own. The discarded shells of ancient foraminiferans make up extensive limestone deposits in various parts of the world, forming a layer hundreds to thousands of meters deep over mil-

lions of square kilometers of ocean bottom. Foraminiferan shells also make up much of the sand of some beaches. A single gram of such sand may contain as many as 50,000 foraminiferan shells and shell fragments.

The shells of individual foraminiferans are easily preserved as fossils in marine sediments. The shells of foraminiferan species have distinctive shapes (**Figure 27.11**), and each geological period has a distinctive assemblage of foraminiferan species. For this reason, and because they are so abundant, the remains of foraminiferans are especially valuable in classifying and dating sedimentary rocks, as well as in oil prospecting. Analyses of foraminiferan shells are also used in determining the global temperatures prevalent at the time of their existence.

27.3 RECAP

Protists have many effects, both positive and negative, on other organisms and on global ecosystems. Some species are primary producers, many are endosymbionts, and some are pathogens. They are among the most important producers of petroleum products, and they are important for producing and dating sedimentary rock formations.

- Can you describe the role of female mosquitoes of the genus *Anopheles* in the transmission of malaria? **See pp. 570–571 and Figure 27.9**
- Do you understand the role of dinoflagellates in the very different phenomena of coral bleaching and red tides? **See pp. 569 and 571**

This section has presented a brief overview of the many ways protists interact with one another and with other species. Next we examine their diverse forms of reproduction.

27.11 Foraminiferan Shells Are Building Blocks Some foraminiferan shells are made of calcium carbonate that has been mineralized on an organic matrix external to the cell. Over millions of years, the remains of foraminiferans have formed limestone deposits and sandy beaches. Several species are shown in this micrograph.

27.4 How Do Protists Reproduce?

Although most protists engage in both asexual and sexual reproduction, sexual reproduction has yet to be observed in some groups. As we will see, some protists separate the acts of sex and reproduction, so that the two are not directly linked.

Asexual reproductive processes found among the protists include:

- **Binary fission:** Equal splitting of one cell into two, with mitosis followed by cytokinesis
- **Multiple fission:** Splitting of one cell into multiple (i.e., more than two) cells
- **Budding:** The outgrowth of a new cell from the surface of an old one
- **Spores:** The formation of specialized cells that are capable of developing into new organisms

Sexual reproduction also occurs among the protists, and it takes various forms. In some protists, as in animals, the gametes are the only haploid cells. In others, the zygote is the only diploid cell. In still others, both diploid and haploid cells undergo mitosis, giving rise to *alternation of generations* (the alternation of multicellular diploid and haploid life stages).

Some protists have reproduction without sex, and sex without reproduction

Members of the genus *Paramecium* are *ciliates*, a protist group characterized by the possession of two types of nuclei in a single cell—commonly one *macronucleus* and from one to several *micronuclei*. The micronuclei, which are typical eukaryotic nuclei, are essential for genetic recombination. The macronucleus is derived from micronuclei. Each macronucleus contains many copies of the genetic information, packaged in units containing very few genes each. The macronuclear DNA is transcribed and translated to regulate the life of the cell. In asexual reproduction, all of the nuclei are copied before the cell divides.

Paramecia also have an elaborate sexual behavior called **conjugation**, in which two paramecia line up tightly against each other and fuse in the oral groove region of the body. Nuclear material is extensively reorganized and exchanged over the next several hours (**Figure 27.12**). Each cell ends up with two haploid micronuclei, one of its own and one from the other cell, which fuse to form a new diploid micronucleus. A new macronucleus develops from the micronucleus through a series of dramatic chromosomal rearrangements. The exchange of nuclei is fully reciprocal—each of the two paramecia gives and receives an equal amount of DNA. The two organisms then separate and go their own ways, each equipped with new combinations of alleles.

27.12 Paramecia Achieve Genetic Recombination by Conjugating

The exchange of micronuclei by two conjugating *Paramecium* individuals results in genetic recombination. After conjugation, the cells separate and continue their lives as two individuals.

Conjugation in *Paramecium* is a *sexual* process of genetic recombination, but it is not a *reproductive* process. Two cells begin the process and two cells are there at the end, so no new cells are created. As a rule, each asexual clone of paramecia must periodically conjugate. Experiments have shown that if some species are not permitted to conjugate, the clones can live through no more than approximately 350 cell divisions before they die out.

Some protist life cycles feature alternation of generations

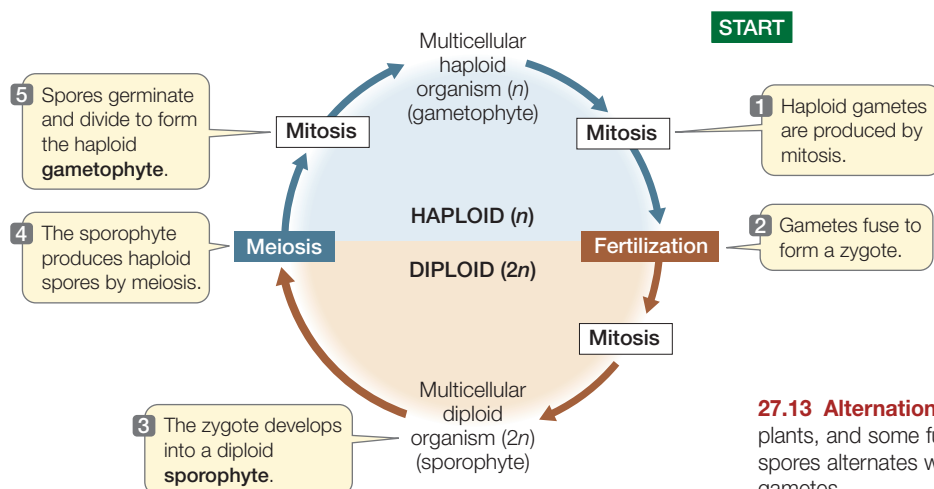

Alternation of generations is a type of life cycle found in many multicellular protists, land plants, and some fungi. The term describes a life cycle in which a multicellular, diploid, spore-producing organism gives rise to a multicellular, haploid, gamete-producing organism. When two haploid gametes fuse (*fertilization*, or *syngamy*), a diploid organism is formed (**Figure 27.13**). The haploid organism, the diploid organism, or both may also reproduce asexually.

The two alternating generations (spore-producing and gamete-producing) differ genetically (one has diploid cells, the other haploid cells), but they may or may not differ morphologically. In **heteromorphic** alternation of generations, the two generations differ morphologically; in **isomorphic** alternation of generations, they do not, despite their genetic difference.

Examples of both heteromorphic and isomorphic alternation of generations are found in both brown algae and green algae. As we discuss the life cycles of land plants and multicellular photosynthetic protists, we will use the terms **sporophyte** (“spore plant”) and **gametophyte** (“gamete plant”) to refer to the multicellular diploid and haploid generations, respectively.

Gametes are not produced by meiosis because the gametophyte generation is already haploid. Instead, specialized cells of the diploid sporophyte, called **sporocytes**, divide meiotically to produce four haploid spores. The spores may eventually germinate and divide mitotically to produce multicellular haploid gametophytes, which produce gametes by mitosis and cytokinesis.

Gametes, unlike spores, can produce new organisms only by fusing with other gametes. The fusion of two gametes produces a diploid zygote, which then undergoes mitotic divisions to produce a diploid organism: the sporophyte generation. The sporocytes of the sporophyte generation then undergo meiosis and produce haploid spores, starting the cycle anew.

27.13 Alternation of Generations In many multicellular protists, land plants, and some fungi, a multicellular diploid generation that produces spores alternates with a multicellular haploid generation that produces gametes.

27.14 An Isomorphic Life Cycle The sexual life cycle of sea lettuce (*Ulva lactuca*) is an example of isomorphic alternation of generations.

yourBioPortal.com

GO TO Web Activity 27.1 • An Isomorphic Life Cycle

Chlorophytes provide examples of several life cycles

The major features of protist life cycles can all be seen in the chlorophytes. Let's begin with the common sea lettuce, *Ulva lactuca*. Like many chlorophytes, sea lettuce exhibits alternation of generations. The diploid sporophyte of this common multicellular seashore organism is a broad sheet only two cells thick. Some of its cells (sporocytes) differentiate and undergo meiosis and cytokinesis, producing motile haploid spores. These *zoospores* swim away, and some find a suitable place to settle. The zoospores begin to divide mitotically, producing a thin filament that develops into a broad sheet only two cells thick. The gametophyte thus produced looks just like the sporophyte—in other words, *Ulva lactuca* has an isomorphic life cycle (Figure 27.14).

In most species of *Ulva*, the gametes are structurally of just a single type, making those species **isogamous**—having gametes of identical appearance. Other chlorophytes, including some other species of *Ulva*, are **anisogamous**—they have female gametes that are distinctly larger than the male gametes.

The life cycles of many other chlorophytes do not feature alternation of generations. Some chlorophytes have a **haplontic** life cycle, in which a multicellular haploid individual produces gametes that fuse to form a zygote. The zygote functions directly as a sporocyte, undergoing meiosis to produce spores, which in turn produce a new haploid individual. In the entire haplontic life cycle, only one cell—the zygote—is diploid. The filamentous organisms of the genus *Ulothrix* are examples of haplontic chlorophytes (Figure 27.15).

Some chlorophytes have a **diploontic** life cycle like that of many animals. In a diploontic life cycle, meiosis of diploid sporocytes produces haploid gametes directly; the gametes fuse, and the resulting diploid zygote divides mitotically to form a new multicellular diploid sporophyte. In such organisms, all cells except the gametes are diploid. Between these two extremes are chlorophytes in which the gametophyte and sporo-

27.15 A Haplontic Life Cycle In the life cycle of *Ulothrix*, a filamentous, multicellular haploid gametophyte alternates with a diploid sporophyte generation consisting of a single cell (the zygote). *Ulothrix* gametophytes can also reproduce asexually.

yourBioPortal.com

GO TO Web Activity 27.2 • A Haplontic Life Cycle

phyte generations are both multicellular, but one generation (usually the sporophyte) is much larger and more prominent than the other.

The life cycles of some protists require more than one host species

The trypanosome diseases discussed at the opening of this chapter share a striking feature with malaria: in each case, the eukaryote pathogen completes part of its life cycle in the human host and part in an insect (see Figure 27.9). Many other protist life cycles require the participation of two different host species.

What might be the advantage of a life cycle with two hosts? This remains an intriguing question. It may be relevant that in the human pathogens described above, the sexual phase of the organism's life cycle—the fusion of gametes into a zygote—takes place in the insect host. Could this imply that the human host is nothing but a copying machine for the products of sexual reproduction in the insect host?

27.4 RECAP

Protists reproduce both asexually and sexually, although sex may occur independently of reproduction in some species. Some multicellular protists exhibit alternation of generations, alternating between multicellular haploid and diploid life stages. Parasitic protists may have complex life cycles in which they infect more than one host species.

- Why is conjugation between paramecia considered a sexual process but not a reproductive process? See p. 573 and Figure 27.12
- Can you explain the difference between the diplontic human life cycle and a life cycle with alternation of generations? See pp. 573–574

The success of protists' diverse adaptations for nutrition, locomotion, and reproduction is evident from the abundance and diversity of eukaryotes living today. In the next section we survey that diversity.

27.5 What Are the Evolutionary Relationships among Eukaryotes?

Biologists used to classify the various groups of protists largely on the basis of life history and reproductive features. However, scientists using electron microscopy and gene sequencing have revealed many new patterns of evolutionary relatedness. Analyses of slowly evolving gene sequences are making it possible to explore evolutionary relationships among eukaryotes in ever greater detail and with greater confidence. Today we recognize great diversity among the many distantly related protist clades, whose members have explored a great variety of lifestyles.

Most eukaryotes can be classified in one of five major hypothesized clades: chromalveolates, Plantae, excavates, rhizaria,

or unikonts (see Figure 27.1 and Table 27.1). As we will see, some of these groups consist of organisms with enormously diverse body forms and nutritional lifestyles. The phylogenetic relationships among the major groups of eukaryotes comprise an active area of study, and new data from genomes are rapidly changing our understanding of the evolution of these species. These relationships also help us understand how the major multicellular eukaryotic groups (brown algae, plants, fungi, and animals) originated from the microbial eukaryotes.

CHROMALVEOLATES

We begin our tour of protist groups with the **chromalveolates**, a group of photosynthetic organisms, usually with cellulose in their cell walls, that includes the haptophytes, alveolates and stramenopiles. The monophyly of the chromalveolates is not yet well established. The **haptophytes** are unicellular organisms with flagella; many are “armored” with elaborate scales (see Figure 27.10B). The alveolates and stramenopiles are large and diverse clades that we explore here in greater detail.

Alveolates have sacs under their plasma membrane

The synapomorphy that characterizes the **alveolate** clade is the possession of sacs called *alveoli* just below their plasma membranes. The alveoli may play a role in supporting the cell surface. These organisms are all unicellular, but they are diverse in body form. The alveolate groups we consider in detail here are the dinoflagellates, apicomplexans, and ciliates.

DINOFLAGELLATES The **dinoflagellates** are of great ecological, evolutionary, and morphological interest. Most dinoflagellates are marine, and they are important primary photosynthetic producers of organic matter in the oceans. A distinctive mixture of photosynthetic and accessory pigments gives dinoflagellate chloroplasts a golden brown color. (Section 27.1 describes the endosymbiotic events that gave rise to dinoflagellates with different numbers of membranes surrounding their chloroplasts.) Some are photosynthetic endosymbionts living in the cells of other organisms, including invertebrate animals (such as corals) and other marine protists (see Figure 27.8). Some are nonphotosynthetic and live as parasites within other marine organisms.

Dinoflagellates have a distinctive appearance. They are unicellular and generally have two flagella, one in an equatorial groove around the cell, the other starting near the same point as the first and passing down a longitudinal groove before extending into the surrounding medium (Figure 27.16). Some dinoflagellates can take on different forms, including amoeboid ones, depending on environmental conditions. It has been claimed that the dinoflagellate *Pfiesteria piscicida* can occur in at least two dozen distinct forms, although this claim is highly con-

Peridinium sp.

27.16 A Dinoflagellate The dinoflagellates are an important group of alveolates. Most of them are photosynthetic and are a crucial component of the world's phytoplankton. They are often endosymbiotic (see Figure 27.8) and can be the agents of deadly ocean "blooms" (see Figure 27.10A).

troversal. In any case, this remarkable dinoflagellate is harmful to fish and can, when present in great numbers, both stun and feed on them.

APICOMPLEXANS The exclusively parasitic **apicomplexans** derive their name from the *apical complex*, a mass of organelles contained in the *apical* end (the tip) of a cell. These organelles help the apicomplexan invade its host's tissues. For example, the apical complex enables the merozoites and sporozoites of *Plasmodium*, the causative agent of malaria, to enter their target cells in the human body.

Like many obligate parasites, apicomplexans have elaborate life cycles featuring asexual and sexual reproduction by a series of very dissimilar life stages. Often these stages are associated with two different types of host organisms, as is the case with *Plasmodium*. The apicomplexan *Toxoplasma* alternates between cats and rats to complete its life cycle. A rat infected with *Toxoplasma* loses its fear of cats, making it more likely to be eaten by, and thus transfer the parasite to, a cat.

Apicomplexans lack contractile vacuoles. They contain a much-reduced chloroplast that no longer has a photosynthetic function (derived, like all chromalveolate chloroplasts, from secondary endosymbiosis of a red alga). This chloroplast might be a target for a future antimalarial drug.

CILIATES The **ciliates** are so named because they characteristically have numerous hairlike cilia shorter than, but otherwise

identical to, eukaryotic flagella. This group is noteworthy for its diversity and ecological importance (**Figure 27.17**). Almost all ciliates are heterotrophic (although a few contain photosynthetic endosymbionts), and they are much more complex in body form than are most other unicellular eukaryotes. The definitive characteristic of ciliates is the possession of two types of nuclei (as seen in the paramecia in Figure 27.12).

Paramecium, a frequently studied ciliate genus, exemplifies the complex structure and behavior of ciliates (**Figure 27.18**). The slipper-shaped cell is covered by an elaborate pellicle, a structure composed principally of an outer membrane and an inner layer of closely packed, membrane-enclosed sacs (the alveoli) that surround the bases of the cilia. Defensive organelles

27.17 Diversity among the Ciliates (A) A free-swimming organism, this paramecium belongs to a ciliate group whose members have many cilia of uniform length. (B) Members of this group have cilia on their mouthparts. (C) In this group, cilia are replaced by tentacles as development proceeds. (D) Some of the cilia in *Euplotes* are grouped into flat sheets that sweep food particles into the oral groove.

27.18 Anatomy of *Paramecium* This diagram shows the complex structure of a typical paramecium, detailing the pellicle (outer covering) with its trichocysts and alveoli.

—yourBioPortal.com—

GO TO Web Activity 27.3 • Anatomy of *Paramecium*

called *trichocysts* are also present in the pellicle. In response to a threat, a microscopic explosion expels the trichocysts in a few milliseconds, and they emerge as sharp darts, driven forward at the tip of a long, expanding filament.

The cilia provide a form of locomotion that is generally more precise than locomotion by flagella or pseudopods. A paramecium can coordinate the beating of its cilia to propel itself either forward or backward in a spiraling manner. It can also back off swiftly when it encounters a barrier or a negative stimulus. The coordination of ciliary beating is probably the result of a differential distribution of ion channels in the plasma membrane near the two ends of the cell.

Stramenopiles have two unequal flagella, one with hairs

A morphological synapomorphy shared by most **stramenopiles** is the possession of rows of tubular hairs on the longer of their two flagella. Some stramenopiles lack flagella, but they are descended from ancestors that possessed flagella. The stramenopiles include the diatoms and the brown algae, which are photosynthetic, and the oomycetes and slime nets, which are not. Most golden algae are photosynthetic, but nearly all of them become heterotrophic when light intensity is limited or when there is a plentiful food supply; some even feed on diatoms or bacteria. The slime nets (not to be confused with slime molds) are unicellular organisms that produce networks of filaments along which the cells move.

DIATOMS All of the **diatoms** are unicellular, although some species associate in filaments. Many have sufficient carotenoids in their chloroplasts to give them a yellow or brownish color. All make carbohydrates and oils as photosynthetic storage products. Diatoms lack flagella except in male gametes.

Architectural magnificence on a microscopic scale is the hallmark of the diatoms. As mentioned earlier, almost all diatoms deposit silica (hydrated silicon dioxide) in their cell walls. The cell wall is constructed in two pieces, with the top overlapping the bottom like the top and bottom of a petri plate. The silica-impregnated walls have intricate patterns unique to each species (**Figure 27.19**). Despite their remarkable morphological diversity, all diatoms are symmetrical—either bilaterally (with “right” and “left” halves) or radially (with the type of symmetry possessed by a circle).

Diatoms reproduce both sexually and asexually. Asexual reproduction is by binary fission and is somewhat constrained by the stiff, silica-containing cell wall. Both the top and the bottom of the “petri plate” become tops of new “plates” without changing appreciably in size; as a result, the new cell made from the former bottom is smaller than the parent cell. If this process continued indefinitely, one cell line would simply vanish, but sexual reproduction largely solves this potential problem. Gametes are formed, shed their cell walls, and fuse. The resulting zygote then increases substantially in size before a new cell wall is laid down.

27.19 Diatom Diversity This brightfield micrograph of diatoms shows a variety of species-specific forms. Diatoms are photosynthesizers and dominant components of the world's phytoplankton.

(A) *Cystoseira usneoides*(B) *Ectocarpus* sp.(C) *Postelsia palmaeformis*(D) *Postelsia palmaeformis*

Diatoms are found in all the oceans and are frequently present in great numbers, making them major photosynthetic producers in coastal waters. Diatoms are also common in fresh water and even occur on the wet surfaces of terrestrial mosses. They are also the dominant organisms in the dense “blooms” of plankton that occasionally appear in the open ocean.

Because the silica-containing walls of dead diatom cells resist decomposition, certain sedimentary rocks are composed almost entirely of diatom skeletons that sank to the seafloor over time. Diatomaceous earth, which is obtained from such rocks, has many industrial uses, such as insulation, filtration, and metal polishing. It has also been used as an “Earth-friendly” insecticide that clogs the tracheae (breathing structures) of insects.

BROWN ALGAE The **brown algae** obtain their namesake color from the carotenoid *fucoxanthin*, which is abundant in their chloroplasts. The combination of this yellow-orange pigment with the green of chlorophylls *a* and *c* yields a brownish tinge. All brown algae are multicellular, and some are extremely large. Giant kelps, such as those of the genus *Macrocystis*, may be up to 60 meters long.

27.20 Brown Algae (A) This seaweed illustrates the filamentous growth form of the brown algae. (B) Filaments of the microscopic brown alga *Ectocarpus* seen through a light microscope. (C) Sea palms and many other brown algal species are “glued” to the substratum by tough, branched structures called holdfasts. (D) Sea palms exemplify the leaflike form of brown algae. Holdfasts allow them to withstand the pounding of the surf.

The brown algae are almost exclusively marine. They are composed either of branched filaments (Figure 27.20A,B) or of leaflike growths (Figure 27.20D). Some float in the open ocean; the most famous example is the genus *Sargassum*, which forms dense mats in the Sargasso Sea in the mid-Atlantic. Most brown algae, however, are attached to rocks near the shore. A few thrive only where they are regularly exposed to heavy surf; a notable example is the sea palm *Postelsia palmaeformis* of the Pacific coast. All of the attached forms develop a specialized structure, called a *holdfast*, that literally glues them to the rocks (Figure 27.20C). The “glue” of the holdfast is *alginic acid*, a gummy polymer of sugar acids found in the walls of many brown algal cells. In addition to its function in holdfasts, alginic acid cements algal cells and filaments together, and is harvested and used by humans as an emulsifier in ice cream, cosmetics, and other products.

Some brown algae differentiate extensively into specialized organs. Some, like the sea palm, have stemlike stalks and leaflike blades. Some develop gas-filled cavities or bladders that serve as floats. In addition to organ differentiation, the larger brown algae also exhibit considerable tissue differentiation. Most of the giant kelps have photosynthetic filaments only in the outermost regions of their stalks and blades. Within the stalks and blades lie filaments of tubular cells that closely resemble the nutrient-conducting tissue of land plants. Called *trumpet cells* because they have flared ends, these tubes rapidly conduct the products of photosynthesis through the body of the organism.

OOMYCETES A nonphotosynthetic stramenopile group called the **oomycetes** consists in large part of the water molds and their terrestrial relatives, such as the downy mildews. Water molds are filamentous and stationary, and they are *absorptive heterotrophs*—that is, they secrete enzymes that digest large food molecules into smaller molecules that the water mold can absorb. If you have seen a whitish, cottony mold growing on dead fish or dead insects in water, it was probably a water mold of the common genus *Saprolegnia* (Figure 27.21).

Don’t be misled by the “mycete” in the name of this group. That term means “fungus,” and it is there because these organisms were once classified as fungi. However, we now know that the oomycetes are more distantly related to the fungi than

Saprolegnia sp.

27.21 An Oomycete The filaments of a water mold radiate from the carcass of an insect.

are many other eukaryote groups, including ourselves (see Figure 27.1), and the similarity of oomycetes to fungi is only superficial. For example, the cell walls of oomycetes are typically made of cellulose, whereas those of fungi are made of chitin.

Some oomycetes are **coenocytes**, which means they have many nuclei enclosed in a single plasma membrane. Their filaments have no cross-walls to separate the many nuclei into discrete cells. Their cytoplasm is continuous throughout the body of the organism, and there is no single structural unit with a single nucleus, except in certain reproductive stages. A distinguishing feature of the oomycetes is their flagellated reproductive cells. Oomycetes are diploid throughout most of their life cycle.

The water molds, such as *Saprolegnia*, are all aquatic and **saprobic**—meaning they feed on dead organic matter. Some other oomycetes are terrestrial. Although most of

the terrestrial oomycetes are harmless or helpful decomposers of dead matter, a few are serious plant parasites that attack crops such as avocados, grapes, and potatoes.

Although their presumed chromalveolate ancestors had chloroplasts and were photosynthetic, the oomycetes lack chloroplasts.

PLANTAE

Plantae contains mostly photosynthetic species and consists of several major clades, including glaucophytes, red algae, chlorophytes, charophytes, and the land plants, all of which probably trace their chloroplasts back to a single incidence of endosymbiosis (see Section 27.1). It is for this reason that the small clade known as the **glaucophytes**, unicellular organisms that live in fresh water, is of particular interest.

The glaucophytes were likely the first group to diverge after the primary endosymbiosis event. Their chloroplast is unique in containing a small amount of peptidoglycan between its inner and outer membranes—the same arrangement as that found in cyanobacteria (see Figure 27.3A). The presence of peptidoglycan, the characteristic cell wall component of bacteria, suggests that this feature has been retained in glaucophytes but lost in the other Plantae groups.

Red algae have a distinctive accessory photosynthetic pigment

Almost all **red algae** are multicellular (**Figure 27.22**). Their characteristic color is a result of the accessory photosynthetic pigment *phycoerythrin*, which is found in relatively large amounts in the chloroplasts of many species. In addition to phycoerythrin, red algae contain phycocyanin, carotenoids, and chlorophyll *a*.

The red algae include species that grow in the shallowest tide pools as well as the photosynthesizers found deepest in the ocean (as deep as 260 meters if nutrient conditions are right and the water is clear enough to permit light to penetrate). Very few red algae inhabit fresh water. Most grow attached to a substratum by a holdfast.

In a sense, the red algae are misnamed. They have the capacity to change the relative amounts of their

various photosynthetic pigments depending on the light conditions where they are growing. Thus the leaflike *Chondrus crispus*, a common North Atlantic red alga, may appear bright green when it is growing at or near the surface of the water and deep red when growing at greater depths. The ratio of pigments present depends to a remarkable degree on the intensity of the light that reaches the alga. In deep water, where the light is dimmest, the alga accumulates large amounts of phycoerythrin. The algae in deep water have as much chlorophyll as the green ones near the surface, but the accumulated phycoerythrin makes them look red.

In addition to being the only photosynthetic eukaryotes with phycoerythrin among their pigments, the red algae have two other distinctive characteristics:

- They store the products of photosynthesis in the form of *floridean starch*, which is composed of very small, branched chains of approximately 15 glucose monomers.
- They produce no motile, flagellated cells at any stage of their life cycle. The male gametes lack cell walls and are slightly amoeboid; the female gametes are completely immobile.

Some red algal species enhance the formation of coral reefs (see Figure 27.22B). Like coral animals, they possess the biochemical machinery for secreting calcium carbonate, which they deposit both in and around their cell walls. After the deaths of corals and algae, the calcium carbonate persists, sometimes forming substantial rocky masses.

Some red algae produce large amounts of mucilaginous polysaccharide substances, which contain the sugar galactose with a sulfate group attached. This material readily forms solid gels and is the source of agar, a substance widely used in the laboratory for making a solid aqueous medium on which tissue cultures and many microorganisms can be grown.

The distinctive chloroplasts of the photosynthetic chromalveolates are derived by secondary endosymbiosis of a red alga, as discussed in Section 27.1.

Chlorophytes, charophytes, and land plants contain chlorophylls a and b

One major clade of “green algae” is the **chlorophytes**. A sister group to the chlorophytes contains another green algal clade—the **charophytes**, or **Charales**—along with the land plants (see Section 28.1). The green algae share several characters that distinguish them from other protists: like the land plants, they contain chlorophylls *a* and *b*, and their reserve of photosynthetic products is stored as starch in chloroplasts. Through secondary endosymbiosis, a chlorophyte became the chloroplast of the euglenids.

There are more than 17,000 species of chlorophytes. Most are aquatic—some are marine, though more are freshwater forms—but others are terrestrial, living in moist environments. The chlorophytes range in size from microscopic unicellular forms to multicellular forms many centimeters long.

The chlorophytes display an incredible variety of shapes and body forms. *Chlamydomonas* is an example of the simplest type: unicellular and flagellated. Surprisingly large and well-formed

27.23 Chlorophytes (A) *Volvox* colonies are precisely spaced arrangements of cells. Specialized reproductive cells produce daughter colonies, which will eventually release new individuals. (B) Sea lettuce grows in ocean tidewaters.

colonies of cells are found in such freshwater groups as the genus *Volvox* (Figure 27.23A). The cells in these colonies are not differentiated into specialized tissues and organs, as in land plants and animals, but the colonies show vividly how the preliminary step of this great evolutionary innovation might have been taken. In *Volvox*, the origins of cell specialization can be seen in certain cells in the colony that are specialized for reproduction.

While *Volvox* is colonial and spherical, *Oedogonium* is multicellular and filamentous, and each of its cells has only one nucleus. *Cladophora* is multicellular, but each cell is multinucleate. *Bryopsis* is tubular and coenocytic, forming cross-walls only when reproductive structures form. *Acetabularia* is a single giant, uninucleate cell a few centimeters in length that becomes multinucleate only at the end of its reproductive stage. *Ulva lactuca* is a thin, membranous sheet a few centimeters across; its distinctive appearance justifies its common name of sea lettuce (Figure 27.23B).

As mentioned above, the chlorophytes are the largest clade of green algae, but there are other green algal clades as well. Those clades are branches of a clade that also includes the land plants, which are described in the next chapter.

EXCAVATES

Excavates include a number of diverse clades, several of which lack mitochondria. This absence of mitochondria once led to the view that these groups might represent early diverging groups of eukaryotes that diversified before the evolution of mitochondria. However, the absence of mitochondria seems to be a derived condition, judging in part from the presence of nuclear genes normally associated with mitochondria. Ancestors of these organisms probably possessed mitochondria that were lost or reduced in the course of evolution. The existence of such organisms today shows that eukaryotic life is feasible without mitochondria, and for that reason, these groups are the focus of much attention.

Diplomonads and parabasalids are excavates that lack mitochondria

The **diplomonads** and **parabasalids**, all of which are unicellular, are distinctive in their lack of mitochondria. *Giardia lamblia*, a diplomonad, is a familiar parasite that contaminates water supplies and causes the intestinal disease giardiasis (Figure 27.24A). This tiny organism contains two nuclei bounded by nuclear envelopes, and it has a cytoskeleton and multiple flagella.

Trichomonas vaginalis is a parabasalid responsible for a sexually transmitted disease in humans (Figure 27.24B). Infection of the male urethra, where it may occur without symptoms, is less common than infection of the vagina. In addition to flagella and a cytoskeleton, the parabasalids have undulating membranes that also contribute to the cell's locomotion.

Heteroloboseans alternate between amoeboid forms and forms with flagella

The amoeboid body form appears in several protist groups—including the **loboseans** and **heteroloboseans**—that are only distantly related to one another. These groups belong, respectively, to the unikonts and excavates. Amoebas of the free-living heterolobosean genus *Naegleria*, some of which can enter humans and cause a fatal disease of the nervous system, usually have a two-stage life cycle, in which one stage has amoeboid cells and the other flagellated cells.

Euglenids and kinetoplastids have distinctive mitochondria and flagella

The euglenids and kinetoplastids, both of which are excavates, together constitute a clade of unicellular organisms with flagella. Their mitochondria contain distinctive, disc-shaped cristae, and their flagella contain a crystalline rod not found in other organisms. They reproduce primarily asexually by binary fission.

EUGLENIDS The **euglenids** possess flagella arising from a pocket at the anterior end of the cell. Spiraling strips of proteins under their plasma membranes control the cell's shape. Some members

(A) *Giardia* sp.

(B) *Trichomonas vaginalis*

27.24 Some Excavate Groups Lack Mitochondria (A) *Giardia*, a diplomonad, has flagella and two nuclei. (B) *Trichomonas*, a parabasalid, has flagella and undulating membranes. Neither of these organisms possesses mitochondria.

of the group are photosynthetic. Euglenids used to be claimed by the zoologists as animals and by the botanists as plants.

Figure 27.25 depicts a cell of the genus *Euglena*. Like most other euglenids, this common freshwater organism has a complex cell structure. It propels itself through the water with

27.25 A Photosynthetic Euglenid Several *Euglena* species possess flagella. In this species, the second flagellum is rudimentary.

TABLE 27.2			
A Comparison of Three Kinetoplastid Trypanosomes			
	<i>Trypanosoma brucei</i>	<i>Trypanosoma cruzi</i>	<i>Leishmania major</i>
Human disease	Sleeping sickness	Chagas' disease	Leishmaniasis
Insect vector	Tsetse fly	Assassin bug	Sand fly
Vaccine or effective cure	None	None	None
Strategy for survival	Changes surface recognition molecules frequently	Causes changes in surface recognition molecules on host cell	Reduces effectiveness of macrophage hosts
Site in human body	Bloodstream; attacks nerve tissue in final stages	Enters cells, especially muscle cells	Enters cells, primarily macrophages
Approximate number of deaths per year	50,000	43,000	60,000

the longer of its two flagella, which may also serve as an anchor to hold the organism in place. The second flagellum is often rudimentary.

Euglenids have diverse nutritional requirements. Many species are always heterotrophic. Other species are fully autotrophic in sunlight, using chloroplasts to synthesize organic compounds through photosynthesis. The chloroplasts of euglenids are surrounded by three membranes as a result of secondary endosymbiosis (see Figure 27.3B). When kept in the dark, these euglenids lose their photosynthetic pigment and begin to feed exclusively on dissolved organic material in the water around them. Such a “bleached” *Euglena* resynthesizes its photosynthetic pigment when it is returned to the light and becomes autotrophic again. But *Euglena* cells treated with certain antibiotics or mutagens lose their photosynthetic pigment completely; neither they nor their descendants are ever autotrophs again. However, those descendants function well as heterotrophs.

KINETOPLASTIDS The **kinetoplastids** are unicellular parasites with two flagella and a single, large mitochondrion. That mitochondrion contains a *kinetoplast*—a unique structure housing multiple circular DNA molecules and associated proteins. Some of these DNA molecules encode “guides” that edit messenger RNA in the mitochondrion.

The trypanosomes described at the opening of this chapter are kinetoplastids. They are able to change their cell surface recognition molecules frequently, which allows them to evade our best attempts to kill them and eradicate the diseases they cause (Table 27.2).

RHIZARIA

The primary groups of **Rhizaria** are unicellular aquatic eukaryotes. Foraminiferans, radiolarians, and cercozoans typically have long, thin pseudopodia that contrast with the broader, lobelike pseudopodia of the familiar amoebas. These groups have contributed to ocean sediments, some of which have become terrestrial features in the course of geological history.

The **cercozoans** are a diverse group, with many forms and habitats. Some are amoeboid, while others have flagella. Some are aquatic; others live in soil. One group of cercozoans possesses chloroplasts derived from a green alga by secondary endosymbiosis—and that chloroplast contains a trace of the green alga’s nucleus.

Foraminiferans have created vast limestone deposits

Some **foraminiferans** secrete external shells of calcium carbonate (see Figure 27.11), which over time have accumulated to produce much of the world’s limestone. Some foraminiferans live as plankton; others live on the seafloor. Living foraminiferans have been found at the deepest point in the world’s oceans—10,896 meters down in the Challenger Deep, in the western Pacific. At that depth, however, they cannot secrete a normal shell because the surrounding water is too poor in calcium carbonate.

Long, threadlike, branched pseudopods reach out through numerous microscopic apertures in the shell and interconnect to create a sticky, reticulated net, which planktonic foraminifera use to catch smaller plankton. The pseudopods provide locomotion in some species.

Radiolarians have thin, stiff pseudopods

The **radiolarians** are recognizable by their thin, stiff pseudopods, which are reinforced by microtubules. These pseudopods:

- greatly increase the surface area of the cell for exchange of materials with the environment
- help the cell float in its marine environment

Found exclusively in marine environments, radiolarians are immediately recognizable by their distinctive radial symmetry (see Figure 27.8B). Almost all radiolarian species secrete glassy *endoskeletons* (internal skeletons). A central capsule lies within the cytoplasm. The skeletons of the different species are as varied as snowflakes, and many have elaborate geometric designs (Figure 27.26). A few radiolarians are among the largest of the unicellular eukaryotes, measuring several millimeters across.

27.26 A Radiolarian's Glass House Radiolarians secrete intricate glassy skeletons such as the one shown here. A living radiolarian with its endosymbionts is shown in Figure 27.8B.

UNIKONTS

We now consider the **unikonts**, a large clade that may be close to the root of the eukaryote tree. The name *unikont* derives from the Greek for “single cone,” and in these eukaryotes, the flagella, if present, are single. Unikonts consist of two major groups, the *opisthokonts* (which include animals and fungi) and the *amoebozoans* (see Figure 27.1).

A morphological synapomorphy of the opisthokonts is that their flagellum, if present, is posterior, as in animal sperm. The flagella of all other eukaryotes are anterior. In addition to the animals and fungi, opisthokonts also include the choanoflagellates. Fungi and animals are discussed in Chapters 30–33. The choanoflagellates, or collar flagellates, are sister to the animals, and the animal–choanoflagellate clade is sister to the fungi.

Some choanoflagellates are colonial (**Figure 27.27A**). They bear a striking resemblance to the most characteristic type of cell found in the sponges (compare **Figure 27.27B** with Figure 31.7).

Amoebozoans use lobe-shaped pseudopods for locomotion

The lobe-shaped pseudopods used by amoebozoans are a hallmark of the amoeboid body plan. The amoebozoan pseudopod differs in form and function from the slender pseudopods of rhizaria. We consider three amoebozoan groups here: the lobeoseans and two clades of slime molds.

LOBOSEANS A lobeosean, such as the *Peloxima carolinensis* shown in Figure 27.4, consists of a single cell. Unlike the cells of the slime molds, lobeoseans live independently of one another and

(A) *Codosiga botrytis*

(B) *Choanoeca* sp.

27.27 A Link to the Animals Choanoflagellates are the sister group to the animals. (A) The formation of colonies by unicellular organisms, as in this choanoflagellate species, is one route to the evolution of multicellularity. (B) A solitary choanoflagellate illustrates the similarity of this microbial protist group to a cell type present in the multicellular sponges (see Figure 31.7).

do not aggregate. A lobeosean feeds on small organisms and particles of organic matter by phagocytosis, engulfing them with its pseudopods. Many lobeoseans are adapted for life on the bottoms of lakes, ponds, and other bodies of water. Their creeping locomotion and their manner of engulfing food particles fit them for life close to a relatively rich supply of sedentary organisms or organic particles. Most lobeoseans exist as predators, parasites, or scavengers.

Some lobeoseans are shelled, living in casings of sand grains glued together (see Figure 27.7A). Others have shells secreted by the organism itself.

SLIME MOLDS The two major groups of *slime molds* share only general characteristics. All are motile, all ingest particulate food by endocytosis, and all form spores on erect structures called *fruiting bodies*. They undergo striking changes in organization during their life cycles, and one stage consists of isolated cells that take up food particles by endocytosis. Some slime molds may cover areas of 1 meter or more in diameter while in their less aggregated stage. Such a large slime mold may weigh more than 50 grams. Slime molds of both types favor cool, moist habitats, primarily in forests. They range from colorless to brilliant yellow and orange.

PLASMODIAL SLIME MOLDS If the nucleus of an amoeba began rapid mitotic division, accompanied by a tremendous increase in cytoplasm and organelles but no cytokinesis, the resulting organism might resemble the multinucleate mass of a plasmodial slime mold. During its vegetative (feeding) phase, a plasmodial slime mold is a wall-less mass of cytoplasm with numerous diploid nuclei. This mass streams very slowly over its substratum in a remarkable network of strands called a *plas-*

27.28 Plasmodial Slime Molds (A) The slime mold *Physarum* is most often seen in its plasmodial form, covering rocks, decaying logs, and other objects as it engulfs bacteria and other food items from the surface. (B) Fruiting structures of *Physarum*.

modium. The plasmodium of such a slime mold is another example of a coenocyte, with many nuclei enclosed in a single plasma membrane. The outer cytoplasm of the plasmodium (closest to the environment) is normally less fluid than the interior cytoplasm and thus provides some structural rigidity (**Figure 27.28A**).

Plasmodial slime molds provide a dramatic example of movement by cytoplasmic streaming. The outer cytoplasmic region of the plasmodium becomes more fluid in places, and cytoplasm rushes into those areas, stretching the plasmodium. This streaming somehow reverses its direction every few minutes as cytoplasm rushes into a new area and drains away from an older one, moving the plasmodium over its substratum. Sometimes an entire wave of plasmodium moves across the substratum, leaving strands behind. Microfilaments and a contractile protein called *myxomyosin* interact to produce the streaming movement. As it moves, the plasmodium engulfs food particles by endocytosis—predominantly bacteria, yeasts, spores of fungi, and other small organisms, as well as decaying animal and plant remains.

A plasmodial slime mold can grow almost indefinitely in its plasmodial stage, as long as the food supply is adequate and other conditions, such as moisture and pH, are favorable. However, one of two things can happen if conditions become unfavorable. First, the plasmodium can form an irregular mass of hardened cell-like components called a *sclerotium*. This resting structure rapidly becomes a plasmodium again when favorable conditions are restored.

Alternatively, the plasmodium can transform itself into spore-bearing fruiting structures (**Figure 27.28B**). These stalked or branched structures rise from heaped masses of plasmodium. They derive their rigidity from walls that form and thicken between their nuclei. The diploid nuclei of the plasmodium divide by meiosis as the fruiting structure develops. One or more knobs, called *sporangia*, develop on the end of the stalk.

Within a sporangium, haploid nuclei become surrounded by walls and form spores. Eventually, as the fruiting body dries, it sheds its spores.

The spores germinate into wall-less, haploid cells called *swarm cells*, which can either divide mitotically to produce more haploid swarm cells or function as gametes. Swarm cells can live as separate individual cells that move by means of flagella or pseudopods, or they can become walled and resistant resting cysts when conditions are unfavorable; when conditions improve again, the cysts release swarm cells. Two swarm cells can also fuse to form a diploid zygote, which divides by mitosis (but without a wall forming between the nuclei) and thus forms a new, coenocytic plasmodium.

CELLULAR SLIME MOLDS Whereas the plasmodium is the basic vegetative (feeding, nonreproductive) unit of the plasmodial slime molds, an amoeboid cell is the vegetative unit of the cellular slime molds. Large numbers of cells called *myxamoebas*, which have single haploid nuclei, engulf bacteria and other food particles by endocytosis and reproduce by mitosis and fission. This simple life cycle stage, consisting of swarms of independent, isolated cells, can persist indefinitely as long as food and moisture are available.

When conditions become unfavorable, the cellular slime molds aggregate and form fruiting structures, as do their plasmodial counterparts. The individual myxamoebas aggregate into a mass called a *slug* or *pseudoplasmodium* (**Figure 27.29**). Unlike the true plasmodium of the plasmodial slime molds, this structure is not simply a giant sheet of cytoplasm with many nuclei; the individual myxamoebas retain their plasma membranes and, therefore, their identity.

A slug may migrate over its substratum for several hours before becoming motionless and reorganizing to construct a delicate, stalked fruiting structure. Cells at the top of the fruiting structure develop into thick-walled spores, which are eventually released. Later, under favorable conditions, the spores germinate, releasing myxamoebas.

The cycle from myxamoebas through slug and spores to new myxamoebas is asexual. Cellular slime molds also have a sex-

Dictyostelium discoideum

27.29 A Cellular Slime Mold The life cycle of the slime mold *Dictyostelium* is shown here in a composite micrograph.

ual cycle, in which two myxamoebas fuse. The product of this fusion develops into a spherical structure that ultimately germinates, releasing new haploid myxamoebas.

In subsequent chapters we explore the three major groups of multicellular eukaryotes. Chapters 28 and 29 describe the origin and diversification of the plants, Chapter 30 presents the fungi, and Chapters 31–33 describe the animals. All three of these groups arose from protist ancestors.

CHAPTER SUMMARY

27.1 How Did the Eukaryotic Cell Arise?

- The modern eukaryotic cell evolved from an ancestral prokaryote. Probable early events in this evolution include the loss of the cell wall and infolding of the plasma membrane. Such infolding probably led to the segregation of the genetic material in a membrane-enclosed nucleus. The development of a cytoskeleton gave the evolving cell increasing control over its shape and distribution of daughter chromosomes. **Review Figure 27.2**
- Some organelles were acquired by endosymbiosis. Mitochondria evolved from a proteobacterium.
- **Primary endosymbiosis** of a eukaryote and a cyanobacterium gave rise to the chloroplasts, beginning with those of glaucophytes, red algae, green algae, and land plants. **Secondary and tertiary endosymbiosis** of these chloroplast-containing eukaryotes within other eukaryotes gave rise to the chloroplasts of euglenids, dinoflagellates, and other groups. **Review Figure 27.3, ANIMATED TUTORIAL 27.1**

27.2 What Features Account for Protist Diversity?

- **Protists** are a diverse, paraphyletic assemblage of mostly unicellular eukaryotes. **Review Figure 27.1**
- Some protists are photosynthetic autotrophs, some are heterotrophs, and some are both.
- The cytoskeleton allows for various means of locomotion. Most protists are motile, moving by amoeboid motion with **pseudopods** or by means of cilia or flagella.
- Some protist cells contain **contractile vacuoles** that pump out excess water, or **digestive vacuoles** where food is digested. **Review Figures 27.5 and 27.6, ANIMATED TUTORIAL 27.2**
- Many protists have protective cell surfaces such as cell walls, external “shells,” or shells constructed from sand.

27.3 How Do Protists Affect the World Around Them?

- The diatoms, part of the plankton, are responsible for about a fifth of all the photosynthetic carbon fixation on Earth.

- **Phytoplankton** are the primary producers in the marine environment.
- Endosymbiosis is common among protists and often helpful to both partners. **Review Figure 27.8**
- Pathogenic protists include species of *Plasmodium* and trypanosomes. **Review Figure 27.9**

27.4 How Do Protists Reproduce?

- Most protists reproduce both asexually and sexually.
- **Conjugation** in paramecia is a sexual process but not a reproductive one. **Review Figure 27.12**
- **Alternation of generations**, which includes a multicellular diploid phase and a multicellular haploid phase, is a feature of many protist life cycles. **Review Figure 27.13**
- Alternation of generations may be **heteromorphic** or **isomorphic**. The alternating generations are the (diploid) **sporophyte** and (haploid) **gametophyte**. Specialized cells of the sporophyte, called **sporocytes**, divide meiotically to produce haploid spores.
- Depending on whether their gametes look identical or dissimilar, species are termed **isogamous** or **anisogamous**.
- In a **diploontic** life cycle, the gametes are the only haploid cells. In a **haplontic** life cycle, the zygote is the only diploid cell. **Review Figures 27.14 and 27.15, WEB ACTIVITIES 27.1 AND 27.2**
- Some protist life cycles involve more than one host species.

27.5 What Are the Evolutionary Relationships Among Eukaryotes?

- Most eukaryotes can be classified in one of five major clades: chromalveolates, Plantae, excavates, rhizaria, or unikonts. **Review Table 27.1 and Figure 27.1**
- The **chromalveolates** include the haptophytes, alveolates, and stramenopiles.
- **Alveolates** are unicellular organisms with sacs (alveoli) beneath their plasma membranes. Alveolate clades include the marine **dinoflagellates**, the parasitic **apicomplexans**, and the diverse, highly motile **ciliates**. **REVIEW WEB ACTIVITY 27.3**

- **Stramenopiles** typically have two flagella of unequal length, the longer one bearing rows of tubular hairs. Included among the stramenopiles are the unicellular **diatoms**, the multicellular **brown algae**, and the nonphotosynthetic **oomycetes**, including the water molds and downy mildews.
- Clades in the **Plantae** include the **glaucophytes**, **red algae**, **chlorophytes**, **charophytes**, and the land plants. All are photosynthetic and contain chloroplasts. Glaucophyte chloroplasts contain peptidoglycan between their inner and outer membranes.
- The **excavates** include the diplomonads, parabasalids, heteroloboseans, euglenids, and kinetoplastids. The **diplomonads** and **parabasalids** lack mitochondria, having apparently lost them during their evolution. **Heteroloboseans** are amoebas with a two-stage life cycle. **Euglenids** are often photosynthetic and have anterior flagella and strips of protein that support their cell surface. **Kinetoplastids** have a single, large mitochondrion in which mitochondrial mRNA is edited.
- **Rhizaria** are unicellular and aquatic; most are amoeboid. This group includes the **foraminiferans**, whose shells have contributed to great limestone deposits; the **radiolarians** with thin, stiff pseudopods and glassy endoskeletons; and the **cercozoans**, which take many forms and live in diverse habitats.
- The **unikonts** encompass organisms with single flagella on their flagellated cells (if any). They can be divided into two subgroups, the opisthokonts and the amoebozoans.
- In the **opisthokonts**, the flagellum (when present) is posterior. The opisthokont subgroups are the fungi, choanoflagellates, and animals. **Choanoflagellates** resemble the cells of sponges and are sister to the animal clade.
- The **amoebozoans** move by means of lobe-shaped pseudopodia. They comprise the **loboseans**, plasmodial slime molds, and cellular slime molds. A lobosean consists of a single cell; these cells do not aggregate. Plasmodial slime molds are amoebozoans whose feeding phase is coenocytic. In the feeding phase, movement is by cytoplasmic streaming. In cellular slime molds, the individual cells maintain their identity at all times but aggregate to form fruiting bodies.

SELF-QUIZ

- Microbial eukaryotes with flagella
 - appear in several clades.
 - are all algae.
 - all have pseudopods.
 - are all colonial.
 - are never pathogenic.
- Which statement about eukaryotic phytoplankton is *not* true?
 - Some are important primary producers.
 - Some contributed to the formation of petroleum.
 - Some form toxic “red tides.”
 - Some are food for marine animals.
 - They constitute a clade.
- Apicomplexans
 - possess flagella.
 - possess a glassy shell.
 - are all parasitic.
 - are algae.
 - include the trypanosomes that cause sleeping sickness.
- The ciliates
 - move by means of short flagella.
 - use amoeboid movement.
 - include *Plasmodium*, the agent of malaria.
 - possess both a macronucleus and micronuclei.
 - are autotrophic.
- The chloroplasts of photosynthetic protists
 - are structurally identical.
 - gave rise to mitochondria.
 - are all descended from a once free-living cyanobacterium.
 - all have exactly two surrounding membranes.
 - are all descended from a once free-living red alga.

6. Which statement about the brown algae is *not* true?
 - a. They are all multicellular.
 - b. They use the same photosynthetic pigments as do land plants.
 - c. They are almost exclusively marine.
 - d. A few are many meters in length.
 - e. They are stramenopiles.
7. Which statement about the chlorophytes is *not* true?
 - a. They use the same photosynthetic pigments as do land plants.
 - b. Some are unicellular.
 - c. Some are multicellular.
 - d. All are microscopic in size.
 - e. They display a great diversity of life cycles.
8. The red algae
 - a. are mostly unicellular.
 - b. are mostly marine.
 - c. owe their red color to a special form of chlorophyll.
 - d. have flagella on their gametes.
 - e. are all heterotrophic.
9. The plasmodial slime molds
 - a. form a plasmodium that is a coenocyte.
 - b. lack fruiting bodies.
 - c. consist of large numbers of myxamoebas.
 - d. consist at times of a mass called a pseudoplasmodium.
 - e. possess flagella.
10. The cellular slime molds
 - a. possess apical complexes.
 - b. lack fruiting bodies.
 - c. form a plasmodium that is a coenocyte.
 - d. have haploid myxamoebas.
 - e. possess flagella.

FOR DISCUSSION

1. For each type of organism below, give a single characteristic that may be used to differentiate it from the other, related organism(s) named in parentheses.
 - a. Foraminiferans (radiolarians)
 - b. *Euglena* (*Volvox*)
 - c. *Trypanosoma* (*Giardia*)
 - d. Plasmodial slime molds (cellular slime molds)
2. In what sense are sex and reproduction independent of each other in the ciliates? What does that suggest about the role of sex in biology?
3. Why are dinoflagellates and apicomplexans placed in one group of microbial eukaryotes and brown algae and oomycetes in another?
4. Unlike many protists, apicomplexans lack contractile vacuoles. Why don't apicomplexans need a contractile vacuole?
5. Giant seaweeds (mostly brown algae) have "floats" that aid in keeping their fronds suspended at or near the surface of the water. Why is it important that the fronds be suspended in this way?
6. Why are algal pigments so much more diverse than those of land plants?
7. Consider the chloroplasts of chlorophytes, euglenids, and red algae. For each of these groups, indicate how many membranes surround their chloroplasts, and offer a reasonable explanation in each case. Why do some dinoflagellates have more membranes around their chloroplasts than other dinoflagellates?

ADDITIONAL INVESTIGATION

Mitochondrial, chloroplast, and nuclear genomes of eukaryotes each contain ribosomal RNA genes. If the endosymbiotic theory for the origin of mitochondria and chloroplasts is correct, would you expect the ribosomal genes of these organelles to be more closely related to the nuclear ribosomal RNA genes, or to ribo-

somal RNA genes in proteobacteria and cyanobacteria? How would you test the endosymbiotic theory for the origin of these organelles using a phylogenetic analysis of ribosomal RNA genes?

What surprises lurk in a rock?

John William Dawson, later Sir William Dawson, was an outspoken critic of Charles Darwin and evolutionary theory. Ironically, Dawson made one of the first contributions to our understanding of the early evolution of plants. While surveying the geology of Nova Scotia, this Canadian scientist found a puzzling fossil fragment on the Gaspé Peninsula. It was 1859—the very year in which Darwin published *The Origin of Species*.

What Dawson found was the remains of a remarkable plant, which he named *Psilophyton*, meaning “naked plant.” The fossilized plant appeared to have no roots and no leaves, and its stem grew both below and above the ground. The aboveground part of the stem, which branched and ended in spore cases, was about 50 cen-

timeters tall. Could this Devonian fossil plant represent one of the stages in the momentous transition of plants from an aquatic existence to the forests that cover the land today? Dawson presented *Psilophyton* and other finds in a major lecture he delivered in 1870, but his audience was unreceptive, with his fellow scientists chuckling that *Psilophyton* grew nowhere but in Dawson’s imagination. His published drawing of the fossil plant was regarded as an amusing curiosity.

Decades later, Dawson’s interpretation of *Psilophyton* was vindicated by the work of two British botanists who studied plant fossils. The year 1915 found Robert Kidston and William Lang in the hills near Rhynie, Scotland, where they discovered evidence that a marsh had existed there 400 million years ago. In the intervening hundreds of millions of years, that Devonian marsh had become a flinty, fossil-laden rock called chert. Although the rock now lay in a hilly site some 50 kilometers from the sea, its original location must have been near the shore.

The most startling feature of the Rhynie chert was the great abundance of fossils of a small plant with spore cases but neither roots nor leaves—a plant, in fact, that looked strikingly like Dawson’s “imaginary” *Psilophyton*! Kidston and Lang described their find in detail and gave it the genus name *Rhynia* in honor of the site of its discovery.

Making It on Land An artist’s reconstruction of the earliest vascular plant ancestors, based on the Rhynie chert fossil bed in Scotland. The plants in this scene are rhyniophytes. Heavily mineralized water from hot springs and geysers may have been partly responsible for the remarkable preservation of plant fossils in the Rhynie bed.

Green Mansions Seedless plants—mosses and ferns—dominate the understory of this pristine rainforest on the island of Maui, Hawaii. The only seed plants to be seen are the trees, which are almost obscured by mosses and ferns.

Rhynia is just one of several ancient groups of plants that lack seeds and other features of more modern plants. The glory days of the seedless plants are long past, but many of them—most notably the mosses and ferns—are still abundant. We rely on these surviving plants, as well as on fossils, to help us understand the evolution of land plants from aquatic algae growing at the edge of a sea or marsh. Much of the fossilized history, and the great bulk of the mass of seedless plants, was preserved as coal, which today is an economically important substance that we burn as fuel and to produce electricity. What a library of botanical history the fossils in the world's coal beds provide!

IN THIS CHAPTER we will see how plants first invaded land, how land plants evolved, and how plant clades diversified, resulting in plants ever better equipped to face the challenges of terrestrial environments. The descriptions here will concentrate on those land plants that lack seeds. Chapter 29 considers the seed plants that dominate the terrestrial scene today.

CHAPTER OUTLINE

- 28.1** How Did the Land Plants Arise?
- 28.2** How Did Plants Colonize and Thrive on Land?
- 28.3** What Features Distinguish the Vascular Plants?
- 28.4** What Are the Major Clades of Seedless Plants?

28.1 How Did the Land Plants Arise?

The question “Where did plants come from?” embraces two questions: “What were the ancestors of plants?” and “Where did those ancestors live?” We consider both questions in this section.

The **land plants** are monophyletic: all land plants descend from a single common ancestor and form a branch of the evolutionary tree of life. Although we refer to this clade of mostly terrestrial species as land plants, some of them actually live in shallow water. One of the key shared derived traits, or *synapomorphies*, of the land plants is development from an embryo protected by tissues of the parent plant. For this reason, land plants are sometimes called **embryophytes** (*phyton*, “plant”). Land plants retain the derived features they share with the “green algae” described in Chapter 27: the use of chlorophylls *a* and *b* in photosynthesis, and the use of starch as a photosynthetic storage product. Both land plants and green algae have cellulose in their cell walls.

There are several ways to define “plant” and still refer to a clade (**Figure 28.1**; see also Figure 27.1). Throughout this book and in everyday language, the unmodified common name “plants” usually refers to the land plants. Some biologists, however, use the term “plants” to include land plants plus some closely related groups of green algae; this monophyletic group is also known as the **streptophytes**. The addition of the remainder of the green algae to the streptophytes results in a more inclusive clade, commonly called the **green plants**, which encompasses all the groups that possess chlorophyll *b*. Green plants, streptophytes, and land plants each have been called “the plant kingdom” by different authorities; others take an even broader view and include red algae and glaucophytes as “plants.” To avoid confusion in this chapter, we will use modifying terms (“land plants” or “green plants,” for example) to refer to the various clades shown in Figure 28.1.

There are ten major groups of land plants

The land plants that exist today fall naturally into ten major clades (**Table 28.1**). Members of seven of those clades possess well-developed vascular systems that transport materials throughout the plant body. We call these seven groups, collectively, the **vascular plants**, or **tracheophytes**, because they all possess fluid-conducting cells called **tracheids**. Taken together, the seven groups of vascular plants constitute a clade.

The remaining three clades (liverworts, hornworts, and mosses) lack tracheids. These three groups are sometimes collectively called *bryophytes*, but in this text we reserve that term for the largest monophyletic group—the mosses—and refer to these three clades collectively as **nonvascular land plants**.

28.1 What Is a Plant? In its broadest definition, the term “plant” includes the green plants, red algae, and glaucophytes—all the groups descended from a common ancestor with primary chloroplasts. Some biologists restrict the term to the green plants (those with chlorophyll *b*) or, even more narrowly, to the land plants (embryophytes).

Note, however, that *these three groups do not form a clade*. Some nonvascular land plants have conducting cells, but none have tracheids.

Where did the land plants come from? To determine which living organisms are most closely related to land plants, biologists have considered several of the synapomorphies of land plants and looked for their origins in various other groups.

The land plants arose from a green algal clade

Several microscopic structural features, backed by clear-cut evidence from molecular studies, indicate that the closest relatives of the land plants are two groups of aquatic green algae, the **Coleochaetales** and the **Charales** (see Figure 28.1). Both of these algal groups retain their eggs in the parental organism, as do land plants. Of these two candidates, Charales is thought to be the sister-group of land plants, based on the following synapomorphies:

- Plasmodesmata join the cytoplasm of adjacent cells (see Figure 34.6)
- Growth is branching and apical (from the tip)

TABLE 28.1		
Classification of Land Plants		
GROUP	COMMON NAME	CHARACTERISTICS
NONVASCULAR LAND PLANTS		
Hepatophyta	Liverworts	No filamentous stage; gametophyte flat
Anthocerophyta	Hornworts	Embedded archegonia; sporophyte grows basally (from the ground)
Bryophyta	Mosses	Filamentous stage; sporophyte grows apically (from the tip)
VASCULAR PLANTS		
Lycopodiophyta	Lycophytes: Club mosses and allies	Microphylls in spirals; sporangia in leaf axils
Monilophyta	Horsetails, whisk ferns, ferns	Differentiation between main stem and side branches (overtopping growth)
SEED PLANTS		
Gymnosperms		
Cycadophyta	Cycads	Compound leaves; swimming sperm; seeds on modified leaves
Ginkgophyta	Ginkgo	Deciduous; fan-shaped leaves; swimming sperm
Gnetophyta	Gnetophytes	Vessels in vascular tissue; opposite, simple leaves
Coniferophyta	Conifers	Seeds in cones; needlelike or scalelike leaves
Angiosperms	Flowering plants	Endosperm; carpels; gametophytes much reduced; seeds within fruit

(A) *Chara vulgaris* (stonewort)(B) *Coleochaete* sp.

28.2 The Closest Relatives of Land Plants (A) The land plants probably evolved from a common ancestor shared with the Charales, a green algal group. (B) This species of *Coleochaete* is a representative of the Coleochaetales, the sister group of Charales plus land plants.

- Similar peroxisome contents, mechanics of mitosis and cytokinesis, and chloroplast structure

Both of these algal groups, however, have some features that are similar to groups of land plants. The Charales, as represented by stoneworts of the genus *Chara* (Figure 28.2A), exhibit the branching growth form found among most land plants. But the flattened growth form of many members of Coleochaetales, as represented by the genus *Coleochaete* (Figure 28.2B), is more like the growth form of basal land plants such as liverworts.

28.1 RECAP

Land plants are photosynthetic organisms that develop from embryos protected by parental plant tissue.

- Explain the different possible uses of the term “plant.” See p. 589 and Figure 28.1
- What is the key difference between the vascular plants and the other three clades of land plants? See pp. 589–590 and Table 28.1
- What evidence supports the phylogenetic relationship between land plants and Charales? See p. 590

The green algal ancestors of the land plants lived at the margins of ponds or marshes, ringing them with a green mat. It was from such a marginal habitat, which was sometimes wet and sometimes dry, that early plants made the transition onto land.

28.2 How Did Plants Colonize and Thrive on Land?

Land plants, or their immediate ancestors in those ancient green mats, first appeared in the terrestrial environment between 400 and 500 million years ago. How did they survive in an environment that differed so dramatically from the aquatic environment of their ancestors? While the water essential for life is everywhere in the aquatic environment, water is difficult to obtain and retain in the terrestrial environment.

Adaptations to life on land distinguish land plants from green algae

No longer bathed in fluid, organisms on land faced potentially lethal desiccation (drying). Large terrestrial organisms had to develop ways to transport water to body parts distant from the source. And whereas water provides aquatic organisms with support against gravity, a plant living on land must either have some other support system or sprawl unsupported on the ground. A land plant must also use different mechanisms for dispersing its gametes and progeny than its aquatic relatives, which can simply release them into the water. Survival on land required numerous adaptations. The first colonists—the *nonvascular land plants*—met at least some of these challenges.

Most of the characteristics that distinguish land plants from green algae are evolutionary adaptations to life on land:

- The *cuticle*, a waxy covering that retards water loss
- *Stomata*, small closable openings in leaves and stems that are used to regulate gas exchange (stomata are not present in liverworts)
- *Gametangia*, multicellular organs that enclose plant gametes and prevent them from drying out
- *Embryos*, young plants contained within a protective structure
- Certain *pigments* that afford protection against the mutagenic ultraviolet radiation that bathes the terrestrial environment
- Thick *spore walls* containing a polymer (called sporopollenin) that protects the spores from desiccation and resists decay
- A *mutually beneficial association with a fungus* that promotes nutrient uptake from the soil

The **cuticle** may be the most important—and earliest—of these features. Composed of several unique waxy lipids (see Section 3.4) that coat the leaves and stems of land plants, the cuticle has several functions, the most obvious and important of which is to keep water from evaporating from the plant body.

As ancient plants colonized land, they modified the terrestrial environment by contributing to the formation of soil. Acid secreted by plants helps break down rock, and the organic compounds produced by the breakdown of dead plants contribute to soil structure. Such effects are repeated today as plants grow in new areas.

Nonvascular land plants usually live where water is readily available

Living species of liverworts, mosses, and hornworts are thought to be similar in many ways to the earliest land plants. Most of these plants grow in dense mats, usually in moist habitats. Even the largest of these species are only about half a meter tall, and most are only a few centimeters tall or long. Why have they not evolved to be taller? The probable answer is that they lack an efficient vascular system for conducting water and minerals from the soil to distant parts of the plant body.

The nonvascular land plants lack the leaves, stems, and roots that characterize the vascular plants, although they have structures analogous to each. Their growth pattern allows water to move through the mats of plants by capillary action. They have leaflike structures that readily catch and hold any water that splashes onto them. They are small enough that minerals can be distributed throughout their bodies by diffusion. As in all land plants, layers of maternal tissue protect their embryos from desiccation. Nonvascular land plants also have a cuticle, although it is often very thin (or even absent in some species) and thus is not highly effective in retarding water loss.

Most nonvascular land plants live on the soil or on vascular plants, but some grow on bare rock, dead and fallen tree trunks, and even on buildings. The ability to grow on such marginal surfaces results from a mutualistic association with the glomeromycetes, a clade of fungi. The earliest association of land plants and fungi dates back at least 460 million years. This mutualism probably facilitated the absorption of water and minerals, especially phosphorus, from the first soils.

Nonvascular land plants are widely distributed over six continents and even exist (albeit very locally) on the coast of the seventh, Antarctica. They are well adapted to their environments. Most are terrestrial. Although a few species live in fresh water, these aquatic forms are descended from terrestrial ones. None live in the oceans.

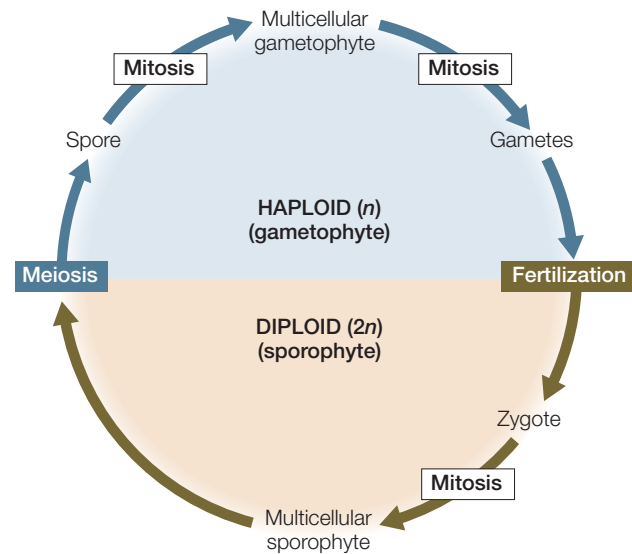

Land plants and green algae differ not just in structure but also in their life cycles. Differences in the life cycles of land plants and those of their ancestors are partially a function of the relative dependence of these respective plant groups on a water supply for reproduction.

Life cycles of land plants feature alternation of generations

A universal feature of the life cycles of land plants is alternation of generations (Figure 28.3). Recall from Section 27.4 the two hallmarks of alternation of generations:

- The life cycle includes both a multicellular diploid stage and a multicellular haploid stage.
- Gametes are produced by mitosis, not by meiosis. Meiosis produces spores that develop into multicellular haploid organisms.

If we begin looking at the land plant life cycle at the single-cell stage—the diploid zygote—then the first phase of the cycle is the formation, by mitosis and cytokinesis, of a multicellular em-

28.3 Alternation of Generations in Plants A multicellular diploid sporophyte generation produces spores by meiosis and alternates with a multicellular haploid gametophyte generation that produces gametes by mitosis.

bryo, which eventually grows into a mature diploid plant. This multicellular diploid plant is the **sporophyte** (“spore plant”).

Cells contained within **sporangia** (singular *sporangium*) of the sporophyte undergo meiosis to produce haploid, unicellular spores. By mitosis and cytokinesis, a spore forms a haploid plant. This multicellular haploid plant, called the **gametophyte** (“gamete plant”), produces haploid gametes by mitosis. The fusion of two gametes (*syngamy*, or *fertilization*) forms a single diploid cell—the zygote—and the cycle is repeated (Figure 28.4).

The *sporophyte generation* extends from the zygote through the adult multicellular diploid plant and sporangium formation; the *gametophyte generation* extends from the spore through the adult multicellular haploid plant to the gametes. The transitions between the generations are accomplished by fertilization and meiosis. In all land plants, the sporophyte and gametophyte differ genetically: the sporophyte has diploid cells, and the gametophyte has haploid cells.

There is a trend toward reduction of the gametophyte generation in plant evolution. In the nonvascular land plants, the gametophyte is larger, longer-lived, and more self-sufficient than the sporophyte. In those groups that appeared later in plant evolution, however, the sporophyte generation is the larger, longer-lived, and more self-sufficient one. In the seed plants, this evolutionary trend has led to a condition in which water is not required for the sperm to reach the egg.

The sporophytes of nonvascular land plants are dependent on gametophytes

In nonvascular land plants, the conspicuous green structure visible to the naked eye is the gametophyte (see Figure 28.4). This is in contrast to vascular plants, such as ferns and seed plants, in which the familiar forms are sporophytes. The gametophyte of liverworts, hornworts, and mosses is photosynthetic and

28.4 A Moss Life Cycle The life cycles of nonvascular land plants, exemplified here by that of a moss, are dependent on an external source of liquid water for their fertilization. The visible green structure of such plants is the gametophyte.

GO TO Animated Tutorial 28.1 • Life Cycle of a Moss

therefore nutritionally independent; the sporophyte may or may not be photosynthetic, but it is always nutritionally dependent on the gametophyte and remains permanently attached to it.

In nonvascular land plants, a sporophyte produces unicellular haploid spores as products of meiosis within a sporangium. A spore germinates, giving rise to a multicellular haploid gametophyte whose cells contain chloroplasts and are thus photosynthetic. Eventually gametes form within specialized sex organs, the **gametangia**. The **archegonium** is a multicellular, flask-shaped female sex organ with a long neck and a swollen base, which produces a single egg. The **antheridium** is a male sex organ in which sperm, each bearing two flagella, are produced in large numbers (see the insets in Figure 28.4). Both archegonia and antheridia are produced on the same individ-

ual, so each individual can have both male and female reproductive structures. Fertilization is often between adjacent individuals, however, which helps maintain genetic diversity in the population.

Once released from the antheridium, the sperm must swim or be splashed by raindrops to a nearby archegonium on the same or a neighboring plant—a constraint that reflects the aquatic origins of the nonvascular land plants' ancestors. The sperm are aided in this task by chemical attractants released by the egg or the archegonium. Before sperm can enter the archegonium, cer-

tain cells in the neck of the archegonium must break down, leaving a water-filled canal through which the sperm swim to complete their journey. Note that *all of these events require liquid water*.

On arrival at the egg, the nucleus of a sperm fuses with the egg nucleus to form a diploid zygote. Mitotic divisions of the zygote produce a multicellular, diploid sporophyte embryo. The base of the archegonium grows and surrounds the embryo, which protects the embryo during its early development. Eventually, the developing sporophyte elongates sufficiently to break out of the archegonium, but it remains connected to the gametophyte by a “foot” that is embedded in the parent tissue and absorbs water and nutrients from it. The sporophyte then produces a sporangium, within which meiotic divisions produce spores and thus the next gametophyte generation.

28.2 RECAP

Nonvascular land plants were the first plants to inhabit a terrestrial environment. The transition to land required numerous evolutionary developments, including the cuticle, gametangia, and protected embryos.

- Describe several adaptations of plants to the terrestrial environment. **See p. 591**
- Explain what is meant by alternation of generations. **See p. 592 and Figure 28.3**
- Why do nonvascular land plants require liquid water for fertilization? **See pp. 592–594**
- In the nonvascular land plants, how is the sporophyte dependent on the gametophyte? **See pp. 593–594**

Further adaptations to the terrestrial environment appeared as plants continued to evolve. One of the most important of these later adaptations was the appearance of vascular tissues.

28.3 What Features Distinguish the Vascular Plants?

The first land plants were nonvascular, lacking both water-conducting and food-conducting tissues. These plants did not leave a very complete fossil record, however, because most nonvascular plant species readily decompose, leaving little or nothing to fossilize.

That the nonvascular land plants evolved tens of millions of years before the earliest vascular plants is supported by extensive phylogenetic and molecular-clock analyses of DNA sequences. The first plants possessing vascular tissue (characterized by fluid-conducting tracheid cells) arose much later (**Figure 28.5**).

Vascular tissues transport water and dissolved materials

Vascular plants differ from the other land plants in crucial ways, one of which is the possession of a well-developed **vascular sys-**

tem consisting of tissues specialized for the transport of materials from one part of the plant to another. One type of vascular tissue, the **xylem**, conducts water and minerals from the soil to aerial parts of the plant. Because some of its cell walls contain a stiffening substance called *lignin*, xylem also provides support against gravity in the terrestrial environment. The other type of vascular tissue, the **phloem**, conducts the products of photosynthesis from sites where they are produced or released to sites where they are used or stored. (Xylem and phloem are further discussed in Chapters 34 and 35.)

Familiar vascular plants include the club mosses, ferns, conifers, and angiosperms (flowering plants). Although they are an extraordinarily large and diverse group, the vascular plants can be said to have been launched by a single evolutionary event. Sometime during the Paleozoic era, probably in the mid-Silurian (430 Mya), the sporophyte generation of a now long-extinct plant produced a new cell type, the tracheid. The tracheid is the principal water-conducting element of the xylem in all vascular plants except the angiosperms, and even in the angiosperms, tracheids persist along with a more specialized and efficient system of vessels and fibers that are derived from them.

The evolution of tracheid cells had two important consequences. First, these cells provided a pathway for transport of water and mineral nutrients from a source of supply to regions of need in the plant body. Second, the stiff cell walls of tracheids provided something almost completely lacking among nonvascular plants: rigid structural support. Support is important in a terrestrial environment because it allows plants to grow upward as they compete for sunlight to power photosynthesis. A taller plant can receive direct sunlight and photosynthesize more readily than a shorter plant, whose leaves may be shaded by the taller one. Increased height also improves the dispersal of spores. Thus tracheids set the stage for the complete and permanent invasion of land by plants.

The vascular plants featured another evolutionary novelty: a branching, independent sporophyte. A branching sporophyte can produce more spores than an unbranched body, and it can develop in complex ways. The sporophyte of a vascular plant is nutritionally independent of the gametophyte at maturity. Among the vascular plants, the sporophyte is the large and obvious plant that one normally pays attention to in nature. In contrast, the sporophyte of nonvascular land plants is attached to, dependent on, and usually much smaller than the gametophyte.

The present-day evolutionary descendants of the early vascular plants include the lycophytes, monilophytes, and seed plants (see Figure 28.5; the vascular plant groups are bracketed on the right). Two types of life cycles are seen in the vascular plants: one that involves seeds and another that does not. As we discuss in greater detail in the next chapter, a **seed** consists of a plant embryo, together with a food source, surrounded by a protective coat. The life cycles of the club mosses, ferns, whisk ferns, and horsetails do not involve seeds. We will describe these seedless vascular plant groups in detail after taking a closer look at vascular plant evolution. The major groups of seed plants are described in Chapter 29.

28.5 The Evolution of Plants Three key characteristics that emerged during plant evolution—protected embryos, vascular tissues, and seeds—are adaptations to life in a terrestrial environment.

Vascular plants have been evolving for almost half a billion years

The evolution of an effective cuticle and protective layers for the gametangia (archegonia and antheridia) helped make the first vascular plants successful, as did the initial absence of herbivores (plant-eating animals) on land. By the late Silurian period (about 425 Mya), vascular plants were being preserved as fossils that we can study today. During the Silurian, the largest vascular plants were only a few centimeters tall, yet fossils uncovered in Wales in 2004 give clear evidence for the earliest known wildfire, which burned vigorously even in the Silurian atmosphere, which had 14 percent less oxygen than today's atmosphere (see Figure 25.6). The small plants must have been abundant to sustain fire in such an atmosphere. Their proliferation made the terrestrial environment more hospitable to animals. Amphibians and insects arrived on land soon after land plants became established.

Trees of various kinds appeared in the Devonian period and dominated the landscape of the Carboniferous period (359–297 Mya). Forests of lycophytes (club mosses) up to 40 meters tall, along with horsetails and tree ferns, flourished in the tropical swamps of what would become

North America and Europe (Figure 28.6). Plant parts from those forests sank in the swamps and were gradually covered by sediment. Over millions of years, as the buried plant material was subjected to intense pressure and elevated temperatures, it was

28.6 Reconstruction of an Ancient Forest This Carboniferous forest once thrived in what is now Michigan. The “trees” to the left and in the background are lycophytes of the genus *Lepidodendron*; abundant ferns are visible to the right. The plant in the foreground is a relative of the modern horsetails.

transformed into coal. Today that coal provides over half of our electricity (and contributes to air pollution and global warming). The world's coal deposits, although huge, are not infinite, and they cannot be renewed because the conditions that created coal no longer exist.

In the subsequent Permian period, the continents came together to form a single gigantic land mass called Pangaea. The continental interior became warmer and drier, but late in the period glaciation was extensive. The 200-million-year reign of the lycophyte–fern forests came to an end as they were replaced by forests of seed plants (gymnosperms), which were prevalent until a different group of seed plants (angiosperms) overtook the landscape about 65 million years ago.

The earliest vascular plants lacked roots and leaves

The earliest known vascular plants belonged to the now-extinct group called **rhyniophytes**. The rhyniophytes were one of a very few types of vascular plants in the Silurian period. The landscape at that time probably consisted of bare ground, with stands of rhyniophytes in low-lying moist areas. Early versions of the structural features of all the other vascular plant groups appeared in the rhyniophytes of that time. These shared features strengthen the case for the origin of all vascular plants from a common nonvascular plant ancestor.

The beginning of this chapter described the discovery of some important fossils in Devonian rocks near Rhynie, Scotland. The preservation of these plants was remarkable, considering that the rocks were more than 395 million years old. These fossil plants had a simple vascular system of phloem and xylem, but not all had the tracheids characteristic of today's vascular plants.

These plants also lacked roots. Like most modern ferns and lycophytes, they were apparently anchored in the soil by horizontal portions of stem, called **rhizomes**, which bore water-absorbing unicellular filaments called **rhizoids**. These rhizomes also bore aerial branches, and sporangia—homologous to the sporangia of mosses—were found at the tips of those branches. Their branching pattern was *dichotomous*; that is, the apex (tip) of the shoot divided to produce two equivalent new branches, each pair diverging at approximately the same angle from the original stem (**Figure 28.7**). Scattered fragments of such plants had been found earlier, but never in such profusion or as well preserved as those discovered by Kidston and Lang.

Although they were apparently ancestral to the other vascular plant groups, the rhyniophytes themselves are long gone. None of their fossils appear anywhere after the Devonian period.

The vascular plants branched out

The **lycophytes** (club mosses and their relatives) first appeared in the Silurian period. The **monilophytes** (ferns and fern allies) appeared during the Devonian period. These two groups, both still with us today, arose from rhyniophyte-like ancestors. Important new features of the vascular plants are found in these groups, such as true roots, true leaves, and a differentiation between two types of spores. The monilophytes and seed plants constitute a clade called the **euphyllophytes** (*eu*, “true”; *phyllos*, “leaf”).

28.7 An Ancient Vascular Plant

Relative The extinct rhyniophyte *Aglaophyton major* lacked roots and leaves. It had a central column of xylem running through its stems, but no true tracheid cells. The rhizome is a horizontal underground stem, not a root. The dichotomously branching aerial stems were less than 50 centimeters tall. Some stems were topped by sporangia. (See the chapter-opening figure for an artist's reconstruction of rhyniophytes.)

An important synapomorphy of the euphyllophytes is **overtopping**, a growth pattern in which one branch differentiates from and grows beyond the others. Overtopping growth would have given these plants an advantage in the competition for light for photosynthesis, enabling them to shade their dichotomously growing competitors. And, as we'll see, the overtopping growth of the euphyllophytes enabled a new type of leaf to evolve.

Roots may have evolved from branches

The rhyniophytes had only rhizoids arising from a rhizome with which to gather water and minerals. How, then, did subsequent groups of vascular plants come to have the complex roots we see today?

It is probable that roots had their evolutionary origins as a branch, either of a rhizome or of the aboveground portion of a stem. That branch presumably penetrated the soil and branched further. The underground portion could anchor the plant firmly, and even in this primitive condition, it could absorb water and minerals. The discovery of several fossil plants from the Devonian period, all having horizontal stems (rhizomes) with both underground and aerial branches, supports this hypothesis.

Underground and aboveground branches, growing in sharply different environments, were subjected to very different selection pressures during the succeeding millions of years. Thus the two parts of the plant body—the aboveground shoot system and the underground root system—diverged in structure and evolved distinct internal and external anatomies. In spite of these differences, scientists believe that the root and shoot systems of vascular plants are homologous—that they were once part of the same organ.

28.8 The Evolution of Leaves

(A) Microphylls are thought to have evolved from sterile sporangia. (B) The megaphylls of monilophytes and seed plants may have arisen as photosynthetic tissue developed between branch pairs that were “left behind” as dominant branches overtopped them.

Monilophytes and seed plants have true leaves

Thus far we have used the term “leaf” rather loosely. In the strictest sense, a *leaf* is a flattened photosynthetic structure emerging laterally from a stem or branch and possessing true vascular tissue. Using this precise definition as we take a closer look at true leaves in the vascular plants, we see that there are two different types of leaves, very likely of different evolutionary origins.

The first leaf type, the **microphyll**, is usually small and only rarely has more than a single vascular strand, at least in existing plants. Lycophytes, of which only a few genera survive, have such simple leaves. Some biologists believe that microphylls had their evolutionary origins as sterile sporangia (**Figure 28.8A**). The principal characteristic of this type of leaf is a vascular strand that departs from the vascular system of the stem in such a way that the structure of the stem’s vascular system is scarcely disturbed. This was true even in the lycophyte trees of the Carboniferous period, many of which had leaves many centimeters long.

The other leaf type is found in monilophytes and seed plants. This larger, more complex leaf is called a **megaphyll**. The megaphyll is thought to have arisen from the flattening of a dichotomously branching stem system with overtopping growth. This change was followed by the development of photosynthetic tissue between the members of overtopped groups of branches (**Figure 28.8B**), which had the advantage of increasing the photosynthetic surface area of those branches.

The first megaphylls, which were very small, appeared in the Devonian period. We might expect that evolution should have led swiftly to the appearance of more and larger megaphylls because of their greater photosynthetic capacity. However, it took some 50 million years, until the Carboniferous period, for large megaphylls to become common. Why should this have been so, especially given that other advances in plant structure were taking place during that time?

According to one theory, the high concentration of CO₂ in the atmosphere during the Devonian period reduced selection for the tiny pores, called **stomata**, that allow a leaf to take up CO₂ for use in photosynthesis. With more CO₂ available, fewer stomata were needed. Today, when stomata are open, they allow water vapor to escape the leaf and CO₂ to enter. In the Devonian, larger leaves would have absorbed heat from sunlight, but they would have been unable to lose heat fast enough by evaporation of water through their limited number of stomata. The resulting overheating would have been lethal. Recent research has supported this hypothesis, indicating that larger megaphylls evolved only as CO₂ concentrations dropped over millions of years (**Figure 28.9**).

Heterospory appeared among the vascular plants

In the lineages of present-day vascular plants that are most similar to their ancestors, the gametophyte and the sporophyte are

INVESTIGATING LIFE

28.9 CO₂ Levels and the Evolution of Megaphylls

High concentrations of atmospheric CO₂ may have acted as a constraint on the evolution of leaf size. C. P. Osborne and colleagues compared the leaf sizes of fossil plants against estimates of CO₂ concentrations in the atmosphere at the time the plants were alive.

HYPOTHESIS High atmospheric CO₂ concentrations during the Devonian constrained the evolution of leaf size, with selection pressure maintaining relatively small leaves.

- METHOD**
1. Analyze 300 plant fossils from the Devonian and Carboniferous periods and calculate the sizes of their leaves.
 2. Compare the pattern of change in leaf size with that of the estimated change in atmospheric CO₂ concentrations over the same time frame.

RESULTS

CONCLUSION Leaf size increased as levels of CO₂ in the atmosphere decreased.

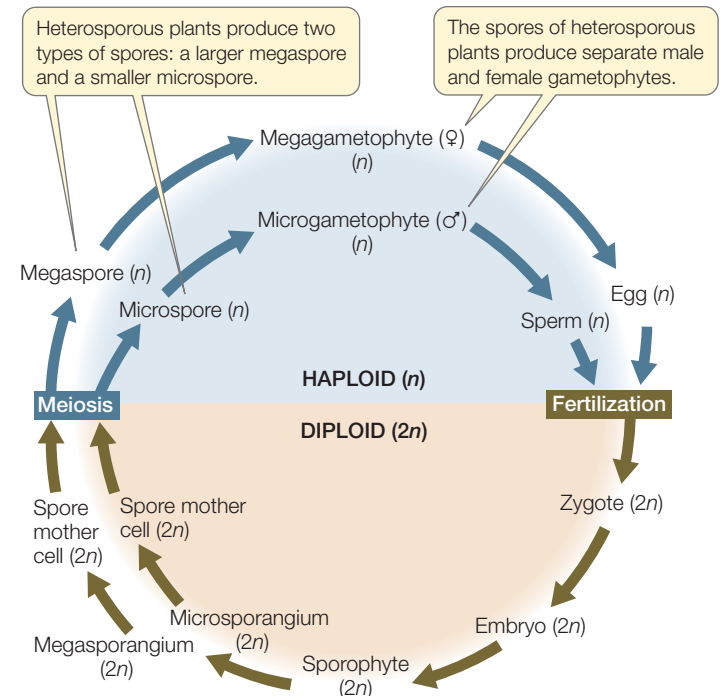

FURTHER INVESTIGATION: What sort of experiment would you do to determine the effects of stomata on overheating of fern leaves today?

(A) Homospory

(B) Heterospory

28.10 Homospory and Heterospory (A) Homosporous plants bear a single type of spore. Each gametophyte has two types of sex organs, antheridia (male) and archegonia (female). (B) Heterosporous plants bear two types of spores that develop into distinctly male and female gametophytes.

yourBioPortal.com

GO TO Web Activities 28.1 and 28.2 • Homospory and Heterospory

independent, and both are usually photosynthetic. Spores produced by the sporophyte are of a single type and develop into a single type of gametophyte that bears both female and male reproductive organs. The female organ is a multicellular archegonium.

nium containing a single egg. The male organ is an antheridium, producing many sperm. Such plants, which bear a single type of spore, are said to be **homosporous** (Figure 28.10A).

A system with two distinct types of spores evolved somewhat later. Plants of this type are said to be **heterosporous** (Figure 28.10B). In heterospory, one type of spore—the **megaspore**—develops into a specifically female gametophyte (a *megagametophyte*) that produces only eggs. The other type, the **microspore**, is smaller and develops into a male gametophyte (a *microgametophyte*) that produces only sperm. The sporophyte produces megaspores in small numbers in *megasporangia*, and microspores in large numbers in *microsporangia*. Heterospory affects not only the spores and the gametophyte but also the sporophyte plant itself, which must develop two types of sporangia.

The most ancient vascular plants were all homosporous, but heterospory evidently evolved several times in the early descendants of the rhyniophytes. The fact that heterospory evolved repeatedly suggests that it affords selective advantages. Subsequent evolution in the land plants featured ever greater specialization of the heterosporous condition.

28.3 RECAP

A new type of cell, the tracheid, marked the origin of the vascular plants. Later evolutionary events included the appearance of roots and leaves.

- How do the vascular tissues xylem and phloem serve the vascular plants? See p. 594
- Describe the difference between the two leaf types (microphylls and megaphylls). See p. 597 and Figure 28.8
- Explain the concept of heterospory. See p. 599 and Figure 28.10

The liverworts, hornworts, mosses, lycophytes, and monilophytes have come a long way from the aquatic environment to meet the challenges of life on dry land. Let's look at the diversity within these groups.

28.4 What Are the Major Clades of Seedless Plants?

Three principal clades of living land plants lack tracheids; these nonvascular land plants are the liverworts, hornworts, and mosses. The structure and growth pattern of the sporophyte differ among the three groups. There are four principal clades of seedless vascular plants—lycophytes (club mosses and their relatives), horsetails, whisk ferns, and leptosporangiate ferns. Most plants known as “ferns” are leptosporangiate ferns, although there are also small groups called “ferns” that are more closely related to horsetails and whisk ferns.

Liverworts may be the most ancient surviving plant clade

There are about 9,000 species of **liverworts** (Hepatophyta, “liver-plants”). Most liverworts have leafy gametophytes (Figure 28.11A). Some have *thalloid* gametophytes—green, leaflike layers that lie flat on the ground (Figure 28.11B). The simplest liverwort gametophytes, however, are flat plates of cells, a centimeter or so long, that produce antheridia or archegonia on their upper surfaces and rhizoids on their lower surfaces.

Liverwort sporophytes are shorter than those of mosses and hornworts, rarely exceeding a few millimeters. The liverwort sporophyte has a stalk that connects sporangium and foot. In most species, the stalk elongates by expansion of cells throughout its length. This elongation raises the sporangium above ground level, allowing the spores to be dispersed more widely. The sporangia of liverworts are simple: a globular sporangium wall surrounds a mass of spores. In some species of liverworts, spores are not released by the sporophyte until the surrounding sporangium wall rots. In other liverworts, however, the

28.11 Liverwort Structures Liverworts display various characteristic structures. (A) The gametophyte of a leafy liverwort. (B) Gametophytes of a thalloid liverwort. (C) This thalloid liverwort bears archegonia in the structures that look like bunches of bananas. It also bears cups containing gemmae.

(C) *Marchantia* sp.

These cups contain gemmae—small, lens-shaped outgrowths of the plant body, each capable of developing into a new plant.

The banana-like structures bear archegonia.

spores are thrown from the sporangium by structures that shorten and compress a “spring” as they dry out. When the stress becomes sufficient, the compressed spring snaps back to its resting position, throwing spores in all directions.

Among the most familiar thalloid liverworts are species of the genus *Marchantia*. *Marchantia* is easily recognized by the characteristic structures on which its male and female gametophytes bear their antheridia and archegonia (Figure 28.11C). Like most liverworts, *Marchantia* also reproduces asexually by simple fragmentation of the gametophyte. *Marchantia* and some other liverworts and mosses also reproduce asexually by means of *gemmae* (singular *gemma*), which are lens-shaped clumps of cells. In a few liverworts, the gemmae are held in structures called *gemmae cups*, which promote dispersal of the gemmae by raindrops (see Figure 28.11C).

Water- and sugar-transport mechanisms first emerged in the mosses

The most familiar of the nonvascular land plants are the **mosses (Bryophyta)**. These hardy little plants, of which there are about 15,000 species, are found in almost every terrestrial environment. They are often found on damp, cool ground, where they form thick mats (Figure 28.12). The mosses are the sister lineage to the vascular plants plus the hornworts (see Figure 28.5).

The mosses, along with the hornworts and vascular plants, share an advance over the liverwort clade in their adaptation to life on land: they have stomata, which are important for both water and gas exchange. Stomata are a shared derived trait of mosses and all other land plants except liverworts.

In mosses, the gametophyte begins its development following spore germination as a branched, filamentous structure called a *protonema* (see Figure 28.4). Although the protonema looks a bit like a filamentous green alga, this structure is unique to the mosses. Some of the filaments contain chloroplasts and are photosynthetic; others, called rhizoids, are nonphotosynthetic and anchor the protonema to the substratum. After a period of linear growth, cells close to the tips of the photosynthetic filaments divide rapidly in three dimensions to form *buds*. The buds eventually develop a distinct tip, or apex, and produce the familiar leafy moss shoot with leaflike structures arranged spirally. These leafy shoots produce antheridia or archegonia (see Figure 28.4).

Some moss gametophytes are so large they could not transport enough water solely by diffusion. Gametophytes and sporophytes of many mosses contain a type of cell called a *hydroid*, which dies and leaves a tiny channel through which water can travel. The hydroid is functionally similar to the tracheid, the characteristic water-conducting cell of the vascular plants, but it lacks lignin and the cell-wall structure found in tracheids. The possession of hydroids and of a limited system for transport of sugar by some mosses (via cells called *leptoids*) shows that the term “nonvascular plant” is somewhat misleading when applied to mosses. Despite their simple system of internal transport, however, the mosses are not vascular plants because they lack true xylem and phloem.

(B) *Polytrichum* sp.

28.12 Mosses Grow in Dense Mats (A) Dense layers of moss carpet a field of solidified volcanic lava in Iceland. (B) A close-up view of moss growing on a forest floor in Michigan.

Mosses of the genus *Sphagnum* (Figure 28.13A) often grow in cool, swampy places, where the plants begin to decompose in the water after they die. Rapidly growing upper layers of moss compress the deeper-lying, decomposing layers. Partially decomposed plant matter is called *peat*. In some parts of the world, people derive the majority of their fuel from peat bogs (Figure 28.13B). *Sphagnum*-dominated peatlands cover an area approximately half the size of the United States—more than 1 percent of Earth’s surface. Millions of years ago, continued compression of peat composed primarily of other seedless plants gave rise to coal.

Hornworts have distinctive chloroplasts and sporophytes without stalks

The approximately 100 species of **hornworts** comprise the group Anthocero-phyta (“horn plants”), so named because their sporophytes look like little horns (Figure 28.14). Hornworts appear at first glance to be liverworts with very simple gametophytes. Their gametophytes are flat plates of cells a few cells thick.

Hornworts have two characteristics that distinguish them from liverworts and mosses. First, the cells of hornworts each

*Anthoceros* sp.

28.14 A Hornwort The sporophytes of many hornworts resemble little horns.

contain a single large, platelike chloroplast, whereas the cells of the other two groups contain numerous small, lens-shaped chloroplasts. Second, of the sporophytes in all three groups, those of the hornworts come closest to being capable of growth without a set limit. Liverwort and moss sporophytes have a stalk that stops growing as the sporangium matures, so elongation of the sporophyte is strictly limited. The hornwort sporophyte, however, has no stalk. Instead, a basal region of the sporangium remains capable of indefinite cell division, continuously producing new spore-bearing tissue above. The sporophytes of some hornworts growing in mild and continuously moist conditions can become as tall as 20 centimeters. Eventually, however, the sporophyte's growth is limited by the lack of a transport system.

Hornworts have evolved a symbiotic relationship that promotes their growth by providing them with greater access to nitrogen, which is often a limiting resource. Hornworts have internal cavities filled with mucilage; these cavities are often populated by cyanobacteria that convert atmospheric nitrogen gas into a form usable by their host plant.

We present the hornworts here as sister to the vascular plants, but this is only one possible interpretation of the current data. The hornworts and vascular plants are united by DNA sequence analyses, and they also share a persistently green sporophyte. The exact evolutionary position of the hornworts is still unclear, and in some morphological analyses they are placed as the sister group to the mosses plus the vascular plants (the two groups that express apical cell division).

Some vascular plants have vascular tissue but not seeds

The earliest vascular plants did not have seeds, and several major clades of seedless vascular plants have survived to the present. These plants have a large, independent sporophyte and a small gametophyte that is independent of the sporophyte. The gametophytes of the surviving seedless vascular plants are rarely more than 2 centimeters long and are short-lived, whereas their sporophytes are often highly visible and long-lived; the sporophyte of a tree fern, for example, may be up to 20 meters tall and live for many years.

The most prominent resting stage in the life cycle of the seedless vascular plants is the single-celled spore. A spore may “rest” for some time before developing further. This feature makes the life cycle of seedless vascular plants similar to those of the fungi, green algae, and nonvascular land plants, but not, as we will see in the next chapter, to that of the seed plants. Like nonvascular land plants, seedless vascular plants must have an aqueous environment for at least one stage of their life cycle because fertilization is accomplished by flagellated, swimming sperm.

The leptosporangiate ferns are the most abundant and diverse group of seedless vascular plants today, but the club mosses and horsetails were once dominant elements of Earth's vegetation. A fourth group, the whisk ferns, contains only two genera. Let's look at the characteristics of these four groups and at some of the evolutionary advances that appeared in them.

The lycophytes are sister to the other vascular plants

The club mosses and their relatives, the spike mosses and quillworts, together called **lycophytes**, are the sister-group of the remaining vascular plants. There are relatively few surviving species of lycophytes—just over 1,200.

The lycophytes have roots that branch dichotomously. The arrangement of vascular tissue in their stems is simpler than in the other vascular plants. They bear only microphylls, and these simple leaves are arranged spirally on the stem. Growth in club mosses comes entirely from apical cell division, and branching in the stems is also dichotomous, by a division of the apical cluster of dividing cells.

The sporangia of many club mosses are aggregated in cone-like structures called *strobili* (singular *strobilus*; **Figure 28.15**). The strobilus of a club moss is a cluster of spore-bearing leaves inserted on an axis (linear supporting structure). Other club mosses lack strobili and bear their sporangia on (or adjacent to) the upper surfaces of leaves called *sporophylls*. This placement contrasts with the terminal sporangia of the rhyniophytes. There are both homosporous and heterosporous species of club mosses.

Although they are only a minor element of present-day vegetation, the lycophytes are one of two groups that appear to have been the dominant vegetation during the Carboniferous period. One type of coal (cannel coal) is formed almost entirely from fossilized spores of the tree lycophyte *Lepidodendron*—which gives us an idea of the abundance of this genus in the forests of that time (see Figure 28.6). Other major elements of Carboniferous vegetation included horsetails and ferns.

Horsetails, whisk ferns, and ferns constitute a clade

Once thought to be only distantly related, the horsetails, whisk ferns, and ferns form a clade, the monilophytes, or “ferns and fern allies.” Within that clade, the whisk ferns and the horsetails are both monophyletic; the ferns are not. However, most ferns do belong to a single clade, the *leptosporangiate ferns*. Other small groups that are commonly called ferns are actually more closely related to horsetails or whisk ferns. In the monilophytes—as in all seed plants—there is differentiation between the main stem and side branches. This pattern contrasts with the dichotomous branching characteristic of the lycophytes and rhyniophytes, in which each split gives rise to two branches of similar size (see Figure 28.7).

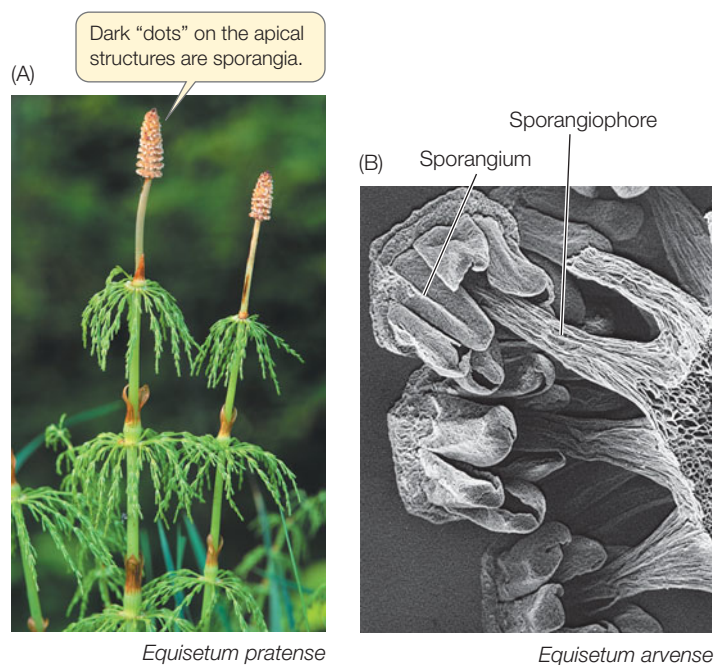

HORSETAILS Today there are only about 15 species of **horsetails**, all in the genus *Equisetum*. Horsetails have been sometimes called “scouring rushes” because rough silica deposits found in their cell walls made them useful for cleaning. They have true roots that branch irregularly. Horsetails have a large sporophyte and a small gametophyte, both independent.

Lycopodium obscurum

28.15 Club Mosses (A) A strobilus is visible at the tip of this club moss. Club mosses have microphylls arranged spirally on their stems. (B) A thin section through a strobilus of a club moss, showing microsporangia.

The small leaves of horsetails are reduced megaphylls and form in distinct whorls (circles) around the stem (**Figure 28.16**). Growth in horsetails originates to a large extent from discs of dividing cells just above each whorl of leaves, so each segment of the stem grows from its base. Such basal growth is uncommon in plants, although it is found in the grasses, a major group of flowering plants, as well as in the hornworts.

28.16 Horsetails (A) Horsetails have a distinctive growth pattern in which the stem grows in segments above each whorl of leaves. These are fertile shoots, with sporangia-bearing structures at the apex. (B) Scanning electron micrograph of horsetail sporangia.

*Psilotum flaccidum*

28.17 A Whisk Fern DNA sequence data reveals that *Psilotum*—once considered to be a surviving rhyniophyte—is in fact a much more recent genus that arose from a fernlike ancestor. Whisk ferns are now grouped with the monilophytes.

WHISK FERNS There once was some disagreement about whether the rhyniophytes are entirely extinct. The confusion arose because of the existence today of about 15 species in two genera of rootless, spore-bearing plants, *Psilotum* and *Tmesipteris*, collectively called the **whisk ferns**. *Psilotum* (**Figure 28.17**) has minute scales instead of true leaves, but plants of the genus *Tmesipteris* have flattened photosynthetic organs—reduced megaphylls—with well-developed vascular tissue. Are these two genera the living relics of the rhyniophytes, or do they have more recent origins?

The whisk ferns once were thought to be evolutionarily ancient descendants of anatomically simple ancestors. That hypothesis was weakened by an enormous hole in the fossil record between the rhyniophytes, which apparently became extinct more than 300 million years ago, and *Psilotum* and *Tmesipteris*, which are modern plants. DNA sequence data finally settled the question in favor of a more recent origin of the whisk ferns from fernlike ancestors. The whisk ferns are a clade of highly specialized plants that evolved fairly recently from anatomically more complex ancestors by loss or reduction of megaphylls and true roots. Whisk fern gametophytes live below the surface of the ground and lack chlorophyll. They depend on fungal partners for their nutrition.

LEPTOSPORANGIATE FERNS The first **leptosporangiate ferns** appeared during the Devonian period; today this group comprises more than 12,000 species. The sporangia of leptosporangiate ferns are borne on a stalk and have walls only one cell thick. The name “leptosporangiate” refers to these thin-walled sporangia (*lepton*, “thin”). Two other small groups that are also called ferns are actually more closely related to horsetails and whisk ferns, even though they are superficially similar to the leptosporangiate ferns.

The sporophytes of ferns, like those of the seed plants, have true roots, stems, and leaves. Ferns are characterized by large leaves with branching vascular strands (**Figure 28.18A**). During its development, the fern leaf unfurls from a tightly coiled “fiddlehead” (**Figure 28.18B**). Some fern leaves become climbing organs and may grow to be as long as 30 meters. A few species have small leaves as a result of evolutionary reduction, but even these small leaves have more than one vascular strand, and are thus megaphylls (**Figure 28.18C**).

28.18 Fern Leaves Take Many Forms (A) Tree ferns and crown ferns dominate this forest on Stewart Island, New Zealand. (B) The “fiddlehead” (developing leaf) of a common forest fern will unfurl and expand, giving rise to a complex adult leaf such as that of a crown fern. (C) The leaves of two species of water ferns.

THE FERN LIFE CYCLE In all ferns, *spore mother cells* inside the sporangia undergo meiosis to form haploid spores. Once shed, the spores may be blown great distances by the wind and eventually germinate to form independent gametophytes far from the parent sporophyte. A case in point is Old World climbing fern (*Lygodium microphyllum*), which is currently spreading disastrously through the Florida Everglades, choking off the growth of other plants. This rapid spread is testimony to the effectiveness of windborne spores. Another example is the remarkable diversity of ferns that have spread through the isolated Hawaiian Islands.

Fern gametophytes have the potential to produce both antheridia and archegonia, although not necessarily at the same time or on the same gametophyte. Sperm swim through water to archegonia—often to those on other gametophytes—where they unite with an egg. The resulting zygote develops into a new sporophyte embryo. The young sporophyte sprouts a root and can thus grow independently of the gametophyte. In the alternating generations of a fern, the gametophyte is small, del-

icate, and short-lived, but the sporophyte can be very large and can sometimes survive for hundreds of years (**Figure 28.19**).

Because they require liquid water for the transport of the male gametes to the female gametes (as do all other plant groups discussed in this chapter), most ferns inhabit shaded, moist woodlands and swamps. Tree ferns can reach heights of 20 meters. Tree ferns are not as rigid as woody plants, and they have poorly developed root systems. Thus they do not grow in sites exposed directly to strong winds, but rather in ravines or beneath trees in forests. The sporangia of ferns typically are found on the undersurfaces of the leaves, sometimes covering the entire undersurface and sometimes only at the edges. In most species, the sporangia are found in clusters called *sori* (singular *sorus*).

Most ferns are homosporous. However, two groups of aquatic ferns, the Marsileaceae and the Salviniaceae (see Figure 28.18C),

GO TO Web Activity 28.3 • The Fern Life Cycle

28.19 The Life Cycle of a Homosporous Fern The most conspicuous stage in the fern life cycle is the mature diploid sporophyte. The inset photograph shows sori on the underside of a fern leaf. Each sorus contains many spore-producing sporangia.

are derived from a common ancestor in which heterospory evolved. The megaspores and microspores of these plants (which germinate to produce female and male gametophytes, respectively) are produced in different sporangia (megasporangia and microsporangia), and the microspores are always much smaller and greater in number than the megaspores.

A few genera of ferns produce a tuberous, fleshy gametophyte instead of the characteristic flattened, photosynthetic structure produced by most ferns. These tuberous gametophytes depend on a mutualistic fungus for nutrition. In some genera, even the sporophyte embryo must become associated with the fungus before its development can proceed. Chapter 30 discusses many other important plant–fungus mutualisms.

The seedless vascular plants, and especially the ferns, were long considered an evolutionary cul-de-sac—that is, a group with great diversity in the fossil record but less diversity in the present. However, recent DNA-based research has suggested that the diversification of today’s ferns took place much more recently than previously thought. The expansion of seed plants and their dominance of forests actually predates the diversification of extant ferns, which presumably took advantage of the new environments created by those forests.

28.4 RECAP

Three clades of land plants lack true vascular systems (liverworts, mosses, and hornworts). The seedless vascular plants include the club mosses, horsetails, whisk ferns, and leptosporangiate ferns.

- Describe the different branching patterns of lycophytes and monilophytes. **See pp. 602–603**
- Why were whisk ferns once thought to be close relatives of the rhyniophytes? **See p. 603**
- Why do most ferns live in moist, shady areas? **See p. 604**

All of the groups described in this chapter—the nonvascular land plants and the seedless vascular plants—require water at a key stage in their life cycles, because their sperm can reach their eggs only by means of liquid water. In addition, the vascular plant groups we have discussed thus far all disperse by spores. The next chapter describes the *seed plants* that dominate Earth’s vegetation today, and in which the seed affords new sporophytes protection unavailable to the progeny of seedless plants.

CHAPTER SUMMARY

28.1 How Did the Land Plants Arise?

- **Land plants**, sometimes referred to as **embryophytes**, are photosynthetic eukaryotes that develop from embryos protected by parental tissue. **Review Figure 28.1**
- **Streptophytes** include the land plants and certain green algae. **Green plants** include the streptophytes and the remaining green algae.
- Land plants arose from an aquatic green algal ancestor related to today’s **Charales**.
- The **vascular plants** have well developed water-conducting tissues with cells including **tracheids**; the three major groups of **nonvascular land plants** do not. **Review Table 28.1**

28.2 How Did Plants Colonize and Thrive on Land?

- The acquisition of a **cuticle**, **stomata**, **gametangia**, a protected embryo, protective pigments, thick spore walls with a protective polymer, and a mutualistic association with a fungus are all adaptations to terrestrial life.
- All land plant life cycles feature alternation of generations, in which a multicellular diploid **sporophyte** alternates with a multicellular haploid **gametophyte**. **Review Figure 28.3**
- Spores form in **sporangia**; gametes form in gametangia. In seedless land plants, the female and male gametangia are, respectively, an **archegonium** and an **antheridium**.
- In liverworts, hornworts, and mosses, the sporophyte is smaller than the gametophyte and depends on it for water and nutrition. **Review Figure 28.4, ANIMATED TUTORIAL 28.1**

28.3 What Features Distinguish the Vascular Plants?

- A **vascular system** consisting of **xylem** and **phloem** conducts water, minerals, and products of photosynthesis through the bodies of vascular plants.

- Among living vascular plant groups, the **lycophytes** (club mosses and relatives) have only small, simple leaves (**microphylls**). Larger, more complex leaves (**megaphylls**) are found in **monilophytes** (horsetails, ferns, and allies) and seed plants. These latter two groups comprise the **euphyllophytes**. **Review Figure 28.5**
- In vascular plants, the sporophyte is larger than and independent of the gametophyte.
- The **rhyniophytes**, the earliest vascular plants, are known to us only in fossil form. They lacked roots and leaves but possessed **rhizomes** and **rhizoids**. **Review Figure 28.7**
- Roots may have evolved either from rhizomes or from branches. Microphylls probably evolved from sterile sporangia, and megaphylls may have resulted from the flattening and reduction of an **overtopping** branching stem system. **Review Figure 28.8**
- Many seedless vascular plants are **homosporous**, but **heterospory**—the production of distinct **megaspores** and **microspores**—evolved several times. Megaspores develop into megagametophytes; microspores develop into microgametophytes. **Review Figure 28.10, WEB ACTIVITIES 28.1 and 28.2**

28.4 What Are the Major Clades of Seedless Plants?

- The nonvascular land plant clades are the **liverworts**, the **mosses**, and the **hornworts**. The seedless vascular plant groups are the **lycophytes** (club mosses and their relatives) and the monilophytes (**horsetails**, **whisk ferns**, and **leptosporangiate ferns**). **Review Figure 28.5**
- Mosses, hornworts, and vascular plants all have surface pores (stomata) in their leaves.
- The gametophyte of ferns is small, delicate, and short-lived, whereas the sporophyte of ferns is typically much larger and longer lived. **Review Figure 28.19, WEB ACTIVITY 28.3**

SELF-QUIZ

- Land plants differ from photosynthetic protists in that only the plants
 - are photosynthetic.
 - are multicellular.
 - possess chloroplasts.
 - have multicellular embryos protected by the parent.
 - are eukaryotic.
- Which statement about alternation of generations in land plants is *not* true?
 - The gametophyte and sporophyte differ in appearance.
 - Meiosis occurs in sporangia.
 - Gametes are always produced by meiosis.
 - The zygote is the first cell of the sporophyte generation.
 - The gametophyte and sporophyte differ in chromosome number.
- Which statement is *not* evidence for the origin of land plants from the green algae?
 - Some green algae have multicellular sporophytes and multicellular gametophytes.
 - Both plants and green algae have cellulose in their cell walls.
 - The two groups have the same photosynthetic pigments.
 - Both plants and green algae produce starch as their principal storage carbohydrate.
 - All green algae produce large, stationary eggs.
- Liverworts, mosses, and hornworts
 - lack a sporophyte generation.
 - grow in dense masses, allowing capillary movement of water.
 - possess xylem and phloem.
 - possess true leaves.
 - possess true roots.
- Which statement is *not* true of the mosses?
 - The sporophyte is dependent on the gametophyte.
 - Sperm are produced in archegonia.
 - There are more species of mosses than of liverworts and hornworts combined.
 - The sporophyte grows by apical cell division.
 - Mosses are probably sister to the vascular plants plus hornworts.
- Megaphylls
 - probably evolved only once.
 - are found in all the vascular plant groups.
 - probably arose from sterile sporangia.
 - are the characteristic leaves of club mosses.
 - are the characteristic leaves of horsetails and ferns.
- The rhyniophytes
 - lacked tracheids.
 - possessed true roots.
 - possessed sporangia at the tips of stems.
 - possessed leaves.
 - lacked branching stems.
- Club mosses and horsetails
 - have larger gametophytes than sporophytes.
 - possess small leaves.
 - are represented today primarily by trees.
 - have never been a dominant part of the vegetation.
 - produce fruits.
- Which statement about ferns is *not* true?
 - The sporophyte is larger than the gametophyte.
 - Most are heterosporous.
 - The young sporophyte can grow independently of the gametophyte.
 - The leaf is a megaphyll.
 - The gametophytes produce archegonia and antheridia.
- The leptosporangiate ferns
 - are not a monophyletic group.
 - have sporangia with walls more than one cell thick.
 - constitute a minority of all ferns.
 - are monilophytes.
 - produce seeds.

FOR DISCUSSION

- Mosses and ferns share a common trait that makes water droplets a necessity for sexual reproduction. What is that trait?
- Are the mosses well adapted to terrestrial life? Explain your answer.
- Ferns display a dominant sporophyte generation (with large leaves). Describe the major advance in anatomy that enables most ferns to grow much larger than mosses.
- What features distinguish club mosses from horsetails? What features distinguish these groups from rhyniophytes? From ferns?
- Why did some botanists once believe that the whisk ferns should be classified together with the rhyniophytes?
- Contrast microphylls with megaphylls in terms of structure, evolutionary origin, and occurrence among plants.

ADDITIONAL INVESTIGATION

The findings of Osborne and co-workers on the evolution of megaphylls (see Figure 28.9) support the concept that large megaphylls became common only after the atmospheric CO₂ level had dropped, so that more stomata were produced, allow-

ing water to evaporate and cool larger leaves. How might you extend that work to confirm the involvement of temperature as a factor limiting leaf size?

A seed from biblical times germinates after 2,000 years

The fruit of the Judean date palm was once much prized. The prophet Muhammad admired its nutritional and medicinal properties; in the Koran, it is associated with heaven and described as a symbol of goodness. The Judean date was the source of the “honey” in the biblical “land of milk and honey.” Today that ancient strain of date is extinct. Or is it?

Around two thousand years ago, at the beginning of the Common Era, a seed developed in a fruit on a Judean date palm. The fruit that contained that seed found its way to a

storeroom in the fortress Masada in Judea. In 73 C.E. almost a thousand Jewish Zealots involved in a religious revolt against Rome fled to this refuge with their families. Roman legions followed, and the ensuing siege lasted more than two years. In the end, rather than be killed or enslaved by the Roman soldiers, the Zealots are said to have killed themselves and their families in a dramatic mass suicide.

Twenty centuries later, archeologists working in Masada discovered the date seed that was long ago stored in the Masada fortress and confirmed its age. The previous record for seed survival and germination was 1,300 years, held by lotus seeds that recently germinated under the care of scientists in China. But botanist Elaine Solowey succeeded in making the 2,000-year-old date seed germinate! The resulting seedling (nicknamed Methuselah) has continued to thrive and grow. Perhaps the ancient Egyptians knew what they were doing when they placed date seeds in the tombs of the Pharaohs as symbols of immortality.

Seeds are important structures for the survival of plants. They protect the plant embryo within from environmental extremes through what may be a long and stressful resting period—in the case of the Judean date, many centuries in a harsh desert. Seeds of the coconut palm remain dormant for years as they float across vast expanses of ocean, finally washing up on a distant shore, where they germinate and grow. Such hardiness is one of the properties that have contributed to making seed plants the predominant plants on Earth. All of today’s forests are dominated by seed plants.

So will the seedling growing under Dr. Solowey’s care serve as the parent of a new population of Judean dates, thus resurrecting that genotype from extinction? Unfortunately, it cannot do so alone, because date trees are of two different sexes. However, it may be possible to germinate

A Refuge King Herod of Judea fortified Masada and stocked it with water and food—including Judean dates.

The Hardy Seed This coconut seed arrived on a beach, where it germinated successfully. The evolution of seeds was a major factor in the eventual dominance of the seed plants.

other Judean dates, and/or to cross the tree with Moroccan, Egyptian, or Iraqi varieties of date palms. Although these latter varieties differ from Judean dates at almost half of the gene loci that have been examined, crossing these varieties may introduce many beneficial alleles from Judean dates back into modern date plantations.

Today, humans are collecting and storing seeds from many species in seed banks (see Chapter 34). Many plant species or cultivars that would otherwise be lost to extinction are thus being preserved for restoration projects or other uses by future generations.

IN THIS CHAPTER we will describe the defining characteristics of the seed plants as a group. Living seed plants include the gymnosperms, which produce seeds not protected by ovary or fruit tissue, and the angiosperms, which are characterized by flowers and fruits. We will cover some of the unsolved problems in seed plant evolution, concluding with a survey of the diversity of living seed plants.

CHAPTER OUTLINE

- 29.1** How Did Seed Plants Become Today's Dominant Vegetation?
- 29.2** What Are the Major Groups of Gymnosperms?
- 29.3** What Features Contributed to the Success of the Angiosperms?
- 29.4** How Do Plants Support Our World?

29.1 How Did Seed Plants Become Today's Dominant Vegetation?

By the late Devonian period, more than 360 million years ago, Earth was home to a great variety of land plants, many of which are discussed in Chapter 28. The land plants shared the hot, humid terrestrial environment with insects, spiders, centipedes, and fishlike amphibians (early tetrapods). The plants and animals affected one another, acting as agents of natural selection.

In the Devonian an innovation had appeared: some plants developed extensively thickened woody stems, which resulted from the proliferation of xylem. This type of growth in the diameter of stems and roots is called **secondary growth**. Among the first plants with this adaptation were seedless vascular plants called *progymnosperms*, all species of which are now extinct.

The earliest fossil evidence of seed plants is found in late Devonian rocks. Like the *progymnosperms*, these *seed ferns* were woody. They possessed fernlike foliage but had seeds attached to their leaves. By the end of the Permian, other groups of seed plants became dominant (**Figure 29.1**).

The living seed plants fall into two major groups, the **gymnosperms** (such as pines and cycads) and the **angiosperms** (flowering plants). There are several competing phylogenetic hypotheses regarding the major groups of gymnosperms relative to the angiosperms, but **Figure 29.2** shows the most widely supported relationships. All living gymnosperms and many angiosperms show secondary growth. The life cycles of all seed plants also share distinctive features, as we are about to see.

Features of the seed plant life cycle protect gametes and embryos

Section 28.2 describes a trend in plant evolution: the sporophyte became less dependent on the gametophyte, which became smaller in relation to the sporophyte. This trend continued with the appearance of the seed plants, whose gametophyte generation is reduced even further than it is in the ferns (**Figure 29.3**). The haploid gametophyte develops partly or entirely while attached to and nutritionally dependent on the diploid sporophyte.

Among the seed plants, only the earliest groups of gymnosperms (such as cycads and ginkgos) had swimming sperm. Later groups of gymnosperms and the angiosperms evolved other means of bringing eggs and sperm together. The culmination of this striking evolutionary trend in seed plants was independence from the liquid water that earlier plants needed to assist sperm in reaching the egg. The advent of the seed gave seed plants the opportunity to colonize drier areas and spread over the terrestrial environment.

29.1 The Fossil Record of Seed Plants and Some of Their Extinct Seedless Relatives Woody growth evolved in the seedless progymnosperms. The now-extinct seed ferns had woody growth, fernlike foliage, and seeds attached to their leaves. New lineages of seed plants arose during the Carboniferous, but the earliest known fossils of flowering plants are from the late Jurassic.

Seed plants are heterosporous (see Figure 28.9B); that is, they produce two types of spores, one that becomes the male gametophyte and one that becomes the female gametophyte. They form separate microsporangia and megasporangia on structures that are grouped on short axes, such as the stamens and pistils of an angiosperm flower.

Within the microsporangium, the meiotic products are microspores, which divide mitotically within the spore wall one or a few times to form a multicellular male gametophyte called a **pollen grain**. Pollen grains are released from the microsporangium to be distributed by wind or by an animal pollinator (Figure 29.4). The wall of the pollen grain contains *sporopollenin*, the most chemically resistant biological compound known, which protects the pollen

grain against dehydration and chemical damage—another advantage in terms of survival in the terrestrial environment. Recall that sporopollenin in spore walls contributed to the successful colonization of the terrestrial environment by the earliest land plants.

In contrast to the pollen grains produced by the microsporangia, the megaspores of seed plants are not shed. Instead, they develop into female gametophytes within the megasporangia. These megagametophytes are dependent on the sporophyte for food and water.

29.2 The Major Groups of Living Seed Plants There are four groups of gymnosperms and one of angiosperms. Their exact evolutionary relationship is still uncertain, but this cladogram represents one current interpretation.

29.3 The Relationship between Sporophyte and Gametophyte In the course of plant evolution, the gametophyte has been reduced and the sporophyte has become more prominent.

Betula pendula

29.4 Pollen Grains Pollen grains are the male gametophytes of seed plants. The pollen of this silver birch is dispersed by the wind, and grains may land near the female gametophytes of the same or other silver birch trees.

In most seed plant species, only one of the meiotic products in a megasporangium survives. The surviving haploid nucleus divides mitotically, and the resulting cells divide again to produce a multicellular female gametophyte. The megasporangium is surrounded by sterile sporophytic structures, which form an **integument** that protects the megasporangium and its contents. Together, the megasporangium and integument constitute the **ovule**, which will develop into a seed after fertilization (**Figure 29.5**).

The arrival of a pollen grain at an appropriate landing point, close to a female gametophyte on a sporophyte of the same species, is called **pollination**. A pollen grain that reaches this point develops further. It produces a slender **pollen tube** that elongates and digests its way toward the megagametophyte (see **Figure 29.5**). When the tip of the pollen tube reaches the megagametophyte, sperm are released from the tube and fertilization occurs.

The resulting diploid zygote divides repeatedly, forming an embryonic sporophyte. After a period of embryonic development, growth is temporarily suspended (the embryo enters a *dormant* stage). The end product at this stage is a multicellular **seed**.

The seed is a complex, well-protected package

A seed contains tissues from three generations. A **seed coat** develops from the integument—tissues of the diploid sporophyte parent that surround the megasporangium. Within the megasporangium is the haploid female gametophytic tissue from the next generation, which contains a supply of nutrients for the developing embryo. (This tissue is fairly extensive in most gymnosperm seeds. In angiosperm seeds it is greatly reduced, and nutrition for the embryo is supplied by a tissue called **endosperm**, which is described below.) In the center of the seed is the third generation, the embryo of the new diploid sporophyte.

The seed of a gymnosperm or an angiosperm is a well-protected resting stage. The seeds of some species may remain dormant but stay *viable* (capable of growth and development) for

29.5 Pollination in an Angiosperm In all seed plants, a pollen tube grows from the pollen to the megagametophyte, where sperm are released. (A) Scanning electron micrograph of a pollen tube growing in a prairie gentian flower. (B) The process of pollination is diagrammed for a generalized angiosperm flower.

GO TO Web Activity 29.1 • Flower Morphology

many years, germinating only when conditions are favorable for the growth of the sporophyte, as happened with the 2,000-year-old Judean date seed mentioned at the beginning of this chapter. In contrast, the embryos of seedless plants develop directly into sporophytes, which either survive or die, depending on environmental conditions. Spores of some seedless plants may remain dormant and viable for long periods of time, but seeds provide a more secure and lasting dormant stage.

During the dormant stage, the seed coat protects the embryo from excessive drying and may also protect it against potential predators that would otherwise eat the embryo and its nutrient reserves. Many seeds have structural adaptations that promote their dispersal by wind or, more often, by animals. When the young sporophyte resumes growth, it draws on the food reserves in the seed. The possession of seeds is a major reason for the enormous evolutionary success of the seed plants, which are the dominant life forms of most modern terrestrial floras.

A change in anatomy enabled seed plants to grow to great heights

The most ancient seed plants produced **wood**—extensively proliferated xylem—which gave them the support to grow taller than other plants around them, thus capturing more light for

photosynthesis. The younger portion of wood is well adapted for water transport, whereas older wood becomes clogged with resins or other materials. Although no longer functional in transport, the older wood continues to provide support for the plant.

Not all seed plants are woody. In the course of seed plant evolution, many seed plants lost the woody growth habit; however, other advantageous attributes helped them become established in an astonishing variety of places.

29.1 RECAP

Pollen, seeds, and wood are major evolutionary innovations of the seed plants. Protection of the gametes and embryos is a hallmark of seed plants.

- Distinguish between the roles of the megagametophyte and the pollen grain. **See p. 609**
- Explain the importance of pollen in freeing seed plants from dependence on liquid water. **See pp. 609–610 and Figure 29.5**
- What are some of the advantages afforded by seeds? By wood? **See pp. 610–611**

The seed ferns have long been extinct, but the surviving seed plants have been remarkable successes. Next we examine the gymnosperms, the next group of plants to dominate terrestrial environments.

29.2 What Are the Major Groups of Gymnosperms?

The gymnosperms are seed plants that do not form flowers. Gymnosperms (which means “naked-seeded”) are so named because their ovules and seeds are not protected by ovary or fruit tissue. Although there are probably fewer than 1,200 species of living gymnosperms, these plants are second only to the angiosperms in their dominance of the terrestrial environment.

Although the modern gymnosperms are probably a clade, their monophyly has not been established beyond a doubt. The four major groups of living gymnosperms bear little superficial resemblance to one another.

- The **cycads** (**Cycadophyta**) are palmlike plants of the tropics and subtropics, growing as tall as 20 meters (**Figure 29.6A**). Of the present-day gymnosperms, the cycads are probably the earliest-diverging clade. There are about 300 species. Their tissues are often highly toxic to humans if ingested.
- **Ginkgos** (**Ginkgophyta**), which were common during the Mesozoic era, are represented today by a single genus and species: *Ginkgo biloba*, the maidenhair tree (**Figure 29.6B**).

There are both male (microsporangiate) and female (megasporeangiate) maidenhair trees. The difference is determined by X and Y sex chromosomes, as in humans; few other plants have distinct sex chromosomes.

- **Gnetophytes** (**Gnetophyta**) number about 90 species in three very different genera, which share certain characteristics analogous to ones found in the angiosperms, as we will see. One of the gnetophytes is *Welwitschia* (**Figure 29.6C**), a long-lived desert plant with just two straplike leaves that sprawl on the sand and can grow as long as 3 meters.

29.6 Diversity among the Gymnosperms (A) Many cycads have growth forms that resemble both ferns and palms, but cycads are not closely related to either. (B) The characteristic fleshy seed coat and broad leaves of the maidenhair tree. (C) A gnetophyte growing in the Namib Desert of Africa. Straplike leaves grow throughout the life of the plant, breaking and splitting as they grow. (D) Conifers, like this giant sequoia growing in Sequoia National Park, California, dominate many modern forests.

(A) *Encephalartos villosus*

(B) *Ginkgo biloba*

(C) *Welwitschia mirabilis*

(D) *Sequoiadendron giganteum*

- **Conifers (Coniferophyta)** are by far the most abundant of the gymnosperms. There are about 700 species of these cone-bearing plants, including the pines and redwoods (Figure 29.6D).

With the exception of the gnetophytes, the living gymnosperm groups have only tracheids as water-conducting and support cells within the xylem. In most angiosperms, cells called vessel elements and fibers (specialized for water conduction and support, respectively) are found alongside tracheids. While the gymnosperm water-transport and support system may thus seem somewhat less efficient than that of the angiosperms, it serves some of the largest trees known. The coastal redwoods of California are the tallest gymnosperms; the largest are well over 100 meters tall.

During the Permian, as environments became warmer and dryer, the conifers and cycads flourished. Gymnosperm forests changed over time as the gymnosperm groups evolved. Gymnosperms dominated the Mesozoic era, during which the continents drifted apart and large dinosaurs walked the Earth. Gymnosperms were the principal trees in all forests until about 65 million years ago, and even down to the present day, conifers are the dominant trees in many forests, especially of higher latitudes and altitudes. The oldest living single organism on Earth today is a gymnosperm in California—a bristlecone pine that germinated about 4,800 years ago, at about the time the ancient Egyptians were just starting to develop writing.

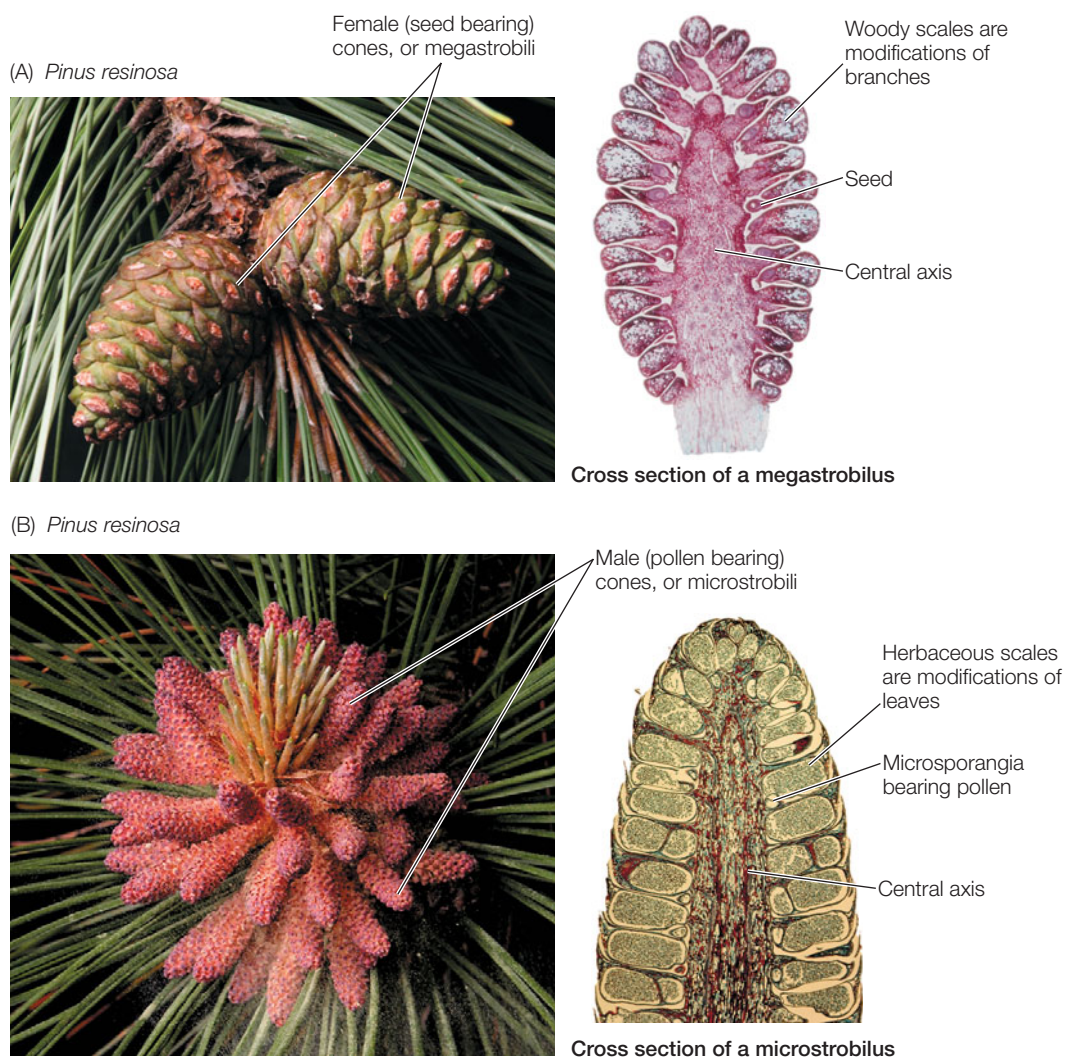

Conifers have cones but no motile gametes

The great Douglas fir and cedar forests found in the northwestern United States and the massive boreal forests of pine, fir, and spruce of the northern regions of Eurasia and North America, as well as on the upper slopes of mountain ranges everywhere, rank among the great vegetation formations of the world. All these trees belong to one group of gymnosperms, Coniferophyta—the conifers, or cone-bearers.

Male and female **cones** contain the reproductive structures

of conifers. The female (seed-bearing) cone is known as a **megastrobilus** (plural: *megastrobili*); this is the familiar woody cone of pine trees. The seeds in a megastrobilus are protected by a tight cluster of woody scales, which are modifications of branches extending from a central axis (Figure 29.7A). The typically much smaller male (pollen-bearing) cone is known as a **microstrobilus**. The microstrobilus is typically herbaceous rather than woody, as its scales are composed of modified leaves, beneath which are the pollen-bearing microsporangia (Figure 29.7B).

We will use the life cycle of a pine to illustrate reproduction in gymnosperms (Figure 29.8). The production of male gametophytes in the form of pollen grains frees the plant completely from its dependence on liquid water for fertilization. Wind, rather than water, assists conifer pollen grains in their first stage of travel from the strobilus to the female gametophyte inside a cone (see Figure 29.4). The pollen tube provides the sperm with the means for the last stage of travel by elongating through maternal sporophytic tissue, as diagrammed for an angiosperm in Figure 29.5. When it reaches the female gametophyte, it releases two sperm, one of which degenerates after the other unites with an egg. Union of sperm and egg results in a zygote; mitotic di-

GO TO Web Activity 29.2 and Animated Tutorial 29.1 • Life Cycle of a Conifer

The megasporangium, in which the female gametophyte will form, is enclosed in a layer of sporophytic tissue—the integument—that will eventually develop into the seed coat that protects the embryo. The integument, the megasporangium inside it, and the tissue attaching it to the maternal sporophyte constitute the ovule. The pollen grain enters through a small opening in the integument at the tip of the ovule, the **micropyle**.

Most conifer ovules (which will develop into seeds after fertilization) are borne exposed on the upper surfaces of the mod-

29.9 From Devastation, New Life Emerges A stand of lodgepole pines in Yellowstone National Park. The mature trees were destroyed by a forest fire in 1988. The fire released large numbers of lodgepole pine seeds from the cones, and now many young lodgepole pine trees are emerging in the burn area.

ified branches that form the scales of the cone (megastrobilus). The only protection of the ovules comes from the scales, which are tightly pressed against one another within the cone. Some pines, such as the lodgepole pine, have such tightly closed cones that only fire suffices to split them open and release the seeds. A fire devastated lodgepole pine forests in Yellowstone National Park in 1988 but also released large numbers of seeds from the cones. As a result, large numbers of lodgepole pine seedlings are now emerging in the burn area (**Figure 29.9**).

About half of all conifer species have soft, fleshy modifications of cones that envelop their seeds; examples are the fruit-like cones or “berries” of juniper and yew. Animals may eat these tissues and then disperse the seeds in their feces, often carrying them considerable distances from the parent plant.

29.2 RECAP

Living gymnosperms include cycads, ginkgos, gnetophytes, and conifers, all of which are woody and have seeds that are not protected by ovaries.

- Explain the different functions of a megastrobilus and a microstrobilus. **See p. 613 and Figure 29.8**
- What is the role of the integument in a gymnosperm seed? **See p. 614 and Figure 29.8**
- Do you understand how fire can be necessary for the survival of some species? **See p. 615**

The “berries” on some gymnosperms (such as juniper and yew) are not true fruits but rather are fleshy cones. As we will see, true fruits are the ripened ovaries of plants. Ovaries are absent in gymnosperms but are a characteristic of the plant group that is dominant today: the angiosperms. Let’s look at other ways in which angiosperms differ from gymnosperms.

29.3 What Features Contributed to the Success of the Angiosperms?

The oldest fossil evidence of angiosperms dates back to the late Jurassic period, about 150 million years ago (see **Figure 29.1**). The angiosperms radiated explosively in the Tertiary (beginning 65 million years ago) and became the dominant plant life on Earth. Today there are more than a quarter million species of angiosperms.

The female gametophyte of the angiosperms is even more reduced than that of the gymnosperms, usually consisting of just seven cells. Thus the angiosperms represent the current extreme of the trend we have traced throughout the evolution of the vascular plants: the sporophyte generation becomes larger and more independent of the gametophyte, while the gametophyte generation becomes smaller and more dependent on the sporophyte. What else sets the angiosperms apart from other plants?

The major synapomorphies (shared derived traits) that characterize the angiosperms include:

- Double fertilization
- Production of a nutritive tissue called the endosperm
- Ovules and seeds enclosed in a carpel
- Flowers
- Fruits
- Phloem with companion cells
- Reduced gametophytes

In the angiosperms, pollination consists of the arrival of a microgametophyte—a pollen grain—on a receptive surface in a flower (the *stigma*). As in the gymnosperms, pollination is the first in a series of events that result in the formation of a seed. The next is the growth of a pollen tube extending to the megagametophyte (see **Figure 29.5**). The third event is a fertilization process that, in detail, is unique to the angiosperms.

Double fertilization is often considered the single most reliable distinguishing characteristic of the angiosperms. *Two* male gametes, contained in a single microgametophyte, participate in fertilization events in the megagametophyte of an angiosperm. The nucleus of one sperm combines with that of the egg to produce a diploid zygote, the first cell of the sporophyte generation. In most angiosperms, the other sperm nucleus combines with two other haploid nuclei of the female gametophyte to form a *triploid* ($3n$) nucleus (further discussed below; see **Figure 29.15**). That nucleus, in turn, divides to form a triploid tissue, the **endosperm**, that nourishes the embryonic sporophyte during its early development. This process, in which two fertilization events take place, is known as **double fertilization**.

Double fertilization occurs in nearly all present-day angiosperms. We are not sure when and how it evolved because there is no known fossil evidence on this point. It may have first resulted in two diploid embryos, as it does in the three existing genera of the gnetophytes.

The name *angiosperm* (“enclosed seed”) is drawn from another distinctive characteristic of these plants: the ovules and seeds are enclosed in a modified leaf called a **carpel**. Besides protecting the ovules and seeds, the carpel often interacts with incoming pollen to prevent self-pollination, thus favoring cross-pollination and increasing genetic diversity. Of course, the most obvious diagnostic feature of angiosperms is that they have **flowers**. Production of **fruits** is another of their unique characteristics. As we will see, both flowers and fruits afford major advantages to angiosperms.

Most angiosperms are distinguished by the possession of specialized water-transporting cells called **vessel elements** in their xylem (see Chapter 34). These cells are broad in diameter and connect without obstruction, allowing easy water movement. A second distinctive cell type in angiosperm xylem is the **fiber**, which plays an important role in supporting the plant body. Angiosperm phloem possesses another unique cell type, called a **companion cell**. Like the gymnosperms, woody angiosperms show secondary growth, producing secondary xylem and secondary phloem and growing in diameter.

In the remainder of this section we examine the structure and function of flowers, evolutionary trends in flower structure, the functions of pollen and fruits, and the angiosperm life cycle.

The sexual structures of angiosperms are flowers

If you examine any familiar flower, you will notice that the outer parts look somewhat like leaves. In fact, all the parts of a flower are modified leaves.

We showed a generalized flower (for which there is no exact counterpart in nature) in Figure 29.5. The structures bearing microsporangia are called **stamens**. Each stamen is composed of a **filament** bearing an **anther** that contains pollen-producing microsporangia. The structures bearing megasporangia are the carpels. A structure composed of one carpel or two or more fused carpels is called a **pistil**. The swollen base of the pistil, containing one or more ovules (each containing a megasporangium surrounded by its protective integument), is called the **ovary**. The apical stalk of the pistil is the **style**, and the terminal surface that receives pollen grains is the **stigma**.

In addition, a flower often has several specialized sterile (non-spore-bearing) leaves. The inner ones are called **petals** (collectively, the **corolla**) and the outer ones **sepals** (collectively, the **calyx**). The corolla and calyx (collectively, the *perianth*) can be quite showy and often play roles in attracting animal pollinators to the flower. The calyx more commonly protects the immature flower in bud. From base to apex, the sepals, petals, stamens, and carpels (which are referred to as the *floral organs*; see Figure 19.14) are usually positioned in circular arrangements or whorls and attached to a central stalk called the **receptacle**.

The generalized flower in Figure 29.5 has functional megasporangia and microsporangia; such flowers are referred to as

perfect (or hermaphroditic). Many angiosperms produce two types of flowers, one with only megasporangia and the other with only microsporangia. Consequently, either the stamens or the carpels are nonfunctional or absent in a given flower, and the flower is referred to as **imperfect**.

Species such as corn or birch, in which both megasporangiate (female) and microsporangiate (male) flowers occur on the same plant, are said to be **monoecious** (meaning “one-housed”—but, it must be added, one house with separate rooms). Complete separation is the rule in some other angiosperm species, such as willows and date palms; in these species, a given plant produces either flowers with stamens or flowers with carpels, but never both. Such species are said to be **dioecious** (“two-housed”).

Flowers come in an astonishing variety of forms—just think of some of the flowers you recognize. The generalized flower in Figure 29.5 has distinct petals and sepals arranged in distinct whorls. In nature, however, petals and sepals sometimes are indistinguishable. Such appendages are called **tepals**. In other flowers, petals, sepals, or tepals are completely absent.

Flowers may be single, or they may be grouped together to form an **inflorescence**. Different families of flowering plants have characteristic types of inflorescences, such as the compound umbels of the carrot family (Figure 29.10A), the heads of the aster family (Figure 29.10B), and the spikes of many grasses (Figure 29.10C).

Flower structure has evolved over time

The flowers of the most basal clades of angiosperms have a large and variable number of tepals (or sepals and petals), carpels, and stamens (Figure 29.11A). Evolutionary change within the angiosperms has included some striking modifications of this early condition: reductions in the number of each type of floral organ to a fixed number, differentiation of petals from sepals, and changes in symmetry from radial (as in a lily or magnolia) to bilateral (as in a sweet pea or orchid), often accompanied by an extensive fusion of parts (Figure 29.11B).

According to one theory, the first carpels to evolve were leaves with marginal sporangia, folded but incompletely closed. Early in angiosperm evolution, the carpels fused and became progressively more buried in receptacle tissue, forming the ovary (Figure 29.12A). In some flowers, the other floral organs are attached at the top of the ovary, rather than at the bottom as in Figure 29.5. The stamens of the most ancient flowers may have appeared leaflike (Figure 29.12B), little resembling those of the generalized flower in Figure 29.5.

Why do so many flowers have pistils with long styles and anthers with long filaments? Natural selection has favored length in both of these structures, probably because length increases the likelihood of successful pollination. Long filaments may bring the anthers into contact with insect bodies, or they may place the anthers in a better position to catch the wind. Similar arguments apply to long styles.

A perfect flower represents a compromise of sorts. On the one hand, in attracting a pollinating bird or insect, the plant is attending to both its female and male functions with a single

29.10 Inflorescences (A) The inflorescence of bishop's goutweed (a member of the carrot family) is a compound umbel. Each umbel bears flowers on stalks that arise from a common center. (B) Sunflowers are members of the aster family; their inflorescence is a head. In a head, each of the long, petal-like structures is a ray flower; the central portion of the head consists of dozens to hundreds of disc flowers. (C) Grasses such as this fountain grass have inflorescences called spikes.

29.11 Flower Form and Evolution (A) A magnolia flower shows the major features of early flowers: it is radially symmetrical, and the individual tepals, carpels, and stamens are separate, numerous, and attached at their bases. (B) Orchids, such as this ladyslipper, have a bilaterally symmetrical structure that evolved much later.

(A) Carpel evolution

(B) Stamen evolution

29.12 Carpels and Stamens Evolved from Leaflike Structures

(A) Possible stages in the evolution of a carpel from a more leaflike structure. (B) The stamens of three modern plants show the various stages in the evolution of that organ. It is *not* implied that these species evolved from each other; their structures simply illustrate the possible stages.

29.13 An Unusual Solution to Selfing Both long stamens and long styles facilitate cross pollination, but if these male and female structures are too close to each other, the likelihood of (disadvantageous) self-pollination increases. In *Mimulus aurantiacus*, initially the stigma is open, blocking access to the anthers. A hummingbird's touch as it deposits pollen on the stigma causes one lobe of the stigma to retract, creating a path to the anthers and allowing pollen dispersal.

flower type, whereas plants with imperfect flowers must create that attraction twice—once for each type of flower. On the other hand, the perfect flower can favor self-pollination, which is usually disadvantageous. Another potential problem is that the female and male functions might interfere with each other—for example, the stigma might be so placed as to make it difficult for pollinators to reach the anthers, thus reducing the export of pollen to other flowers.

Might there be a way around these problems? One solution is seen in the bush monkeyflower (*Mimulus aurantiacus*), which is pollinated by hummingbirds and has a stigma that initially serves as a screen, hiding the anthers (Figure 29.13). Once a hummingbird touches the stigma, one of the stigma's two lobes folds, so that subsequent hummingbirds pick up pollen from the previously screened anthers. The first bird transfers pollen from another plant to the stigma, eventually leading to fertilization. Later visitors pick up pollen from the now-accessible anthers, fulfilling the flower's male function. Figure 29.14 describes the experiment that revealed the function of this mechanism.

Angiosperms have coevolved with animals

Whereas many gymnosperms are wind-pollinated, most angiosperms are animal-pollinated. The many different pollination symbioses between plants and animals are vital to both par-

INVESTIGATING LIFE

29.14 Stigma Behavior in *Mimulus* Flowers

Elizabeth Fetscher's experiments showed that the unusual stigma retraction mechanism in monkeyflowers (see Figure 29.13) enhances the dispersal of pollen from the anthers.

HYPOTHESIS Stigma responses in *M. aurantiacus* increase the likelihood that an individual's pollen will be exported once pollen from another individual has been deposited on the stigma.

METHOD

1. Set up experimental arrays such that only one flower in each array can donate pollen. In control arrays, the pollen donor styles function normally. In another set of arrays, donor stigmas are artificially sealed closed; in a third set, the pollen donor stigmas are permanently propped open.
2. Allow hummingbirds to visit the arrays, then count the pollen grains from each donor on the next flower visited.

RESULTS

CONCLUSION Stigma responses enhance the male function of the flower (dispersal of pollen) once the female function (receipt of pollen) has been performed.

FURTHER INVESTIGATION: How might you test how this mechanism affects self-pollination of the flower?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

ties. This fascinating coevolutionary field is covered in more detail in Chapter 56, but we mention some aspects here.

Many flowers entice animals to visit them by providing food rewards. Some flowers produce a sugary fluid called nectar, and the pollen grains themselves sometimes serve as food for animals. In the process of visiting flowers to obtain nectar or pollen, animals often carry pollen from one flower to another or from one plant to another. Thus, in their quest for food, the animals contribute to the genetic diversity of the plant population. In-

29.15 The Life Cycle of an Angiosperm The formation of a triploid endosperm is one of the features that distinguishes the angiosperms from the gymnosperms. One sperm nucleus fertilizes the egg to form the zygote, while the other combines with the two polar nuclei to form the endosperm.

Life Cycle of an Angiosperm

Double fertilization results in a $2n$ zygote and $3n$ endosperm.

sects, especially bees, are among the most important pollinators; birds and some species of bats are also major pollinators.

For more than 150 million years, angiosperms and their animal pollinators have coevolved in the terrestrial environment. The animals have affected the evolution of the plants, and the plants have affected the evolution of the animals. Flower structure has become incredibly diverse under these selection pressures. Some of the products of coevolution are highly specific; for example, some yucca species are pollinated by only one species of moth. Pollination by just one or a few animal species provides a plant species with a reliable mechanism for transferring pollen from one of its members to another.

Most plant–pollinator interactions are much less specific; that is, many different animal species pollinate the same plant

species, and the same animal species pollinate many different plant species. However, even these less specific interactions have developed some specialization. Bird-pollinated flowers are often red and odorless. Many insect-pollinated flowers have characteristic odors, and bee-pollinated flowers may have conspicuous markings, or *nectar guides*, that may be visible only in the ultraviolet region of the spectrum, where bees have better vision than in the red region (see Table 56.1 and Figure 56.10).

The angiosperm life cycle features double fertilization

The angiosperm life cycle is considered in detail in Chapter 38, but let's look at it briefly here, comparing **Figure 29.15** with the conifer life cycle shown in Figure 29.8.

29.16 Fruits Come in Many Forms (A–C) Simple fruits. (A) The single-seeded drupe of the fleshy-fruited plum is dispersed by animals. (B) Each macadamia seed is covered by a hard, woody fruit that allows it to survive drought and other hardships. (C) The highly reduced fruits of dandelions are dispersed by wind. (D) A multiple fruit (pineapple). (E) An aggregate fruit (raspberry). (F) An accessory fruit (strawberry).

Like all seed plants, angiosperms are heterosporous. As we have seen, their ovules are contained within carpels rather than being exposed on the surfaces of scales, as in most gymnosperms. The male gametophytes, as in the gymnosperms, are pollen grains.

The ovule develops into a seed containing the products of the double fertilization that characterizes angiosperms: a diploid zygote and a triploid endosperm. The endosperm serves as storage tissue for starch or lipids, proteins, and other substances that will be needed by the developing embryo.

The zygote develops into an embryo, which consists of an embryonic axis (the “backbone” that will become a stem and a root) and one or two **cotyledons**, or seed leaves. The cotyledons have three different possible fates in different plants. In many, they serve as absorptive organs that take up and digest the endosperm. In others, they enlarge and become photosynthetic when the seed germinates. Often they play both roles.

Angiosperms produce fruits

The ovary of a flower (together with the seeds it contains) develops into a fruit after fertilization. The fruit protects the seeds and can also promote seed dispersal by becoming attached to or being eaten by an animal. Other fruits are adapted for dispersal by wind or water. A fruit may consist only of the mature ovary and its seeds, or it may include other parts of the flower or structures associated with it (**Figure 29.16**). A *simple fruit*, such as a plum, is one that develops from a single carpel or several united carpels. A raspberry is an example of an *aggregate fruit*—one that develops from several separate carpels

of a single flower. Pineapples and figs are examples of *multiple fruits*, formed from a cluster of flowers (an inflorescence). Fruits derived from parts in addition to the carpel and seeds are called *accessory fruits*; examples are apples, pears, and strawberries. Fruits are not necessarily fleshy; they can be hard and woody or small and have modified structures that allow the seeds to be dispersed by wind. The development, ripening, and dispersal of fruits are considered in Chapters 37 and 38.

Recent analyses have revealed the oldest split among the angiosperms

Figure 29.17 shows the relationships among the major angiosperm clades. The two largest clades—the **monocots** and the **eudicots**—include the great majority of angiosperm species. The monocots are so called because they have a single embryonic cotyledon; the eudicots have two. (Chapter 34 describes other differences between these two groups.)

Some familiar angiosperms belong to other clades, including the water lilies, star anise and its relatives, and the magnoliid complex (**Figure 29.18**). The magnoliids are less numerous than the monocots and eudicots, but they include many familiar and useful plants such as magnolias, avocados, cinnamon, and black pepper.

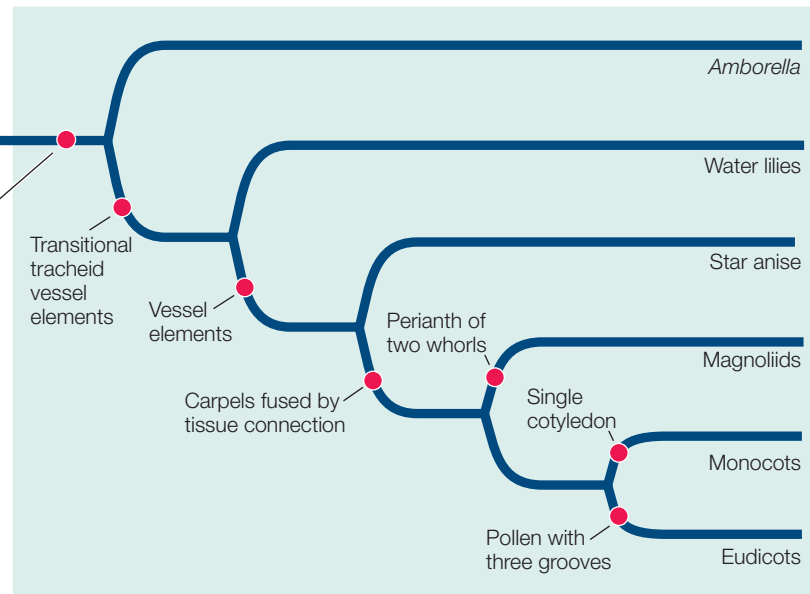

The root of the evolutionary tree of flowering plants was once a matter of great controversy. A fundamental issue was identifying the group that is sister to the remaining angiosperms, and the magnoliid clade was a leading candidate for the position. At the close of the twentieth century, however, an impressive convergence of molecular and morpholog-

29.17 Evolutionary Relationships among the Angiosperms

Recent analyses of many angiosperm genes have clarified the relationships among the major groups.

Common ancestor of angiosperms

Carpels; endosperm; seeds in fruit; reduced gametophytes; double fertilization; flowers; phloem with companion cells

(A) *Amborella trichopoda*

(B) *Nymphaea* sp.

(C) *Illicium anisatum*

(D) *Piper nigrum*

(E) *Aristolochia macrophylla*

(F) *Persea americana*

29.18 Monocots and Eudicots Are Not the Only Surviving Angiosperms

(A) *Amborella*, a shrub, is the sister to the remaining extant angiosperms. Of interest in this photo of a female flower is the pair of false anthers (male flower parts), possibly serving to lure insects that are searching for pollen. (B) The water lily clade is the next clade to diverge

after *Amborella*. (C) Star anise and its relatives belong to another basal clade. (D–F) The largest clade other than the monocots and eudicots is the magnoliid complex, represented here by (D) black pepper, (E) Dutchman's pipe, and (F) avocado. The magnolia in Figure 29.11A is another magnoliid.

ical evidence led to the conclusion that the sister group to the remaining flowering plants is a clade that today consists of a single species of the genus *Amborella* (see Figure 29.18A). This woody shrub, with cream-colored flowers, lives only on New Caledonia, an island in the South Pacific. Its 5 to 8 carpels are in a spiral arrangement, and it has 30 to 100 stamens. The xylem of *Amborella* lacks vessel elements, which evolved after this deepest split in the angiosperm evolutionary tree.

29.3 RECAP

The synapomorphies of angiosperms include double fertilization, endosperm (triploid in most species), flowers, fruit, and distinctive cells in their xylem and phloem. The largest angiosperm clades are the monocots and the eudicots.

- Explain the difference between pollination and fertilization. **See pp. 615–616**
- Give some examples of how animals have affected the evolution of the angiosperms. **See pp. 618–619**
- What are the respective roles of the two sperm in double fertilization? **See pp. 619–620 and Figure 29.15**
- What are the different functions of flowers, fruits, and seeds?

The remarkable diversity of the seed plants has been shaped in part by the different environments in which these and other plants have evolved. In turn, land plants—and seed plants in particular—affect their environments.

29.4 How Do Plants Support Our World?

Once life moved onto land, it was plants that shaped the environment, and today's environment is dominated by angiosperms. Representatives of the two largest angiosperm clades are everywhere. The monocots (**Figure 29.19**) include grasses, cattails, lilies, orchids, and palms. The eudicots (**Figure 29.20**) include the vast majority of familiar seed plants, including most herbs (i.e., nonwoody plants), vines, trees, and shrubs. Among the eudicots are such diverse plants as oaks, willows, beans, snapdragons, and sunflowers.

Plants make profound contributions to ecosystem services—processes by which the environment maintains resources that benefit humans. These benefits include the effects of plants on soil, water, the atmosphere, and the climate. Plants produce oxygen and remove carbon dioxide from the atmosphere, as well as play important roles in forming and renewing the fertility of soils. Plant roots help hold soil in place, providing a defense against erosion by wind and water. They also moderate local climate in various ways, such as by increasing humidity, providing shade, and blocking wind.

Seed plants are our primary food source

Plants are **primary producers**; that is, their photosynthesis traps energy and carbon, making those resources available not only for their own needs but also for the herbivores and omnivores that consume them, for the carnivores and omnivores that eat the herbivores, and for the prokaryotes and fungi that complete the food chain. The earliest steps in human civilization involved cultivating angiosperms to provide a reliable food supply.

Today, twelve species of seed plants stand between the human race and starvation: rice, coconut, wheat, corn (also called maize), potato, sweet potato, cassava (also called tapioca or man-

(A) *Phoenix dactylifera*

(B) *Triticum aestivum*

(C) *Lilium* sp.

29.19 Monocots (A) Palms are among the few monocot trees. Date palms are a major food source in some areas of the world. (B) Grasses such as this cultivated wheat and the fountain grass in Figure 29.10C are monocots. (C) Monocots include popular garden flowers such as these lilies. Orchids (Figure 29.11B) are also highly sought-after monocot flowers.

(B) *Mimosa nuttallii*(C) *Crataegus viridis*

29.20 Eudicots (A) The cactus family is a large group of eudicots, with about 1,500 species in the Americas. This black lace cactus bears large pink flowers for a brief period of the year. (B) This sensitive briar is a legume (“bean and pea family”), an economically important plant group with a large number of species. (C) The green hawthorn is a small eudicot tree and a member of the family that includes roses.

ioc), sugarcane, sugar beet, soybean, common bean (*Phaseolus vulgaris*), and banana. Hundreds of other seed plants are cultivated for food, but none rank with these twelve in importance.

Indeed, more than half of the world’s human population derives the bulk of its food energy from the seeds of a single plant: rice, *Oryza sativa*. Rice is particularly important in the Far East, where it has been cultivated for more than 8,000 years. People also use rice straw in many ways, such as thatching for roofs, food and bedding for livestock, and clothing. Rice hulls, too, have many uses, ranging from fertilizer to fuel.

Another vitally important angiosperm is the coconut (*Cocos nucifera*), whose seed is illustrated at the opening of this chapter. In some cultures of the coastal tropics, this monocot tree is known as the “tree of life.” Every aboveground part of the plant—its seeds, fruit, stem (trunk), leaves, buds, and even its sap—is of use and value to humans. Millions of people get most of their protein from the “meat” of coconut seeds, and the seed’s “milk” is vital in areas where water is scarce or unfit to drink.

Seed plants have been sources of medicine since ancient times

One of the oldest human professions is that of medicine man or shaman—a person who cures others with medicines derived from seed plants. It is claimed that a legendary Chinese emperor around 2700 B.C.E. knew some 365 medicinal plants. Although we also use medicines derived from fungi, lichens, and actinobacteria, seed plants are the source of many of our medications, just a few of which are shown in **Table 29.1**. Even in synthetic pharmaceuticals, the chemical structures of active ingredients are often based on the biochemistry of substances isolated from plants.

How are plant-based medicines discovered? These days many are found by systematic testing of tremendous numbers of plants from all over the world, a process that began in the 1960s. One example is taxol, an important anticancer drug. Among the myriad plant samples that had been tested by 1962, extracts of the bark of Pacific yew (*Taxus brevifolia*) showed anti-tumor activity in tests against rodent tumors. The active ingredient, taxol, was isolated in 1971 and tested against human cancers in 1977. After another 16 years, the U.S. Food and Drug Administration approved it for human use, and taxol is now widely used in treating breast and ovarian cancers as well as several other types of cancers.

TABLE 29.1

Some Medicinal Plants and Their Products

PRODUCT	PLANT SOURCE	MEDICAL APPLICATION
Atropine	Belladonna	Dilating pupils for eye examination
Bromelain	Pineapple stem	Controlling tissue inflammation
Digitalin	Foxglove	Strengthening heart muscle contraction
Ephedrine	<i>Ephedra</i>	Easing nasal congestion
Menthol	Japanese mint	Relief of coughing
Morphine	Opium poppy	Relief of pain
Quinine	<i>Cinchona</i> bark	Treatment of malaria
Taxol	Pacific yew	Treatment of ovarian and breast cancers
Tubocurarine	Curare plant	Muscle relaxant in surgery
Vincristine	Periwinkle	Treatment of leukemia and lymphoma

Widespread screening of plant samples eventually was deemphasized in favor of a purely chemical approach. Using automation and miniaturization, pharmaceutical laboratories generate vast numbers of compounds that are screened just as plant materials were screened in the search for taxol and other plant-based medicines. Now, however, the plant screening is getting renewed interest. Both approaches are based on trial and error.

The other leading source of medicinal plants is work by *ethnobotanists*, who study how people use and view plants in their

local environments. This work proceeds all over the globe today. An older example is the discovery of quinine as a treatment for malaria. In the sixteenth century, Spanish priests in Peru became aware that the native population used the bark of local *Cinchona* trees to treat fevers. The priests successfully used the bark to treat malaria. Word of the medicine spread to Europe, where it is said to have been in use in Rome by 1631. The active ingredient of *Cinchona* bark—quinine—was identified in 1820, and quinine remained the standard malarial remedy well into the twentieth century.

CHAPTER SUMMARY

29.1 How Did Seed Plants Become Today's Dominant Vegetation?

- Fossils of woody seed ferns are the earliest evidence of vascular seed plants. The surviving groups of seed plants are the **gymnosperms** and **angiosperms**.
- All seed plants are heterosporous, and their gametophytes are much smaller than (and dependent on) their sporophytes. **Review Figure 29.3**
- An **ovule** consists of the seed plant megagametophyte and the **integument** that protects it. The ovule develops into a **seed**.
- **Pollen grains**, the microgametophytes, do not require liquid water to perform their functions. Following **pollination**, a **pollen tube** emerges from the pollen grain and elongates to deliver gametes to the megagametophyte. **Review Figure 29.5, WEB ACTIVITY 29.1**
- Seeds are well protected, and they are often capable of long periods of dormancy, germinating when conditions are favorable.

29.2 What Are the Major Groups of Gymnosperms?

- The gymnosperms produce seeds that are not protected by ovaries.
- The major gymnosperm groups are the **cycads**, **ginkgos**, **gnnetophytes**, and **conifers**. **Review Figure 29.2.**
- The megaspores of conifers are produced in woody **cones** called **megastrobili**, and microspores are produced in herbaceous cones called **microstrobili**. Pollen reaches the megagametophyte by way of the **micropyle**, an opening in the integument of the ovule. **Review Figure 29.8, WEB ACTIVITY 29.2, ANIMATED TUTORIAL 29.1**

29.3 What Features Contributed to the Success of the Angiosperms?

- Only angiosperms have **flowers** and **fruits**.
- The ovules and seeds of angiosperms are enclosed in and protected by **carpels**. **Review Figure 29.12**

- Angiosperms have **double fertilization**, resulting in the production of a zygote and **endosperm** (which is triploid in most species). **Review Figure 29.15, ANIMATED TUTORIAL 29.2**
- The xylem and phloem of angiosperms are more complex and efficient than those of the gymnosperms. **Vessel elements** in the xylem of angiosperms function in water transport. **Fibers** in angiosperm xylem play an important role in structural support.
- The floral organs, from the apex to the base of the flower, are the **pistil**, **stamens**, **petals**, and **sepals**. Stamens bear microsporangia in **anthers**. The pistil (consisting of one or more carpels) includes an **ovary** containing ovules. The **stigma** is the receptive surface of the pistil. The floral organs are borne on the **receptacle**. **Review Figure 29.5**
- A flower with both megasporangia and microsporangia is **perfect**; all other flowers are **imperfect**. Flowers may be grouped to form an **inflorescence**. Flowers may be pollinated by wind or animals.
- A **monoecious** species has megasporangiate and microsporangiate flowers on the same plant. A **dioecious** species is one in which megasporangiate and microsporangiate flowers occur on different plants.
- The most species-rich angiosperm clades are the **monocots** and the **eudicots**. The magnoliids form the sister group to the monocots and eudicots. **Review Figure 29.17**
- The oldest evolutionary split among the angiosperms is between the single species in the genus *Amborella* and all the remaining flowering plants.

29.4 How Do Plants Support Our World?

- Plants provide **ecosystem services** that affect soil, water, air quality, and climate.
- Plants are **primary producers** and as such are the foundation of the entire terrestrial food web.
- Plants provide many important medicinal products. **Review Table 29.1**

SELF-QUIZ

- Which of the following statements about seed plants is *true*?
 - Seeds are produced only by flowering plants (angiosperms).
 - The sporophyte generation is more reduced in seed plants than in the ferns.
 - The gametophytes of seed plants are independent of the sporophytes.
 - All seed plant species are heterosporous.
 - The zygote of seed plants divides repeatedly to form the gametophyte.
- The gymnosperms
 - dominate all land masses today.
 - have never dominated land masses.
 - have secondary growth.
 - all have vessel elements.
 - lack sporangia.
- Conifers
 - produce ovules in microstrobili and pollen in megastrobili.
 - depend on liquid water for fertilization.
 - have triploid endosperm.
 - have pollen tubes that release two sperm.
 - have vessel elements.
- Most angiosperms
 - have seeds enclosed in a carpel.
 - produce triploid endosperm by the union of two eggs and one sperm.
 - lack secondary growth.
 - bear two kinds of cones.
 - lack flowers.
- Which statement about flowers is *not* true?
 - Pollen is produced in the anthers.
 - Pollen is received on the stigma.
 - An inflorescence is a cluster of flowers.
 - A species having female and male flowers on the same plant is dioecious.
 - A flower with both megasporangia and microsporangia is said to be perfect.
- Which statement about fruits is *not* true?
 - They develop from ovaries.
 - They may include other parts of the flower.
 - A multiple fruit develops from several carpels of a single flower.
 - They are produced only by angiosperms.
 - A cherry is a simple fruit.
- Which statement is *not* true of angiosperm pollen?
 - It is the male gamete.
 - It is haploid.
 - It produces a long tube.
 - It interacts with the carpel.
 - It is produced in microsporangia.
- Which statement is *not* true of carpels?
 - They are thought to have evolved from leaves.
 - They bear megasporangia.
 - They may fuse to form a pistil.
 - They are floral organs.
 - They are absent in perfect flowers.
- Amborella*
 - was the first flowering plant.
 - belongs to the first gymnosperm clade.
 - is the sister group of all other living angiosperms.
 - is a eudicot.
 - has vessel elements in its xylem.
- The eudicots
 - include many herbs, vines, shrubs, and trees.
 - and the monocots are the only extant angiosperm clades.
 - are not a clade.
 - include the magnolias.
 - include orchids and palm trees.

FOR DISCUSSION

- In most seed plant species, only one of the products of meiosis in the megasporangium survives. How might this be advantageous?
- Suggest an explanation for the great success of the angiosperms in occupying terrestrial habitats.
- In many locales, large gymnosperms predominate over large angiosperms. Under what conditions might gymnosperms have the advantage, and why?
- Not all flowers possess all of the following floral organs: sepals, petals, stamens, and carpels. Which floral organ or organs do you think might be found in the flowers that have the smallest number of floral organ types? Discuss the possibilities, both for a single flower and for a species.
- The origin of the angiosperms has long been “an abominable mystery,” as Charles Darwin once put it. The earliest known angiosperm fossils are from the late Jurassic, but fossils of their sister-group, the gymnosperms, are known from as early as the late Carboniferous (about 150 million years earlier). Given that these two sister-groups are thought to have arisen at the same time from a single split in the seed plant tree, what might explain the lack of earlier angiosperms fossils?

ADDITIONAL INVESTIGATION

The flower of a particular species of orchid has a long, spurlike tube into which a pollinating insect can insert its proboscis to suck nectar. The spurs are of different lengths in different habitats, apparently correlated with the lengths of the probosces of

the local pollinators. How might you test the hypothesis that this correlation increases reproductive success, in terms of pollen transfer to the flower?

A fungus battles witchweed

More than 300 million Africans in 25 countries are suffering because their crops have been invaded by witchweed (*Striga*), a parasitic flowering plant. Witchweed has attacked more than two-thirds of the sorghum, corn, and millet crops in sub-Saharan Africa. Reduced crop yields cost an estimated U.S. \$7 billion each year.

A team of Canadian scientists set out to find a biological solution to the *Striga* problem. Their strategy was to look for an organism that would destroy witchweed in the fields. They succeeded in isolating a strain of a fungus—the mold *Fusarium oxysporum*—that has several outstanding properties. First, it grows on *Striga* and kills a high percentage of these parasitic plants. Second, the fungus does

not attack the crop plants that *Striga* parasitizes. And finally, *F. oxysporum* is not toxic to humans. In subsequent fieldwork, the scientists established specific techniques for applying *F. oxysporum* to witchweed. Farmers who apply the fungus to their crops are rewarded by greatly increased crop yields as *Striga* is held in check.

It may be possible to repeat the *Striga* story—the use of a fungus to wipe out a particular type of flowering plant—in a very different context. A different strain of *F. oxysporum* preferentially attacks coca plants, the source of cocaine. A controversial proposal to use *F. oxysporum* to wipe out the coca plantations in Andean South America and other parts of the world has been proposed; however, the specificity of the fungus to infect only coca is not clear. Establishing the degree of host specificity is crucial,

because some naturally occurring strains of *F. oxysporum* attack important crops in various parts of the world. Introducing this plant pathogen on a widespread basis could have unintended consequences for many non-target plant species.

Fungi can also be used to battle animal pests. Research teams reported in 2005 that two fungi, *Beauveria bassiana* and *Metarhizium anisopliae*, killed malaria-carrying mosquitoes when applied to mosquito netting. Certain fungi are already used against other insect pests, notably termites and aphids. In

Pathogenic Fungus, Parasitic Plant

The fungus *Fusarium oxysporum* is a potent pathogen of witchweed (*Striga*), a parasitic plant that attacks crops. The fungal spores are shown in blue; fungal filaments are in tan. Both colors were added to enhance this scanning electron micrograph.

An Alien Meal The tropical fungus whose fruiting body is growing on the stalk projecting from this ant's carcass developed internally in the host, from a spore ingested by the ant.

research conducted thus far, no insect pests have yet been known to develop resistance to fungi (as they can to DDT and other pesticides).

Of course, fungi don't need human help to find organisms to grow on. Fungal spores ingested by suitable animal hosts such as ants can germinate in the host's gut and develop into internal parasites. Absorbing nutrients from their unwitting hosts, some ingested fungi may eventually kill the host, producing new spores to infect new hosts as they do so.

Fungi interact with other organisms in many different ways, some of which are beneficial and some harmful to the other organisms. As we begin our study, recall that the fungi are more closely related to animals than to plants. That means molds and mushrooms are more closely related to you than they are to the plants discussed in Chapter 29.

IN THIS CHAPTER we will see that fungi differ from other eukaryotes in some very interesting ways. We will explore the diversity of body forms, reproductive structures, and life cycles that have evolved among six major groups of fungi. We will also examine the mutually beneficial associations of certain fungi with other organisms.

CHAPTER OUTLINE

- 30.1** What Is a Fungus?
- 30.2** How Do Fungi Interact with Other Organisms?
- 30.3** What Variations Exist among Fungal Life Cycles?
- 30.4** How Have Fungi Evolved and Diversified?

30.1 What Is a Fungus?

Modern fungi are believed to have evolved from a unicellular protist ancestor that had a flagellum. The probable common ancestor of the animals was also a flagellated microbial eukaryote that may have been similar to the existing choanoflagellates (see Figure 27.27). Current evidence suggests that today's choanoflagellates, fungi, and animals share a common ancestor not shared by other eukaryotes, and thus the three lineages are often grouped together as the *opisthokonts*. Synapomorphies that distinguish the fungi among the opisthokonts include absorptive heterotrophy and the presence of chitin in their cell walls (**Figure 30.1**). Molecular sequences of many genes also support these relationships among the opisthokonts. Thus, fungi represent one of four large, independent evolutionary origins of multicellular organisms (plants, brown algae, and animals are the other three).

The fungi live by **absorptive heterotrophy**: they secrete digestive enzymes outside their bodies to break down large food molecules in the environment, then absorb the breakdown products through the plasma membranes of their cells. Absorptive heterotrophy is successful in virtually every conceivable environment. Many fungi are **saprobies**, which absorb nutrients from dead organic matter. Others are **parasites**, which absorb nutrients from living hosts (such as the ant shown at the opening of this chapter). Still others are **mutualists** living in intimate associations with other organisms that benefit both partners.

We will discuss six major groups of fungi (**Table 30.1**): microsporidia, chytrids, zygospor fungi (Zygomycota), arbuscular mycorrhizal fungi (Glomeromycota), sac fungi (Ascomycota), and club fungi (Basidiomycota). The chytrids and zygospor fungi are not thought to represent monophyletic groups, but instead consist of several distantly related lineages that retain some ancestral features. Nonetheless, these groupings represent convenient categories for a general introduction to the fungi. The clades that are thought to be monophyletic within these two paraphyletic groupings are listed in Table 30.1. Major fungal groups were originally defined by their methods and structures for sexual reproduction and also, to a lesser extent, by other morphological differences. More recently, evidence from DNA analyses has established the placement of microsporidia among the fungi, the paraphyly of chytrids and zygospor fungi, the independence of arbuscular mycorrhizal fungi from the other fungal groups, and the monophyly of sac fungi and club fungi (**Figure 30.2**). The chytrids are almost all aquatic, but the other groups are mostly terrestrial.

30.1 Fungi in Evolutionary Context Absorptive heterotrophy and the presence of chitin in their cell walls distinguish the fungi from other opisthokonts.

Unicellular fungi are known as yeasts

Most fungi are multicellular, but single-celled species are found in most of the fungal groups. Unicellular forms of zygomycete fungi, sac fungi, and club fungi are called **yeasts** (Figure 30.3). Some fungi that have yeast stages also include a filamentous stage. Yeasts live in liquid or moist environments and absorb nutrients directly across their cell surfaces. The term “yeast” does not refer to a single taxonomic group of organisms but rather to a lifestyle that has evolved multiple times. The ease with which many yeast species are cultured, combined with their rapid growth rates, has made them ideal model organisms for study in the laboratory. They present many of the same advantages to laboratory investigators as do many bacteria, but since they are eukaryotes, they have genomic structure and cells that are much more like those of humans and other eukaryotes.

30.2 Phylogeny of the Fungi Microsporidia are reduced, parasitic fungi whose relationships among the fungi are uncertain. They may be the sister group of most other fungi or more closely related to particular groups of chytrids or zygomycete fungi. The dashed lines indicate that chytrids and zygomycete fungi are thought to be paraphyletic; the relationships of the lineages within these two informal groups (see Table 30.1) are not yet well resolved. The sac fungi and club fungi together form the clade Dikarya.

GO TO Web Activity 30.1 • Fungal Phylogeny

TABLE 30.1

Classification of the Fungi

GROUP	COMMON NAME	FEATURES
Microsporidia	Microsporidia	Intracellular parasites of animals; greatly reduced, among smallest eukaryotes known; polar tube used to infect hosts
Chytrids (paraphyletic) ^a Chytridiomycota Neocallimastigomycota Blastocladiomycota	Chytrids	Mostly aquatic and microscopic; zoospores have flagella
Zygomycota (paraphyletic) ^a Entomophthoromycotina Kickxellomycotina Mucoromycotina Zoopagomycotina	Zygomycete fungi	Reproductive structure is a unicellular zygospore with many diploid nuclei in a zygosporangium; no regularly occurring septa; usually no fleshy fruiting body
Glomeromycota	Arbuscular mycorrhizal fungi	Form arbuscular mycorrhizae on plant roots; only asexual reproduction is known
Ascomycota	Sac fungi	Sexual reproductive saclike structure known as an ascus, which contains haploid ascospores; perforated septa; dikaryon
Basidiomycota	Club fungi	Sexual reproductive structure is a basidium, a swollen cell at the tip of a specialized hypha that supports haploid basidiospores; perforated septa; dikaryon

^aThe formally named groups within the chytrids and Zygomycota are each thought to be monophyletic, but their relationships to one another (and to Microsporidia) are not yet well resolved.

Saccharomyces cerevisiae

30.3 Yeasts Are Unicellular Fungi Unicellular species of the zygomycota, sac fungi, and club fungi are known as yeasts. Many yeasts reproduce by budding—mitosis followed by asymmetrical cell division—as those shown here are doing.

The body of a multicellular fungus is composed of hyphae

The body of a multicellular fungus is called a **mycelium** (plural *mycelia*). A mycelium is composed of a mass of individual tubular filaments called **hyphae** (singular *hypha*; **Figure 30.4A,B**). The cell walls of the hyphae are greatly strengthened by microscopic fibrils of *chitin*, a nitrogen-containing polysaccharide. In some species of fungi, the hyphae are subdivided into cell-like compartments by *incomplete* cross-walls called **septa** (singular *septum*); these hyphae are referred to as **septate**. Septa do not completely close off compartments in the hyphae. Gaps in the septa known as *pores* allow organelles—sometimes even nuclei—to move in a controlled way between compartments (**Figure 30.4C**). In other species of fungi, the hyphae lack septa but may contain hundreds of nuclei; these hyphae are referred to as **coenocytic**. The coenocytic condition results from repeated nuclear divisions without cytokinesis.

Certain modified hyphae, called *rhizoids*, anchor some fungi to their substratum (the dead organism or other matter on which they feed). These rhizoids are not homologous to the rhizoids of plants, and they are not specialized to absorb nutrients and water. Parasitic fungi, however, may possess modified hyphae that take up nutrients from their host.

The total hyphal growth of a fungal mycelium (not the growth of an individual hypha) may exceed 1 kilometer a day! The hyphae may be widely dispersed to forage for nutrients

over a large area, or they may clump together in a cottony mass to exploit a rich nutrient source. In some members of certain fungal groups, when sexual spores are produced, portions of the mycelium become reorganized into a reproductive *fruiting body*, such as a mushroom. The mycelial mass is often far larger than the mushroom alone. The mycelium of one individual fungus in Michigan covers 15 hectares underground and weighs

30.4 Mycelia Are Made Up of Hyphae (A) The fruiting body of a club fungus is transient, but the filamentous, nutrient-absorbing mycelium can be long-lived and cover large areas. (B) The minute individual hyphae of fungal mycelia can penetrate small spaces. In this artificially colored micrograph, hyphae (yellow structures) of a dry-rot fungus are penetrating the xylem cavities and other woody tissues of a log. (C) The hyphae of septate fungal species are divided into organelle-containing compartments by porous septa, while coenocytic hyphae have no septa.

more than a blue whale. Aboveground, this individual is evident only as isolated clumps of mushrooms.

Fungi are in intimate contact with their environment

The filamentous hyphae of a fungus give it a unique relationship with its physical environment. The fungal mycelium has an enormous surface area-to-volume ratio compared with that of most large multicellular organisms. This large ratio is a marvelous adaptation for absorptive heterotrophy. Throughout the mycelium (except in fruiting structures), all of the hyphae are very close to their environmental food source.

The downside of the great surface area-to-volume ratio of the mycelium is its tendency to lose water rapidly in a dry environment. Thus fungi are most common in moist environments. You have probably observed the tendency of molds, toadstools, and other fungi to appear in damp places.

Another characteristic of some fungi is a tolerance for highly hypertonic environments (those with a solute concentration higher than their own; see Section 6.3). Many fungi are more resilient than bacteria in hypertonic surroundings. Jelly in the refrigerator, for example, will not become a growth medium for bacteria because it is too hypertonic to those organisms, but it may eventually harbor mold colonies. This presence of fungi in the refrigerator illustrates yet another trait of many fungi: tolerance of temperature extremes. Many fungi tolerate temperatures as low as -6°C , and some tolerate temperatures above 50°C .

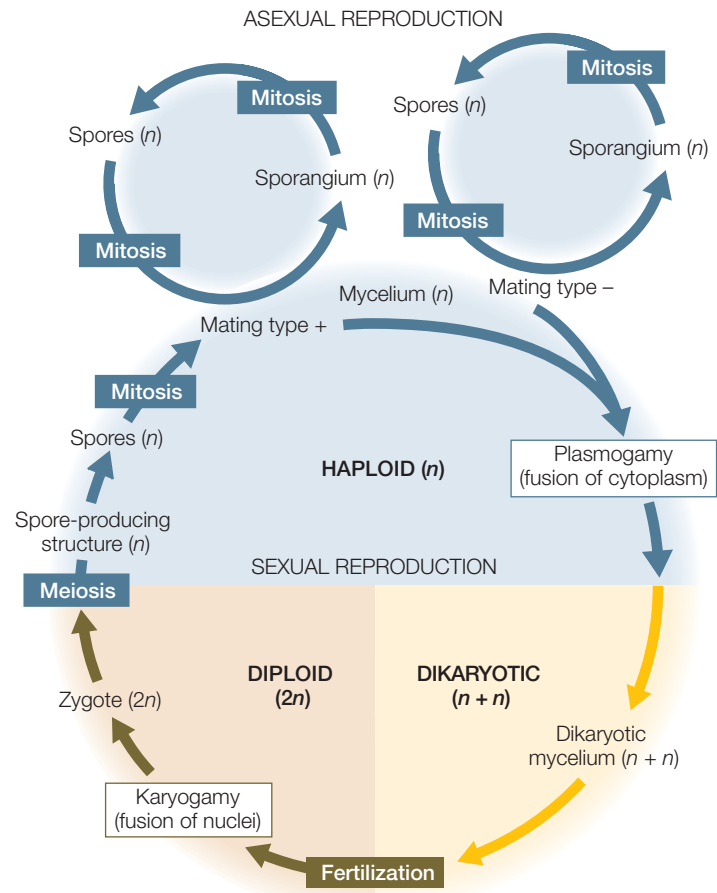

Fungi reproduce both sexually and asexually

Both asexual and sexual reproduction occur among the fungi (Figure 30.5). Asexual reproduction takes several forms:

- The production of (usually) haploid spores within structures called *sporangia*
- The production of haploid spores (not enclosed in sporangia) at the tips of hyphae; such spores are called *conidia* (Greek *konis*, “dust”)
- Cell division by unicellular fungi—either a relatively equal division of one cell into two (*fission*) or an asymmetrical division in which a smaller daughter cell is produced (*budding*)
- Simple breakage of the mycelium

Asexual reproduction in fungi can be spectacular in terms of spore quantity. A 2.5-centimeter colony of *Penicillium*, the mold that produces the antibiotic penicillin, can produce as many as 400 million conidia. The air we breathe contains as many as 10,000 fungal spores per cubic meter.

Sexual reproduction is rare (or even unknown) in some groups of fungi but common in others. Sexual reproduction may not occur, or it may occur so rarely that biologists have never observed it. Species in which no sexual stage has been observed were once placed in a separate taxonomic group, because the sexual life cycle was considered necessary for classifying fungi. Now, however, these species can be related to other species of fungi through analysis of their DNA sequences.

30.5 Asexual and Sexual Reproduction in a Fungal Life Cycle

Environmental conditions may determine which mode of reproduction takes place at a given time. In the sexual phase, many fungi are characterized not by male and female individuals but by genetically distinct mating types (top of figure).

When it does occur, sexual reproduction in many fungi features an interesting twist. There is often no morphological distinction between female and male structures, or between female and male individuals. Rather, there is a genetically determined distinction between two or more **mating types**. Individuals of the same mating type cannot mate with one another, but they can mate with individuals of another mating type within the same species, thus preventing self-fertilization. Individuals of different mating types differ genetically but are often visually and behaviorally indistinguishable. Many protists also have mating type systems.

Fungi reproduce sexually when hyphae (or, in one fungal group, motile cells) of different mating types meet and fuse. In many fungi, the zygote nuclei formed by sexual reproduction are the only diploid nuclei in the life cycle. These nuclei undergo meiosis, producing haploid nuclei that become incorporated into spores. Haploid fungal spores, whether produced sexually or asexually, germinate, and their nuclei divide mitotically to produce haploid hyphae.

We will discuss reproduction in fungi in more detail in Section 30.3.

30.1 RECAP

The rapid growth and large surface area-to-volume ratio of fungal hyphae allow fungi to practice absorptive heterotrophy efficiently in moist environments. Both asexual and sexual reproduction occur in fungi; sexual reproduction occurs between different mating types.

- Describe the relationship between fungal structure and absorptive heterotrophy. **See p. 627**
- Explain the concept of mating types. How is this different from male and female sexes? **See p. 630**

Fungi are important components of healthy ecosystems. Fungi interact with other organisms in many ways, some of which are harmful and some beneficial to other organisms.

30.2 How Do Fungi Interact with Other Organisms?

Without the fungi, our planet would be very different. Picture Earth with only a few stunted plants and watery environments choked with the remains of dead organisms. Fungi do much of Earth's garbage disposal. Fungi that absorb nutrients from dead organisms not only help clean up the landscape and form soil but also play a key role in recycling mineral elements. Furthermore, the colonization of the terrestrial environment was made possible in large part by associations fungi formed with other organisms.

Saprobic fungi are critical to the planetary carbon cycle

Saprobic fungi (those that consume nonliving organic matter), along with bacteria, are the major decomposers on Earth, contributing to decay and thus to recycling the elements used by living things. In forests, for example, the mycelia of fungi absorb nutrients from fallen trees, thus decomposing their wood. Fungi are the principal decomposers of cellulose and lignin, the main components of plant cell walls (most bacteria cannot break down these materials). Other fungi produce enzymes that decompose keratin and thus break down animal structures such as hair and nails.

Were it not for the fungal decomposers, Earth's carbon cycle would fail: great quantities of carbon atoms would remain trapped forever on forest floors and elsewhere (see Chapter 58). Instead, those carbon atoms are returned to the atmosphere in the form of respiratory CO_2 , available for photosynthesis by plants.

In fact, there was a time when populations of saprobic fungi declined significantly. During the Carboniferous period, plants in the vast tropical swamps died and began to form peat (see Section 28.4). Peat formation led to acidification of the swamps; that acidity, in turn, drastically reduced the fungal population. The result? With the decomposers largely absent, large quantities of peat remained on the swamp floor and over time were converted into coal.

In contrast to their decline during the Carboniferous, fungi did very well at the end of the Permian, a quarter of a billion years ago, when the aggregation of continents produced volcanic eruptions that triggered a planetwide extinction event of many other organisms (see Chapter 25). The fossil record shows that even though 96 percent of all species became extinct, fungi flourished, demonstrating both their hardiness and their role in recycling the elements in the dead bodies of plants and animals.

Many saprobic fungi can be grown on artificial media, and it is relatively easy to perform experiments to determine their exact nutritional requirements. Sugars are the favored source of carbon for saprobic fungi. Most fungi obtain nitrogen from proteins or the products of protein breakdown. Many fungi can use nitrate (NO_3^-) or ammonium (NH_4^+) ions as their sole source of nitrogen. No known fungus can get its nitrogen directly from inorganic nitrogen gas as can some bacteria and plant-bacteria associations (that is, fungi cannot "fix" nitrogen; see Section 36.4). Nutritional studies also reveal that most fungi are unable to synthesize certain vitamins and must absorb them from their environment. However, fungi can synthesize some vitamins that animals cannot. Like all organisms, fungi also require some mineral elements.

What happens when a fungus faces a dwindling food supply? A common strategy is to reproduce rapidly and abundantly. When conditions are good, fungi produce great quantities of spores, but the rate of spore production is commonly even higher when nutrient supplies go down. The spores may then remain dormant until conditions improve, or may be dispersed to areas where nutrient supplies are higher.

Not only are fungal spores abundant in number, but they are extremely tiny and easily spread by wind or water (**Figure 30.6**). This virtually assures that the individual that produced them

Lycoperdon pyriforme

30.6 Spores Galore Puffballs (a type of club fungus) disperse trillions of spores in great bursts. Few of the spores travel very far, however; some 99 percent of them fall within 100 meters of the parent puffball.

will have many progeny, which may be scattered over great distances. No wonder we find fungi just about everywhere.

Fungi may engage in parasitic and predatory interactions

Whereas saprobic fungi obtain their energy, carbon, and nitrogen directly from dead organic matter, other species of fungi obtain their nutrition from parasitic—and even predatory—interactions.

PARASITIC FUNGI Biologists distinguish between two classes of parasitic fungi, based on the degree of dependence on their host species. *Facultative* parasites can attack living organisms but can also grow by themselves, including on artificial media. *Obligate* parasites can grow only on their specific living host, usually a plant species. Because their growth depends on a living host, obligate parasites have specialized nutritional requirements.

The filamentous structure of fungal hyphae is especially well suited to a life of absorbing nutrients from plants. The slender hyphae of a parasitic fungus can invade a plant through stomata, through wounds, or in some cases, by direct penetration of epidermal cell walls (**Figure 30.7A**). Once inside the plant, the hyphae branch out to expand the mycelium. Some hyphae produce **haustoria**, branching projections that push through cell walls into living plant cells, absorbing the nutrients within those cells. The haustoria do not break through the plant cell plasma membranes inside the cell walls; they simply invaginate into the membranes, with the plasma membrane fitting them like a glove (**Figure 30.7B**). Fruiting structures may form, either within the plant body or on its surface in a symbiotic relationship that is usually not lethal to the plant. Some parasitic fungi, however, are *pathogenic*, sickening or even killing the hosts from which they derive nutrition.

PATHOGENIC FUNGI Although most human diseases are caused by bacteria or viruses, fungal pathogens are a major cause of

death among people with compromised immune systems. Most people with AIDS die of fungal diseases, such as the pneumonia caused by *Pneumocystis jirovecii* or incurable diarrhea caused by other fungi. *Candida albicans* and certain other yeasts also cause severe diseases, such as esophagitis (which impairs swallowing), in individuals with AIDS and in individuals taking immunosuppressive drugs. Fungal diseases are a growing international health problem, requiring vigorous research. Our limited understanding of the basic biology of these fungi still hampers our ability to treat the diseases they cause. Various fungi cause other, less threatening human diseases, such as ringworm and athlete's foot.

The worldwide decline of amphibian species has been linked to the spread of a chytrid fungus, *Batrachochytrium dendrobatidis*. Genetic analyses indicate that the fungus populations attacking amphibian populations around the world are genetically almost identical, which suggests a recent introduction of the fungus across the globe. This chytrid appears to be endemic to southern Africa, and its spread around the world may have initiated in the 1930s with exports of the African clawed frog (*Xenopus laevis*), which was once widely used in human pregnancy tests.

Fungi are by far the most important plant pathogens, causing crop losses amounting to billions of dollars. Bacteria and viruses are less important as plant pathogens. Major fungal diseases of crop plants include black stem rust of wheat and other diseases of wheat, corn, and oats. The agent of black stem rust is *Puccinia graminis*, which has a complicated life cycle that involves two plant hosts (wheat and barberry). In an epidemic in 1935, *P. graminis* was responsible for the loss of about one-fourth of the entire wheat crop in Canada and the United States. However, as we saw at the beginning of this chapter, pathogenic fungi that kill certain weed species can be a boon to agriculture.

30.7 Attacks on a Leaf (A) The thin, light-colored structures in the micrograph are hyphae of the parasitic fungus *Blumeria graminis* growing on the dark surface of the leaf of a grass. (B) Haustoria are fungal hyphae that push into the living cells of plants, from which they absorb nutrients.

30.8 Some Fungi Are Predators A nematode is trapped by hyphal rings of the soil-dwelling fungus *Arthrobotrys dactyloides*.

PREDATORY FUNGI Some fungi have adaptations that enable them to function as active predators, trapping nearby microscopic protists or animals. The most common predatory strategy seen in fungi is to secrete sticky substances from the hyphae so that passing organisms stick tightly to them. The hyphae then quickly invade the prey, growing and branching within it, spreading through its body, absorbing nutrients, and eventually killing it.

A more dramatic adaptation for predation is the constricting ring formed by some species of *Arthrobotrys*, *Dactylaria*, and *Dactylella* (Figure 30.8). All of these fungi grow in soil. When nematodes (tiny roundworms) are present in the soil, these fungi form three-celled rings with a diameter that just fits a nematode. A nematode crawling through one of these rings stimulates the fungus, causing the cells of the ring to swell and trap the worm. Fungal hyphae quickly invade and digest the unlucky victim.

Some fungi engage in relationships beneficial to both partners

Certain kinds of relationships between fungi and other organisms have nutritional consequences for both partners. Two of these relationships are highly specific and are **symbiotic** (the partners live in close, permanent contact with one another) as well as **mutualistic** (the relationship benefits both partners; see Chapter 56).

Lichens are associations of a fungus with a cyanobacterium, a unicellular photosynthetic alga, or both. **Mycorrhizae** (singular *mycorrhiza*) are associations between fungi and the roots of plants. In these associations, the fungus obtains organic compounds from its

photosynthetic partner and provides it with minerals and water in return, so that the partner's nutrition is also promoted. In fact, many plants grow very poorly without their fungal partners.

LICHENS A lichen is not a single organism but rather a meshwork of two radically different organisms: a fungus and a photosynthetic microorganism. Together the organisms constituting a lichen can survive some of the harshest environments on Earth. The biota of Antarctica, for example, features more than a hundred times as many species of lichens as of plants.

In spite of their hardiness, lichens are highly sensitive to air pollution because they are unable to excrete any toxic substances they absorb. This sensitivity means that lichens are good biological indicators of air pollution levels. It also explains why they are not commonly found in heavily industrialized regions or large cities.

The fungal components of most lichens are sac fungi (Ascomycota), which also include various cup fungi, yeasts, and molds such as the *Fusarium* mentioned at the beginning of the chapter. The photosynthetic component of a lichen is most often a unicellular green alga, but it can be a cyanobacterium, or can include both. Relatively little experimental work has focused on lichens, perhaps because they grow so slowly—typically less than 1 centimeter in a year.

There are nearly 30,000 described “species” of lichens, each of which is assigned the name of its fungal component. These fungal components may constitute as many as 20 percent of all fungal species. Some of these fungi are able to grow independently without a photosynthetic partner, but most have never been observed in nature other than in a lichen association.

Lichens are found in all sorts of exposed habitats: on tree bark, on open soil, and on bare rock. Reindeer moss (not a moss at all, but the lichen *Cladonia subtenuis*) covers vast areas in Arctic, sub-Arctic, and boreal regions, where it is an important part of the diets of reindeer and other large mammals. Lichens come in various forms and colors. *Crustose* (crustlike) lichens look like colored powder dusted over their substratum (Figure 30.9A); *foliose* (leafy) and *fruticose* (shrubby) lichens may have complex forms (Figure 30.9B,C).

30.9 Lichen Body Forms Lichens fall into three principal classes based on their body form. (A) Two crustose lichens are growing on the surface of exposed rock. (B) Foliose lichens have a leafy appearance. (C) The brown and orange growth is of “shrubby” fruticose lichens.

The most widely held interpretation of the lichen relationship is that it is a mutually beneficial symbiosis (a *mutualism*). The hyphae of the fungal mycelium are tightly pressed against the algal or cyanobacterial cells and sometimes even invade them without breaching the plasma membrane (as we described earlier for haustoria in parasitic fungi of plants; see Figure 30.7). The bacterial or algal cells not only survive these indignities but continue their growth and photosynthesis. In fact, the algal cells in a lichen “leak” photosynthetic products at a greater rate than do similar cells growing on their own, and photosynthetic cells from lichens grow more rapidly on their own than when associated with a fungus. On this basis, we could consider lichen fungi to be parasitic on their photosynthetic partners. In many places where lichens grow, however, the photosynthetic cells would not grow at all on their own.

Lichens can reproduce simply by fragmentation of the vegetative body (the *thallus*), or by means of specialized structures called *soredia* (singular *soredium*). Soredia consist of one or a few photosynthetic cells bound by fungal hyphae. The soredia become detached from the lichen, are dispersed by air currents, and upon arriving at a favorable location, develop into a new lichen thallus. Alternatively, the fungal partner may go through its sexual cycle, producing haploid spores. When these spores are discharged, however, they disperse alone, unaccompanied by the photosynthetic partner.

Visible in a cross section of a typical foliose lichen are a tight upper region of fungal hyphae, a layer of photosynthetic cyanobacteria or algae, a looser hyphal layer, and finally hyphal rhizoids that attach the entire structure to its substratum (Figure 30.10). The meshwork of fungal hyphae takes up some nutrients needed by the photosynthetic cells and provides a suitably moist environment for them by holding water tenaciously. The fungi derive fixed carbon from the photosynthetic products of the algal or cyanobacterial cells.

Lichens are often the first colonists on new areas of bare rock. They get most of the nutrients they need from the air and rainwater, augmented by minerals absorbed from dust. A lichen begins to grow shortly after a rain, as it begins to dry. As it grows, the lichen acidifies its environment slightly, and this acidity contributes to the slow breakdown of rocks, an early step in soil formation. After further drying, the lichen’s photosynthesis ceases. The water content of the lichen may drop to less than 10 percent of its dry weight, at which point it becomes highly insensitive to extremes of temperature.

MYCORRHIZAE Many vascular plants depend on a symbiotic association with fungi. Unassisted, the root hairs of such plants often do not take up enough water or minerals to sustain growth. However, their roots usually do become infected with fungi, forming an association called a mycorrhiza. Mycorrhizae are of two types, based on whether or not the fungal hyphae penetrate the plant cell walls.

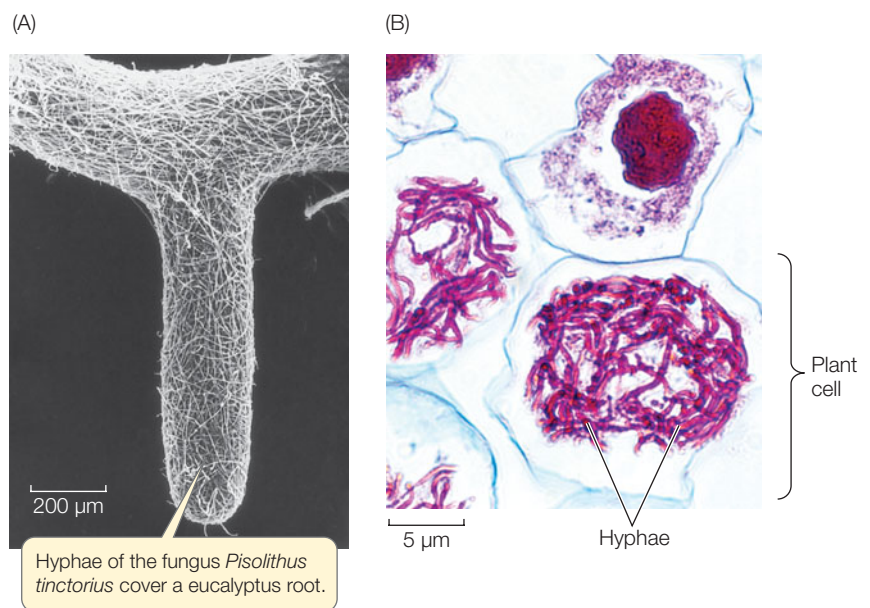

In *ectomycorrhizae*, the fungus wraps around the root, and its mass is often as great as that of the root

30.10 Lichen Anatomy Cross section showing the layers of a foliose lichen and the release of soredia.

itself (Figure 30.11A). The fungal hyphae wrap around individual cells in the root but do not penetrate the cell walls. An extensive web of hyphae penetrates the soil in the area around the root, so that up to 25 percent of the soil volume near the root may be fungal hyphae. The hyphae attached to the root increase the surface area for the absorption of water and minerals, and the mass of the mycorrhiza in the soil, like a sponge, holds water efficiently in the neighborhood of the root. Infected roots characteristically are short, swollen, and club-shaped, and they lack root hairs.

The fungal hyphae of *arbuscular mycorrhizae* enter the root and penetrate the cell wall of the root cells, forming arbuscular (treelike) structures inside the cell wall but outside the plasma membrane. These structures, like the haustoria of par-

30.11 Mycorrhizal Associations (A) Ectomycorrhizal fungi wrap themselves around a plant root, increasing the area available for absorption of water and minerals. (B) Hyphae of arbuscular mycorrhizal fungi infect the root internally and penetrate the root cell walls, branching within the cells and forming treelike (arbuscular) structures that provide the plant with nutrients. Hyphae fill much of the cell outside the nucleus and invaginate the plasma membrane without puncturing it.

asitic fungi and the contact regions of fungi and algal cells in lichens, become the primary site of exchange between plant and fungus (**Figure 30.11B**). As in the ectomycorrhizae, the fungus forms a vast web of hyphae leading from the root surface into the surrounding soil.

The mycorrhizal association is important to both partners. The fungus obtains needed organic compounds, such as sugars and amino acids, from the plant. In return, the fungus, because of its very high surface area-to-volume ratio and its ability to penetrate the fine structure of the soil, greatly increases the plant's ability to absorb water and minerals (especially phosphorus). The fungus may also provide the plant with certain growth hormones and may protect it against attack by disease-causing microorganisms. Plants that have active arbuscular mycorrhizae typically are a deeper green and may resist drought and temperature extremes better than plants of the same species that have little mycorrhizal development. Attempts to introduce some plant species to new areas have failed until a bit of soil from the native area (presumably containing the fungus necessary to establish mycorrhizae) was provided. Trees without ectomycorrhizae will not grow well in the absence of abundant nutrients and water, so the health of our forests depends on the presence of ectomycorrhizal fungi.

The partnership between plant and fungus results in a plant that is better adapted for life on land. It has been suggested that the evolution of mycorrhizae was the single most important step in the colonization of the terrestrial environment by living things. Fossils of mycorrhizal structures 460 million years old have been found. Some liverworts, which are representatives of one of the oldest lineages of terrestrial plants (see Section 28.4), form mycorrhizal associations with fungi.

Certain plants that live in nitrogen-poor habitats, such as cranberry bushes and orchids, invariably have mycorrhizae. Orchid seeds will not germinate in nature unless they are already infected by the fungus that will form their mycorrhizae. Plants that lack chlorophyll always have mycorrhizae, which they often share with the roots of green, photosynthetic plants. In effect, these plants without chlorophyll are feeding on nearby green plants, using the fungus as a bridge.

Biologists had long suspected that roots secrete a chemical signal that enables fungi to find and invade them to form arbuscular mycorrhizae. This was proved to be correct in 2005 when researchers succeeded in isolating the signaling compound. Might the compound also be used by parasitic plants to attack their host plants? Indeed it is. *Striga*, discussed at the beginning of this chapter, turns out to be one of the parasitic plants that use exactly this signal. Thus, in attracting its helper fungus, a plant may also attract a dangerous parasite. The *Striga* story is continued at the end of Chapter 36.

Endophytic fungi protect some plants from pathogens, herbivores, and stress

In a tropical rainforest, 10,000 or more fungal spores land on a single leaf each day. Some are plant pathogens, some do not attack the plant at all, and some invade the plant in a beneficial way. Fungi that live within aboveground parts of plants

without causing obvious deleterious symptoms are called **endophytic fungi**. Recent research has shown that endophytic fungi are abundant in plants in all terrestrial environments.

Grasses with endophytic fungi are more resistant to pathogens and to insect and mammalian herbivores than are grasses lacking endophytes. The fungi produce alkaloids (nitrogen-containing compounds) that are toxic to animals. The alkaloids do not harm the host plant; in fact, some plants produce alkaloids (such as nicotine) themselves. The fungal alkaloids also increase the ability of host plants to resist stress of various types, including drought (water shortage) and salty soils. Such resistance is useful in agriculture.

The role, if any, of endophytic fungi in most broad-leaved plants is unclear, however. They may convey protection against pathogens or simply occupy space within leaves, without conferring any benefit but also without doing harm. The benefit, in fact, might be all for the fungus.

30.2 RECAP

Fungi interact with other organisms in many ways, both harmful and beneficial. Lichens are mutualistic associations of a fungus with an alga and/or a cyanobacterium. Mycorrhizae are associations of fungi and the roots of plants; they are essential for the survival of most plant species.

- What is the role of fungi in Earth's carbon cycle? **See p. 631**
- Describe the nature and benefits of the lichen association. **See pp. 633–635**
- Why do plants grow better in the presence of mycorrhizal fungi? **See p. 635**

One of the most important criteria for assigning fungi to taxonomic groups, before molecular techniques clarified phylogenetic relationships among fungi, was the nature of their life cycles.

30.3 What Variations Exist among Fungal Life Cycles?

Different fungal groups have different life cycles. Some chytrids feature alternation of generations, a type of life cycle found in all plants and some protists. The life cycles of sac fungi and club fungi feature a unique stage called a *dikaryon*, in which a single hypha has two genetically distinct nuclei. In this section we examine the diverse life cycles of major groups of fungi.

Alternation of generations is seen among some aquatic chytrids

The alternation between multicellular haploid (n) and multicellular diploid ($2n$) generations that evolved in plants and certain protist groups (see Section 28.2) is seen in some chytrids as well (**Figure 30.12A**). Alternation of generations is not usual for the life cycles of other fungal groups. The basal chytrids, which are

(A) Chytrids

The life cycle of some aquatic chytrids features alternation of generations.

**(B) Zygosporangium fungi (Zygomycota)**

The sporangium of zygosporangium fungi contains haploid nuclei that are incorporated into spores.

**30.12 Sexual Life Cycles Vary among Different Groups of Fungi**

(A) The chytrids are the only fungi that possess flagella at any stage of the life cycle. Their flagellated gametes and zoospores link them to the animals. (B) A multinucleate zygospore is unique to the zygosporangium fungi. (C,D) The dikaryon stage is definitive of the sac fungi (C) and the club fungi (D). Mycorrhizal fungi are only known to reproduce asexually and are not depicted here.

(C) Sac fungi (Ascomycota)

The products of meiosis in sac fungi are borne in a microscopic sac called an ascus. The fleshy fruiting bodies consist of both dikaryotic and haploid hyphae.

40 μ m

Ascus

**(D) Club fungi (Basidiomycota)**

In club fungi, the products of meiosis are borne exposed on pedestals called basidia. Fruiting bodies consist solely of dikaryotic hyphae, and the dikaryotic phase can last a long time.

aquatic, possess flagellated gametes and flagellated spores. Flagella have been lost in the terrestrial fungi.

What are the consequences of alternation of generations in the chytrids? It is possible that the multicellular haploid organisms serve as a “filter” for harmful mutations. A haploid individual with such a mutation would die, and the mutant allele would not be passed to progeny. In chytrids with alternation of generations, the multicellular diploid stage includes a resistant structure capable of withstanding freezing or drying.

Terrestrial fungi have separate fusion of cytoplasm and nuclei

Although the terrestrial fungi grow in moist places, their gamete nuclei are not motile and are not released into the environment. Instead, the cytoplasm of two individuals of different mating types fuse (**plasmogamy**) before their nuclei fuse (**karyogamy**). Therefore, liquid water is not required for fertilization.

Zygospore fungi reproduce sexually when adjacent hyphae of two different mating types release pheromones, which cause them to grow toward each other. These hyphae produce gametangia, which fuse to form a zygosporangium (**Figure 30.12B**). Sometime later, the gamete nuclei now contained within the zygosporangium fuse to form a unicellular multinucleate **zygospore**, which is the basis of the name of the zygospore fungi. The zygosporangium develops a thick, multilayered wall that protects the zygospore. The highly resistant zygospore may remain dormant for months before its nuclei undergo meiosis and a *sporangiophore* sprouts, bearing a *sporangium*. The sporangium contains the products of meiosis: haploid nuclei that are incorporated into spores. These spores disperse and germinate to form a new generation of haploid hyphae.

The dikaryotic condition is a synapomorphy of sac fungi and club fungi

Certain hyphae of terrestrial sac fungi and club fungi have a nuclear configuration other than the familiar haploid or diploid states (**Figures 30.12C,D**). In these fungi, sexual reproduction begins in two distinctive steps: karyogamy (fusion of nuclei) occurs long after plasmogamy (fusion of cytoplasm), so that *two genetically different haploid nuclei coexist and divide within the same hypha*. Such a hypha is called a **dikaryon** (“two nuclei”). Because the two nuclei differ genetically, such a hypha is also called a *heterokaryon* (“different nuclei”) and is indicated as $n + n$. This dikaryon is a synapomorphy of these two groups, which are placed together in the clade called Dikarya.

Eventually, specialized fruiting structures form, within which the pairs of genetically dissimilar nuclei—one from each parent—fuse, giving rise to zygotes long after the original “mating.” The diploid zygote nucleus undergoes meiosis, producing four haploid nuclei. The mitotic descendants of those nuclei

become spores, which germinate to give rise to the next generation—usually of hyphae.

A life cycle with a dikaryon stage has several unusual features. First, there are no gamete *cells*, only gamete *nuclei*. Second, the only true diploid structure is the zygote, although for a long period the genes of both parents are present in the dikaryon and can be expressed. In effect, the hypha is neither diploid ($2n$) nor haploid (n); rather, it is *dikaryotic* ($n + n$). A harmful recessive mutation in one nucleus may be compensated for by a normal allele on the same chromosome in the other nucleus, and dikaryotic hyphae often have characteristics that are different from their n or $2n$ products. The dikaryotic condition is perhaps the most distinctive of the genetic peculiarities of the fungi.

The dikaryotic condition is short-lived in most sac fungi but often lasts for months or even years in club fungi. Club fungi have an elegant mechanism that ensures that the dikaryotic condition is maintained as new cells are formed. One consequence of a sustained dikaryotic condition is an increased opportunity for fusions of hyphae of two different mating types before fruiting bodies are formed.

30.3 RECAP

Some chytrid fungi exhibit alternation of generations between haploid and diploid multicellular states. The life cycle of zygospore fungi includes a resistant-spore stage with many diploid nuclei. The sac fungi and club fungi share a derived dikaryotic condition, in which two genetically different haploid nuclei coexist in the same cell.

- What is the role of the zygospore in the life cycle of zygospore fungi? **See p. 638**
- Explain the phenomenon of dikaryosis in terms of plasmogamy and karyogamy. **See p. 638**

In examining the most important properties of the fungi as a clade, we have often drawn examples from specific groups. Now let’s look in more detail at the diversity and evolution of fungi.

30.4 How Have Fungi Evolved and Diversified?

In this section we examine representative species from each of the major groups of fungi (see Table 30.1). Recall that the informal groups called chytrids and zygospore fungi are not clades, but the various lineages within these informal groups shown in Table 30.1 are each thought to be monophyletic. In addition, Microsporidia, Glomeromycota (arbuscular mycorrhizal fungi), Ascomycota (sac fungi), and Basidiomycota (club fungi) are all clades, and the latter two groups form a monophyletic group called Dikarya.

Microsporidia are highly reduced, parasitic fungi

Microsporidia are unicellular fungi with walls that contain chitin. They are among the smallest eukaryotes known, with infective spores that are only 1–40 μm in diameter. About 1,500 species have been described, but many more species are thought to exist. Their relationships among the eukaryotes have puzzled biologists for many decades.

Microsporidia lack true mitochondria, although they have reduced structures known as *mitosomes* that are derived from mitochondria. Unlike mitochondria, however, mitosomes contain no DNA; the mitochondrial genome has been completely transferred to the nucleus. Because microsporidia lack mitochondria, biologists initially suspected that they represent an early lineage of eukaryotes that branched before the endosymbiotic event from which mitochondria evolved. The presence of the mitosome, however, indicates that this hypothesis is incorrect. DNA sequence analysis has confirmed that microsporidia are in fact highly reduced, parasitic fungi, although the exact placement of microsporidia among the fungal lineages is still being investigated.

Microsporidia are obligate intracellular parasites of animals, especially of insects, crustaceans, and fishes. Some species are known to infect mammals, including humans. Most infections by microsporidia cause chronic diseases in the hosts, with effects that include weight loss, reduced fertility, and shortened life span. The host cell is penetrated by a *polar tube* of the microsporidian spore, and the contents of the spore are injected into the host (**Figure 30.13**). The sporoplasm then replicates within the host cell and produces new infective spores. The life cycle of some species is complex and involves multiple hosts, whereas other species in-

30.13 Spores of Microsporidia Inject Host Cells The polar tubes of microsporidia spores transfer their contents into the host's cells. This species infects many animals, including humans.

fect a single host. In some insects, the parasitic microsporidia are transmitted vertically (i.e., from parent to offspring).

Chytrids are the only fungi with flagella

Chytrids include several distinct lineages of aquatic microorganisms once classified with the protists. However, morphological evidence (cell walls that consist primarily of chitin) and molecular evidence support their classification as basal fungi. In this book we use the term “chytrid” to refer to all three of the formally named clades shown as chytrids in Table 30.1, but some mycologists use this term to refer to one particular clade, the Chytridiomycota. There are fewer than 1,000 described species among the three taxonomic groups of chytrids.

Like the animals (and many other eukaryotes), most chytrids possess flagellated gametes. The retention of this character reflects the aquatic environment in which fungi first evolved. Chytrids are the only fungi that have flagella at any life cycle stage.

Chytrids may be parasitic (on organisms such as algae, mosquito larvae, and nematodes) or saprobic. Some have complex mutualistic relationships in the compound stomachs of foregut-fermenting animals such as cattle and deer. Many chytrids live in freshwater habitats or in moist soil, but some are marine. Some chytrids are unicellular, others have rhizoids (**Figure 30.14**), and still others have coenocytic hyphae. Chytrids reproduce both sexually and asexually, but they do not have a dikaryon stage.

Allomyces, a well-studied genus of chytrids, is a member of the group of chytrids (**Blastocladiomycota**; see Table 30.1) that displays alternation of generations. Both female and male gametes have flagella. The motile female gamete produces a *pheromone*, a chemical signal that attracts the swimming male gamete. The two gametes fuse, and then their nuclei fuse to form a diploid zygote that germinates to form a diploid mycelium. This is the diploid generation. Mitosis and cytokine-

30.14 A Chytrid Branched rhizoids emerge from the sporangium of a mature chytrid.

sis in the zygote give rise to a small, multicellular, diploid organism, which produces numerous diploid flagellated zoospores. These diploid zoospores disperse and germinate to form more diploid organisms. Eventually, the diploid organisms produce a second kind of zoosporangium, a thick-walled resting sporangium, that can survive unfavorable conditions such as dry weather or freezing. Nuclei in the resting sporangium undergo meiosis, giving rise to haploid zoospores that are released into the water and begin the haploid stage of the life cycle.

The haploid mycelium is similar to that of the diploid mycelium, but it matures to produce female and male *gametangia* (gamete cases; see Figure 30.12A). Note that meiosis occurred in the earlier diploid generation and not immediately before gamete formation, as it does in animals. This life cycle with meiosis in spore formation is similar to the alternation of generations seen in plants.

Zygospor fungi are terrestrial saprobes, parasites, and mutualists

Zygospor fungi (Zygomycota) include four major lineages of terrestrial fungi that live on soil as saprobes, as parasites of insects and spiders, or as mutualists of other fungi and invertebrate animals. They produce no cells with flagella, and only one diploid cell—the zygote—appears in the entire life cycle. Their hyphae are coenocytic. The mycelium spreads over its substratum, growing forward by means of vegetative hyphae. Most species do not form a fleshy fruiting structure; rather, the hyphae spread in an apparently random fashion, with occasional stalked **sporangiophores** reaching up into the air (Figure 30.15). These reproductive structures may bear one or many sporangia.

More than a thousand species of zygospor fungi have been described. One species you may have seen is *Rhizopus stolonifer*, the black bread mold. *Rhizopus* produces many stalked sporangiophores, each bearing a single sporangium containing hundreds of minute spores (see Figure 30.12B). As in other filamentous fungi, the spore-forming structure is separated from the rest of the hypha by a wall.

Arbuscular mycorrhizal fungi form symbioses with plants

Arbuscular mycorrhizal fungi (Glomeromycota) are terrestrial fungi that associate with plant roots in a close symbiotic relationship (see Figure 30.11B). As we noted earlier in this chapter, these associations are important for most species of plants, which benefit from absorption of water and mineral nutrients through the large surface area of the fungal mycelium. Many of the fungi found in soils are arbuscular mycorrhizal fungi. Fewer than 200 species have been described, but 80 to 90 percent of all plants have associations with them. Molecular systematic studies have suggested that arbuscular mycorrhizal fungi are the sister group to Dikarya (sac fungi and club fungi), although this position is still subject to some debate.

30.15 Zygospor Fungi Produce Sporangiophores These transparent structures are sporangiophores (spore-bearing hyphae) growing on decomposing animal dung. Sporangiophores grow toward the light and end in tiny sporangia, which the filamentous sporangiophores can eject as far as 2 meters. Animals ingest those sporangia that land on grass and then disseminate the spores in their feces.

The hyphae of arbuscular mycorrhizal fungi are coenocytic. These fungi use glucose from their plant partners as their primary energy source, converting the glucose to other, fungus-specific sugars that cannot return to the plant. Arbuscular mycorrhizal fungi reproduce asexually; there is not yet any direct evidence that they reproduce sexually.

The next two fungal clades that we'll discuss, the sac fungi and the club fungi, are related groups with many similarities, including a dikaryon stage and septate hyphae. The two clades differ in sexual reproductive structure; in the sac fungi the sexual spores are borne inside a sac, whereas in the club fungi they are borne on a pedestal.

The sexual reproductive structure of sac fungi is the ascus

The **sac fungi** (Ascomycota) are a large and diverse group of fungi found in marine, freshwater, and terrestrial habitats. There are approximately 64,000 known species, nearly half of which are the fungal partners in lichens. The hyphae of sac fungi are segmented by more or less regularly spaced septa. A pore in each septum permits extensive movement of cytoplasm and organelles (including nuclei) from one segment to the next.

Sac fungi are distinguished by the production of sacs called **asci** (singular *ascus*), which after meiosis and cytoplasmic cleavage contain sexually produced haploid *ascospores* (see Figure 30.12C). The ascus is the characteristic sexual reproductive structure of the sac fungi. The sac fungi contain many diverse groups

and in the past were divided on the basis of whether or not the asci are contained within a specialized fruiting structure known as an **ascoma** (plural *ascomata*), and on the morphology of this fruiting structure. DNA sequence analyses have resulted in a revision of these traditional groupings, however.

Some species of sac fungi are unicellular yeasts. Perhaps the best known of the 800 or so species of yeasts in this group is baker's, or brewer's, yeast (*Saccharomyces cerevisiae*; see Figure 30.3). These yeasts are among the most important domesticated fungi. *S. cerevisiae* metabolizes glucose obtained from its environment to ethanol and carbon dioxide by fermentation. It forms carbon dioxide bubbles in bread dough and gives baked bread its light texture. Although they are baked away in bread making (which produces the pleasant aroma of baking bread), the ethanol and carbon dioxide are both retained when yeast ferments grain into beer. Other yeasts live on fruits such as figs and grapes and play an important role in the making of wine. Many other yeasts are associated with insects; in the guts of some insects, yeasts provide enzymes for digestion of refractory materials, especially cellulose.

Sac fungus yeasts reproduce asexually by budding. Sexual reproduction takes place when two adjacent haploid cells of opposite mating types fuse. In some species, the resulting zygote buds to form a diploid cell population. In others, the zygote nucleus undergoes meiosis immediately; when this happens, the entire cell becomes an ascus. Depending on whether the products of meiosis then undergo mitosis, a yeast ascus contains either eight or four ascospores. The ascospores germinate to become haploid cells. The sac fungus yeasts have lost the dikaryon stage.

Most sac fungi are filamentous species, such as the cup fungi (Figure 30.16), in which the ascomata are cup-shaped and can be as large as several centimeters across (although most are much smaller). The inner surfaces of the cups, which are covered with a mixture of specialized hyphae and asci, produce huge numbers of spores. The edible ascomata of some species, including morels and truffles, are regarded by humans as gourmet delicacies (and can sell at prices higher than gold). The un-

derground ascomata of truffles have a strong odor that attracts mammals such as pigs, which then eat and disperse the fungus.

The sac fungi also include many of the filamentous fungi known as molds. Many of these species are parasites of flowering plants. Chestnut blight and Dutch elm disease are both caused by filamentous molds. Between its introduction to the United States in the 1890s and 1940, the chestnut blight fungus destroyed the American chestnut as a commercial species. Before the blight, this species accounted for more than half the trees in the forests of the eastern United States. Another familiar story is that of the American elm. Sometime before 1930, the Dutch elm disease fungus (first discovered in the Netherlands but native to Asia) was introduced into the United States on infected elm logs from Europe. Spreading rapidly—sometimes by way of connected root systems—the fungus destroyed great numbers of American elm trees.

Other plant pathogens among the sac fungi include the powdery mildews that infect cereal grains, lilacs, and roses, among many other plants. Mildews can be a serious problem to farmers and gardeners, and a great deal of research has focused on ways to control these agricultural pests.

Brown molds of the genus *Aspergillus* are important in some human diets. *A. tamarii* acts on soybeans in the production of soy sauce, and *A. oryzae* is used in brewing the Japanese alcoholic beverage sake. Some species of *Aspergillus* that grow on grains and on nuts such as peanuts and pecans produce extremely carcinogenic (cancer-inducing) compounds called *aflatoxins*. In the United States and most other industrialized countries, moldy grain infected with *Aspergillus* is thrown out. In Africa, where food is scarcer, the grain gets eaten, moldy or not, and causes severe health problems, including high levels of certain cancers.

Penicillium is a genus of green molds, of which some species produce the antibiotic penicillin, presumably for defense against competing bacteria. Two species, *P. camembertii* and *P. roquefortii*, are the organisms responsible for the characteristic strong flavors of Camembert and Roquefort cheeses, respectively.

The filamentous sac fungi reproduce asexually by means of conidia that form at the tips of specialized hyphae (Figure 30.17). Small chains of conidia are produced by the millions and can survive for weeks in nature. The conidia are what give molds their characteristic colors. *Fusarium oxysporum*, the plant pathogen mentioned at the beginning of this chapter, is a filamentous sac fungus with no known sexual stage. It produces conidia in abundance.

The sexual reproductive cycle of filamentous sac fungi includes the formation of a dikaryon, although this stage is relatively brief compared with that in club fungi. Many filamentous sac fungi form mating structures of two different mating types (types *A* and *a*; see Figure 30.12C). A nucleus from one of the mating structures (specialized hyphae) on type *a* enters the

(A) *Sarcoscypha coccinea*

30.16 Cup Fungi (A) These brilliant red cups are the ascomata of a cup fungus. (B) Morels, which have a spongelike ascoma and a subtle flavor, are considered a culinary delicacy by humans.

30.17 Conidia Chains of conidia are developing at the tips of specialized hyphae arising from this powdery mildew growing on a leaf.

hypha of type *A* (or vice versa). *Ascogenous* (ascus-forming) hyphae develop from the now dikaryotic hypha. The mating type *a* and *A* nuclei divide simultaneously with the host nuclei, and eventually asci form at the tips of the ascogenous hyphae. Only with the formation of asci do the nuclei finally fuse within the cell that now is defined as the ascus. Both nuclear fusion and the subsequent meiosis to produce the haploid ascospores take place within individual asci. The meiotic products are incorporated into ascospores that are ultimately released (sometimes shot off forcefully) by the ascus to begin the new haploid generation.

The sexual reproductive structure of club fungi is a basidium

Club fungi (Basidiomycota) produce some of the most spectacular fruiting structures found anywhere among the fungi. These fruiting structures, called **basidiomata** (singular, basidioma), include puffballs (see Figure 30.6), some of which may be more than half a meter in diameter, mushrooms of all kinds, and the bracket fungi often encountered on trees and fallen logs in a damp forest. About 30,000 species of club fungi have been described. These include about 4,000 species of mushrooms, including the familiar *Agaricus bisporus* you may enjoy on your pizza, as well as poisonous species such as some members of the genus *Amanita* (Figure 30.18A). Bracket fungi (Figure 30.18B) do great damage both to cut lumber and timber stands;

they also play an important role in returning carbon to the carbon cycle. Some of the most damaging plant pathogens are club fungi, including the rust fungi and the smut fungi that parasitize cereal grains. In contrast, other club fungi contribute to the survival of plants as fungal partners in ectomycorrhizae.

The hyphae of club fungi characteristically have septa with small, distinctive pores. The **basidium** (plural *basidia*), a swollen cell at the tip of a specialized hypha, is the characteristic sexual reproductive structure of the club fungi. In mushroom-forming club fungi, the basidia form on specialized structures known as gills or pores. The basidium is the site of nuclear fusion and meiosis and thus plays the same role in the club fungi as the ascus does in the sac fungi and the zygosporangium does in the zygosporangium fungi.

As seen in Figure 30.12D, after nuclei fuse in the basidium, the resulting diploid nucleus undergoes meiosis, and the four resulting haploid nuclei are incorporated into haploid *basidiospores*, which form on tiny stalks on the outside of the basidium. A single basidioma of the common bracket fungus *Ganoderma applanatum* can produce as many as 4.5 trillion basidiospores in one growing season. Basidiospores typically are forcibly discharged from their basidia and then germinate, giving rise to hyphae with haploid nuclei. As these hyphae grow, haploid hyphae of different mating types meet and fuse, forming dikaryotic hyphae, each cell of which contains two nuclei, one from each parent hypha. The dikaryotic mycelium grows and eventually, when triggered by rain or another environmental cue, produces a basidioma. The dikaryon stage may persist for years—some club fungi live for decades or even centuries. This pattern contrasts with the life cycle of the sac fungi, in which the dikaryon is found only in the stages leading up to formation of the asci.

30.4 RECAP

The ancestor of all fungi was probably aquatic like the chytrids, but fungi have diversified to become important components of terrestrial ecosystems. Sac fungi and club fungi (which together form the clade Dikarya) contain the largest number of species.

- Explain how the microsporidia infect the cells of their animal hosts. **See p. 639 and Figure 30.13**
- What feature of the chytrids suggests an aquatic ancestor to the fungi? **See p. 639**
- What distinguishes the fruiting bodies of sac fungi from those of club fungi? **See pp. 640–642 and Figures 30.12C,D**

Whether living on their own or in symbiotic associations, fungi have spread successfully over much of Earth since their origin from a protist ancestor. That ancestor also gave rise to the choanoflagellates and the animals, as we describe in Chapter 31.

30.18 Club Fungus

Fruiting Structures The basidiomata of the club fungi are probably the most familiar of all fungal structures. (A) These highly poisonous mushrooms were produced by a fungus in the genus *Amanita*, which forms ectomycorrhizal relationships with trees. (B) This edible bracket fungus is an agent of decay on dead wood.

(A) *Amanita muscaria*(B) *Laetiporus sulphureus*

CHAPTER SUMMARY

30.1 What Is a Fungus?

- Fungi are opisthokonts with **absorptive heterotrophy** and with chitin in their cell walls. Fungi have various nutritional modes: some are **saprobies**, others are **parasites**, and some are **mutualists**. **Yeasts** are unicellular fungi. **SEE WEB ACTIVITY 30.1**
- The body of a multicellular fungus is a **mycelium**—a meshwork of **hyphae** that may be **septate** (having **septa**) or **coenocytic**. **Review Figure 30.4**
- Fungi are tolerant of hypertonic environments, and many are tolerant of low or high temperatures.
- Many species of fungi reproduce both sexually and asexually. Sexual reproduction occurs between individuals of different **mating types**.

30.2 How Do Fungi Interact with Other Organisms?

- Saprobic fungi, as decomposers, make crucial contributions to the recycling of elements, especially carbon. Certain fungi have relationships with other organisms that are both **symbiotic** and **mutualistic**.
- Many fungi are parasitic plant pathogens, harvesting nutrients from plant cells by means of **haustoria**. **Review Figure 30.7**
- Some fungi associate with cyanobacteria and/or green algae to form **lichens**, which live on many exposed surfaces of rocks, trees, and soil. **Review Figure 30.10**
- Mycorrhizae** are mutualistic associations of fungi with plant roots. They improve a plant's ability to take up nutrients and water. **Review Figure 30.11**
- Endophytic fungi** live within plants and can provide protection to their hosts from herbivores.

30.3 What Variations Exist among Fungal Life Cycles?

- Some chytrids have a life cycle that includes alternation of generations. **Review Figure 30.12A**
- In the sexual reproduction of terrestrial fungi, hyphae fuse, allowing “gamete” nuclei to be transferred. **Plasmogamy** (fusion of cytoplasm) precedes **karyogamy** (fusion of nuclei).

- Zygosporic fungi have a resistant-spore stage with many diploid nuclei, known as a **zygospore**. **Review Figure 30.12B, ANIMATED TUTORIAL 30.1**
- In sac fungi and club fungi, a **dikaryon** is formed. The dikaryotic ($n + n$) condition is unique to the fungi. **Review Figures 30.12C,D, WEB ACTIVITY 30.2**

30.4 How Have Fungi Evolved and Diversified?

- The relationships of microsporidia, chytrids, and zygosporic fungi are not well resolved, but these groups diversified early in fungal evolution. The mycorrhizal fungi, sac fungi, and club fungi form a monophyletic group, and the latter two groups form the clade Dikarya. **Review Figure 30.2 and Table 30.1**
- Microsporidia** are reduced, intracellular parasitic species of fungi that infect several animal groups, especially insects, crustaceans, and fishes.
- The three distinct lineages of **chytrids** have flagellated gametes. **Review Figure 30.12A**
- The four distinct lineages of **zygosporic fungi** have coenocytic hyphae and a zygospore in their life cycle. Their fruiting structures are simple stalked **sporangiophores**. **Review Figure 30.12B**
- Arbuscular mycorrhizal fungi** form symbiotic associations with plant roots. These mycorrhizae increase water and mineral uptake by the plants and provide a carbon source to the fungi. They are only known to reproduce asexually. Their hyphae are coenocytic.
- Sac fungi** have septate hyphae; their sexual reproductive structures are **asci**. Many sac fungi are partners in lichen and endophytic associations. Filamentous sac fungi produce fleshy fruiting bodies called **ascomata**. The dikaryon stage in the sac fungus life cycle is relatively brief. **Review Figure 30.12C**
- Club fungi** have septate hyphae. Many of the species are plant pathogens, although mushroom-forming species are more familiar to most people. Their fruiting bodies are called **basidiomata**, and their sexual reproductive structures are **basidia**. The dikaryon stage may last for years. **Review Figure 30.12D**

SELF-QUIZ

- Which statement about fungi is *not* true?
 - A multicellular fungus has a body called a mycelium.
 - Hyphae are composed of individual mycelia.
 - Many fungi tolerate highly hypertonic environments.
 - Many fungi tolerate low temperatures.
 - Some fungi are anchored to their substrate by rhizoids.
- The absorptive heterotrophy of fungi is aided by
 - dikaryon formation.
 - spore formation.
 - the fact that they are all parasites.
 - their large surface area-to-volume ratio.
 - their possession of chloroplasts.
- Which statement about fungal nutrition is *not* true?
 - Some fungi are active predators.
 - Some fungi form mutualistic associations with other organisms.
 - All fungi require mineral nutrients.
 - Fungi can make some of the compounds that are vitamins for animals.
 - Facultative parasites can grow only on their specific hosts.
- Which statement about dikaryosis is *not* true?
 - The cytoplasm of two cells fuses before their nuclei fuse.
 - The two haploid nuclei are genetically different.
 - The two nuclei are of the same mating type.
 - The dikaryon stage ends when the two nuclei fuse.
 - Not all fungi have a dikaryon stage.
- Reproductive structures consisting of one or more photosynthetic cells surrounded by fungal hyphae are called
 - ascospores.
 - basidiospores.
 - conidia.
 - soredia.
 - gametes.
- Members of the zygosporangium fungi
 - have hyphae without regularly occurring septa.
 - produce motile gametes.
 - form fleshy fruiting bodies.
 - are haploid throughout their life cycle.
 - have sexual reproductive structures similar to those of the sac fungi.
- Which statement about sac fungi is *not* true?
 - Some species are yeasts.
 - They form reproductive structures called asci.
 - Their hyphae are segmented by septa.
 - Many of their species have a dikaryotic state.
 - All have fruiting structures called ascomata.
- Club fungi
 - often produce fleshy fruiting structures.
 - have hyphae without septa.
 - have no sexual stage.
 - produce basidia within basidiospores.
 - form diploid basidiospores.
- Microsporidia
 - lack true mitochondria.
 - are parasites of animals.
 - contain mitosomes.
 - are among the smallest eukaryotes known.
 - all of the above
- Which statement about lichens is *not* true?
 - They can reproduce by fragmentation of the vegetative body.
 - They are often the first colonists in a new area.
 - They render their environment more basic (alkaline).
 - They contribute to soil formation.
 - They may contain less than 10 percent water by weight.

FOR DISCUSSION

- You are shown an object that looks superficially like a pale green mushroom. Describe at least three criteria (including anatomical and chemical traits) that would enable you to tell whether the object is a piece of a plant or a piece of a fungus.
- Differentiate among the members of the following pairs of related terms:
 - hypha/mycelium
 - ascus/basidium
 - ectomycorrhiza/arbuscular mycorrhiza
- For each type of organism listed below, give a single characteristic that may be used to differentiate it from the other, related organism(s) in parentheses.
 - zygosporangium fungi (sac fungi)
 - sac fungi (club fungi)
 - baker's yeast (*Penicillium*)
- Many fungi are dikaryotic during part of their life cycle. Why are dikaryons described as $n + n$ instead of $2n$?
- If all the fungi on Earth were suddenly to die, how would the surviving organisms be affected?
- How might the first mycorrhizae have arisen?
- What attributes might account for the ability of lichens to withstand the intensely cold environment of Antarctica? Be specific in your answer.
- What factors must be taken into account in using fungi to combat agricultural pests?

ADDITIONAL INVESTIGATION

We noted that lichens are highly sensitive to air pollution. How could you use lichen diversity and abundance to measure air quality? How would you expect lichen diversity to vary with

respect to distance from major metropolitan areas? Would you expect prevailing wind direction to be a factor in this pattern?

Getting back to our roots

In 1883, the zoologist Franz Schulze noticed something unusual in his Austrian laboratory: transparent, flattened organisms were crawling on the sides of his salt-water aquarium. Collected accidentally along with the sponges that were Schulze's primary interest, these organisms were unlike any previously described animals—especially since they continually changed shape as they moved.

Schulze's examination of the new organisms revealed that they were animals. But structurally they were among the simplest animals that he—or anyone else—had ever observed, with only four types of cells. He named the new species *Trichoplax adhaerens*, which means “sticky hairy plate,” and argued that the new species had no close relationships with other major animal groups. For decades,

however, most biologists dismissed Schulze's findings, insisting that the transparent organisms must be larval forms of other, well-known, animals.

In the 1960s, new and more detailed studies confirmed Schulze's findings and the distinctive nature of *Trichoplax*. Even then, this odd animal continued to be known almost exclusively from aquariums. Only in the past decade have biologists been able to locate and study natural field populations of *Trichoplax adhaerens*. A few additional closely related species have been discovered, and they are collectively known as placozoans (Greek, “flat animals”).

The more biologists have studied *Trichoplax*, the odder this animal appears. It has the smallest genome of any animal studied to date. The mature stages lack body symmetry and have no mouth, gut, or nervous system. Is *Trichoplax* a relict representative of a group of animals that appeared early in animal evolution? Indeed, some recent phylogenetic analyses support the possibility that *Trichoplax* is a representative of the most divergent group of animals.

Although biologists agree on which groups of organisms are animals, the root of the animal tree is a subject of considerable investigation and debate. Traditionally, the first split is thought to have been between the sponges and all other animals, and most evidence still favors that view. Some gene sequence analyses, however, suggest that the major groups of sponges are not even each other's closest relatives, and that the glass sponges alone split with all the remaining animals (including other sponges)

Are Placozoans at the Base of Animal Phylogeny?

Is the simplicity of placozoans an ancestral feature, or did these organisms descend from ancestors with more complex body plans? Answering that question requires an understanding of animal phylogeny.

Alternative Candidates Some studies place either sponges (left) or ctenophores (upper right) rather than placozoans as the sister group of all other multicellular animals. Most evidence favors sponges as the most divergent animal group.

at the base of the animal tree. Other genomic investigations have suggested that the ctenophores—comb jellies—may be the sister group to all other animals. Ctenophores are beautiful, transparent organisms whose sticky tentacles capture planktonic prey.

Newly acquired insights into how animal genomes are structured and have evolved play an ever more important role in understanding the relationships among the major animal groups. This chapter explores the earliest branches on the animal tree, and how a few fundamental “body plans” have been modified to yield the remarkable variety of animal forms described in this and the following two chapters.

IN THIS CHAPTER we will review the evidence that has led biologists to conclude that the animals are monophyletic and will then present the best-supported current hypotheses of animal phylogeny. We will describe how the diverse animal forms are derived from a small array of body plans. We will discuss various animal strategies for obtaining food and describe the amazingly varied life cycles of animals—how they are born, grow, disperse, and reproduce. Finally, we will describe members of several basal clades of animals.

CHAPTER OUTLINE

- 31.1** What Characteristics Distinguish the Animals?
- 31.2** What Are the Features of Animal Body Plans?
- 31.3** How Do Animals Get Their Food?
- 31.4** How Do Life Cycles Differ among Animals?
- 31.5** What Are the Major Groups of Animals?

31.1 What Characteristics Distinguish the Animals?

How do we recognize an organism as an animal? That may seem obvious for many familiar animals, but less so for groups like sponges, which were once thought to be plants. Some of the general aspects that we associate with animals include:

- *Multicellularity.* In contrast to the Bacteria, Archaea, and most protists (see Chapters 26 and 27), all animals are multicellular. Animal life cycles feature complex patterns of development from a single-celled zygote into a multicellular adult.
- *Heterotrophic metabolism.* In contrast to most plants (see Chapters 28 and 29), all animals are heterotrophs. Animals are able to synthesize very few organic molecules from inorganic chemicals, so they must take in nutrients from their environment (either through their own actions, or in some cases with the aid of symbiotic species).
- *Internal digestion.* Although the fungi are also heterotrophs (see Chapter 30), animals digest their food differently. Whereas fungi rely on external digestion, most animals use internal processes to break down materials from their environment into the organic molecules they need most. Most animals ingest food into an internal gut that is continuous with the outside environment and in which digestion takes place.
- *Movement.* In contrast to the majority of plants and fungi, most animals can move. Animals must move to find food or bring food to them. Muscle tissue is unique to animals, and many animal body plans are specialized for movement.

Although these general features help us recognize animals, none is diagnostic for all animals. Some animals do not move, at least during certain life stages, and some plants and fungi do have limited movement. Some animals lack a gut. Many multicellular organisms are not animals. So what is the evidence that groups all animals together in a single clade?

Animal monophyly is supported by gene sequences and morphology

The most convincing evidence that all the organisms considered to be animals share a common ancestor comes from phylogenetic analyses of their gene sequences. Relatively few complete animal genomes are available, but many more genomes are being sequenced each year. Analyses of these genomes, as well as many individual gene sequences, have shown that all animals are indeed *monophyletic*; a currently well-supported phylogenetic tree of the animals is shown in **Figure 31.1**.

31.1 The Phylogeny of Animals This tree presents the best supported current hypotheses of evolutionary relationships among major groups of animals. The traits highlighted by red circles will be explained as you read this chapter; you should review this figure closely after you complete your reading.

yourBioPortal.com

GO TO Web Activity 31.1 • Sponge and Diploblast Classification

Although animals were considered to belong to a single clade long before gene sequencing became possible, surprisingly few morphological features are shared across all species of animals. These morphological *synapomorphies* include:

- Unique types of junctions between their cells (tight junctions, desmosomes, and gap junctions; see Figure 6.7).
- A common set of extracellular matrix molecules, including collagen and proteoglycans (see Figure 5.25).

Although some animals in a few groups lack one or another of these characteristics, it is believed that these traits were possessed by the ancestor of all animals and subsequently lost in those groups. Similarities in the organization and function of Hox and other developmental genes (see Chapter 20) provide additional

evidence of developmental mechanisms shared by a common animal ancestor. The Hox genes specify body pattern and axis formation, leading to developmental similarities across animals.

The common ancestor of animals was probably a colonial flagellated protist similar to existing colonial choanoflagellates (see Figure 27.27). The most reasonable current scenario postulates a choanoflagellate lineage in which certain cells in the colony began to be specialized—some for movement, others for nutrition, others for reproduction, and so on. Once this *functional specialization* had begun, cells could have continued to differentiate. Coordination among groups of cells could have improved by means of specific regulatory and signaling molecules that guided differentiation and migration of cells in developing embryos. Such coordinated groups of cells eventually evolved into the larger and more complex organisms that we call animals.

More than a million living animal species have been named and described, and millions of additional animal species await discovery. Clues to the evolutionary relationships among animal groups can be found in fossils, in patterns of embryonic development, in the morphology and physiology of living animals, in the structure of animal proteins, and in gene sequences.

Increasingly, studies of higher-level relationships have come to depend on genomic sequence comparisons, as genomes are ultimately the source of all inherited trait information.

A few basic developmental patterns differentiate major animal groups

Differences in patterns of embryonic development have until recently provided many of the most important clues to animal phylogeny. Analyses of gene sequences, however, are now showing that some developmental patterns are more evolutionarily variable than previously thought. We describe here the basic developmental patterns that vary among the major animal clades.

The first few cell divisions of a zygote are known as **cleavage**. In general, the number of cells in the embryo doubles with each cleavage. As described in Section 44.1, several different **cleavage patterns** exist among animals.

Cleavage patterns are influenced by the configuration of the *yolk*, the nutritive material that nourishes the growing embryo. In reptiles, for example, the presence of a large body of acellular yolk within the fertilized egg creates an *incomplete* cleavage pattern in which the dividing cells form an embryo on top of the yolk mass (see Figure 44.3B). In *echinoderms* such as sea urchins, limited yolk is evenly distributed throughout the egg cytoplasm, so cleavage is *complete*, with the fertilized egg dividing in an even pattern known as **radial cleavage**. Radial cleavage is thought to be the ancestral condition for the animals other than sponges, as it is widely distributed in the other major lineages. **Spiral cleavage**—a complicated permutation of radial cleavage—is found among many *lophotrochozoans*, including earthworms and clams. Lophotrochozoans with spiral cleavage are thus sometimes known as *spiralians*. The early branches of the *ecdysozoans* (molting animals, such as insects and nematodes) have radial cleavage, although most ecdysozoans have an idiosyncratic cleavage pattern that is neither radial nor spiral in organization (see Figure 44.3C).

Distinct layers of cells form during the early development of most animals. These cell layers differentiate into specific organs and organ systems as development continues. The embryos of **diploblastic** animals have two cell layers: an outer *ectoderm* and an inner *endoderm*. Embryos of **triploblastic** animals have, in addition to ectoderm and endoderm, a third distinct cell layer, *mesoderm*, between the ectoderm and the endoderm. The existence of three cell layers in embryos is a synapomorphy of triploblastic animals, whereas the diploblastic animals (placozoans, ctenophores, and cnidarians) exhibit the ancestral condition. Some biologists consider sponges to be diploblastic, but since they do not have clearly differentiated tissue types or embryonic cell layers, the term is not usually applied to them.

During early development in many animals, in a process known as *gastrulation*, a hollow ball one cell thick indents to form a cup-shaped structure. The opening of the cavity formed by this indentation is called the *blastopore* (Figure 31.2). The process of gastrulation is covered in detail in Section 44.2; the

31.2 Gastrulation Illuminates Evolutionary Relationships (A) The blastopore is clear in this scanning electron micrograph of a sea urchin gastrula. Because sea urchins (echinoderms) are deuterostomes, this blastopore will eventually become the anal end of the animal's gut. (B) In this cross section through a later-stage sea urchin gastrula, the cells are beginning to look different from one another. The molecules of the extracellular matrix guide cell movement.

point to remember here is that the *overall pattern* of gastrulation immediately after formation of the blastopore divides the triploblastic animals into two major groups:

- In the **protostomes** (Greek, “mouth first”), the mouth arises from the blastopore, and the anus forms later.
- In the **deuterostomes** (“mouth second”), the blastopore becomes the anus, and the mouth forms later.

Although the developmental patterns of animals are more varied than suggested by this simple dichotomy, sequencing data indicate that the protostomes and deuterostomes represent distinct animal clades. Together, these two groups are known as the **bilaterians** (named for their usual bilateral symmetry), and they account for the vast majority of animal species.

31.1 RECAP

The animals are thought to be monophyletic because they share several derived traits, especially among their gene sequences. Major developmental differences also provide evidence of evolutionary relationships, although phylogenetic analyses of gene sequences have shown that the evolutionary history of these features is more complex than was once thought.

- What general features of animals distinguish this group from other living organisms? **See p. 646**
- Describe the difference between diploblastic and triploblastic embryos, and between protostomes and deuterostomes. **See p. 648**

We devote Chapter 32 to the protostomes and Chapter 33 to the deuterostomes. Later in this chapter, we describe several groups of animals that diverged before the origin of the bilaterians. We begin our exploration of animal diversity by discussing general features of animal body plans.

31.2 What Are the Features of Animal Body Plans?

The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts are referred to as its **body plan**. As Chapter 20 describes, the regulatory and signaling genes that govern the development of body symmetry, body cavities, segmentation, and appendages are widely shared among the different animal groups. Thus we might expect animals to share body plans. Although animal body plans vary tremendously, they can be seen as variations on four key features:

- The *symmetry* of the body
- The structure of the *body cavity*
- The *segmentation* of the body
- *External appendages* that are used for sensing, chewing, locomotion, mating, and other functions

Each of these features affects how an animal moves and interacts with its environment.

Most animals are symmetrical

The overall shape of an animal can be described by its **symmetry**. An animal is said to be *symmetrical* if it can be divided along at least one plane into similar halves. Animals that have no plane of symmetry are said to be *asymmetrical*. Placozoans and many sponges are asymmetrical, but most other animals have some kind of symmetry, which is governed by the expression of regulatory genes during development.

The simplest form of symmetry is **spherical symmetry**, in which body parts radiate out from a central point. An infinite number of planes passing through the central point can divide a spherically symmetrical organism into similar halves. Spherical symmetry is widespread among unicellular protists, but most animals possess other forms of symmetry.

In organisms with **radial symmetry**, body parts are arranged around one main axis at the body's center (**Figure 31.3A**). *Ctenophores* are radially symmetrical, as are many *cnidarians* and *echinoderms*. A perfectly radially symmetrical animal can be divided into similar halves by any plane that contains the main axis. However, most radially symmetrical animals—including the adults of echinoderms such as sea stars and sand dollars—are slightly modified so that fewer planes can divide them into identical halves. Some radially symmetrical animals are sessile (sedentary) or drift with water currents. Others move slowly but can move equally well in any direction.

Bilateral symmetry is characteristic of animals that have a distinct front end, which typically precedes the rest of the body as the animal moves. A bilaterally symmetrical animal can be

(A) Radial symmetry

(B) Bilateral symmetry

31.3 Body Symmetry Most animals are either radially or bilaterally symmetrical.

divided into mirror-image (left and right) halves by a single plane that passes through the midline of its body (**Figure 31.3B**). This plane runs from the front, or **anterior**, end of the body, to its rear, or **posterior**, end.

A plane at right angles to the midline divides the body into two dissimilar sides. The back of a bilaterally symmetrical animal is its **dorsal** surface; the underside is its **ventral** surface.

Bilateral symmetry is strongly correlated with **cephalization**, which is the concentration of sensory organs and nervous tissues in a head at the anterior end of the animal. Cephalization has been evolutionarily favored because the anterior end of a bilaterally symmetrical animal typically encounters new environments first.

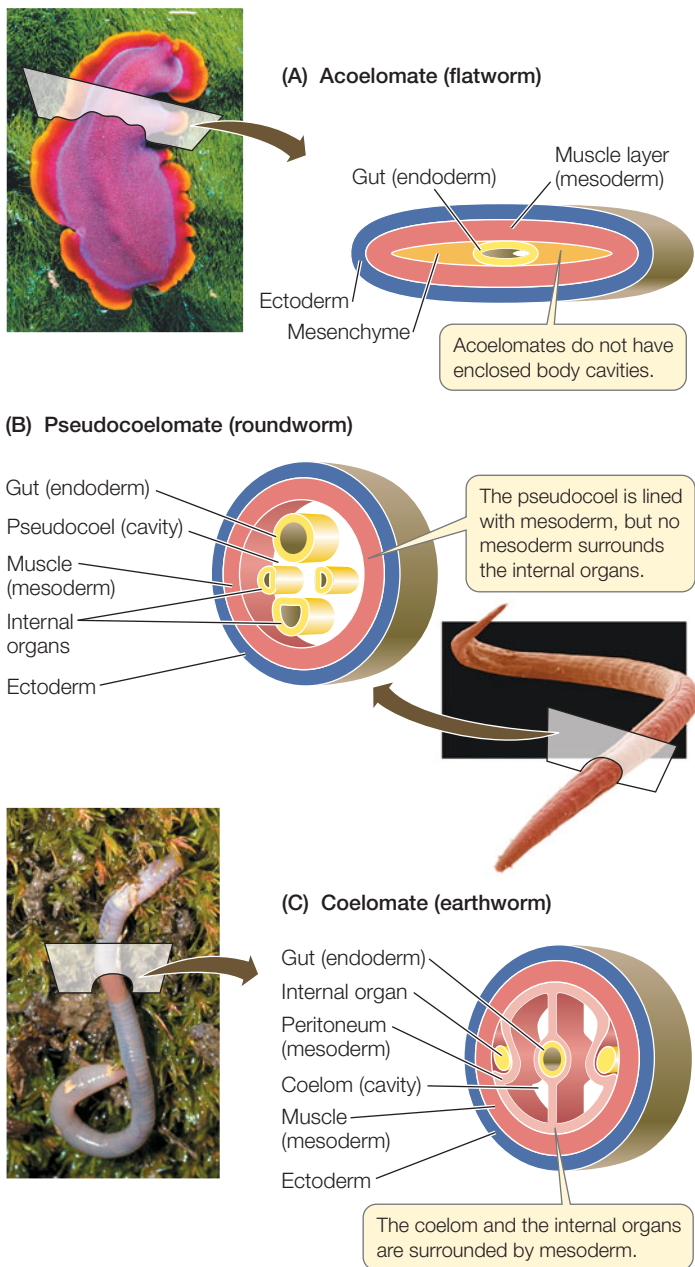

The structure of the body cavity influences movement

Animals can be divided into three types—*acoelomate*, *pseudocoelomate*, and *coelomate*—based on the presence and structure of an internal, fluid-filled **body cavity**. The structure of an animal's body cavity strongly influences the ways in which it can move.

Acoelomate animals such as flatworms lack an enclosed, fluid-filled body cavity. Instead, the space between the gut (derived from endoderm) and the muscular body wall (derived from mesoderm) is filled with masses of cells called *mesenchyme* (**Figure 31.4A**). These animals typically move by beating cilia.

Body cavities come in two types. Some lie between mesoderm and endoderm, and others are enclosed completely within mesoderm.

- **Pseudocoelomate** animals have a body cavity called a *pseudocoel*, a fluid-filled space in which many of the internal

31.4 Animal Body Cavities (A) Acoelomates do not have enclosed body cavities. (B) Pseudocoelomates have a body cavity bounded by endoderm and mesoderm. (C) Coelomates have a peritoneum surrounding the internal organs in a region bounded by mesoderm.

— yourBioPortal.com —

GO TO Web Activity 31.2 • Animal Body Cavities

organs are suspended. A pseudocoel is enclosed by muscles (mesoderm) only on its outside; there is no inner layer of mesoderm surrounding the internal organs (**Figure 31.4B**).

- **Coelomate** animals have a *coelom*, a body cavity that develops within the mesoderm. It is lined with a layer of muscular tissue called the *peritoneum*, which also surrounds the internal organs. The coelom is thus enclosed on both the inside and the outside by mesoderm (**Figure 31.4C**). A coelomate

animal has better control over the movement of the fluids in its body cavity than a pseudocoelomate animal does.

The body cavities of many animals function as **hydrostatic skeletons**. Fluids are relatively incompressible, so when the muscles surrounding them contract, fluids shift to another part of the cavity. If the body tissues around the cavity are flexible, fluids squeezed out of one region can cause some other region to expand. The moving fluids can thus move specific body parts. (You can see how a hydrostatic skeleton works by watching a snail emerge from its shell.) An animal with both *circular muscles* (encircling the body cavity) and *longitudinal muscles* (running along the length of the body) has even greater control over its movement.

In terrestrial environments, the hydrostatic function of fluid-filled body cavities applies mostly to relatively small, soft-bodied organisms. Most larger animals (as well as many smaller ones) have hard skeletons that provide protection and facilitate movement. Muscles are attached to those firm structures, which may be inside the animal or on its outer surface (in the form of a shell or cuticle).

Segmentation improves control of movement

Many animal bodies are divided into segments. **Segmentation** facilitates specialization of different body regions. It also allows an animal to alter the shape of its body in complex ways and to control its movements precisely. If an animal's body is segmented, muscles in each individual segment can change the shape of that segment independently of the others. In only a few segmented animals is the body cavity separated into discrete compartments, but even partly separated compartments allow better control of movement. As we see in Chapters 32 and 33, segmentation occurs in several groups of protostomes and deuterostomes.

In some animals, segments are not apparent externally (as with the segmented vertebrae of vertebrates). In other animals, such as annelids, similar body segments are repeated many times (**Figure 31.5A**). And in yet other animals, including most arthropods, segments are visible but differ strikingly (**Figure 31.5B**). As described in Chapter 32, the dramatic evolutionary radiation of the arthropods (including the insects, spiders, centipedes, and crustaceans) was based on changes in a segmented body plan that features muscles attached to the inner surface of an external skeleton, including a variety of external appendages that move these animals.

Appendages have many uses

Getting around under their own power is important to many animals. It allows them to obtain food, to avoid predators, and to find mates. Even some sedentary species, such as sea anemones, have larval stages that use cilia to swim, thus increasing the animal's chances of finding a suitable habitat.

Appendages that project externally from the body greatly enhance an animal's ability to move around. Many echinoderms, including sea urchins and sea stars, have myriad *tube feet* that allow them to move slowly across the substratum. Highly con-

31.5 Segmentation The body cavities of many animals are segmented. (A) All of the segments of this marine fireworm, an annelid, are similar. Its appendages are tipped with bristles (setae) that are used for locomotion and (in this species) for protection—the setae contain a noxious toxin. (B) Segmentation allows the evolution of differentiation among the segments. The segments of this scorpion, an arthropod, differ in their form, function, and the appendages they bear.

(A) *Hermodice carunculata*

The fireworm is a marine worm that displays an evenly segmented body plan.

Protective bristles

Abdominal segments are modified for digestion and reproduction.

Tail segments are modified for hunting and defense.

Anterior segments have fused and bear appendages for locomotion and feeding.

(B) *Hadrurus arizonensis*

trolled, rapid movement is greatly enhanced in animals whose appendages have become modified into specialized *limbs*. In the arthropods and the vertebrates, the presence of *jointed limbs* has been a prominent factor in their evolutionary success (see Figure 31.5B). In four independent instances—among the arthropod insects and among the vertebrate pterosaurs, birds, and bats—body plans emerged in which limbs were modified into wings, allowing these animals to take to the air.

Appendages also include many structures that are not used for locomotion. Many animals have antennae, which are specialized appendages used for sensing the environment. Other appendages (such as claws and mouth parts of many arthropods) are adaptations for capturing prey or chewing food. In some species, appendages are used for reproductive purposes, such as sperm transfer or egg incubation.

31.2 RECAP

The body plans of animals are variations on patterns of symmetry, body cavities, segmentation, and appendages. All four can affect movement and locomotion, which are important aspects of the animal way of life.

- Describe the main types of symmetry found in animals. How can an animal's symmetry influence the way it moves? **See p. 649 and Figure 31.3**
- Explain several ways in which body cavities and segmentation improve control over movement. **See pp. 649–650**

Many of the modifications to animal body plans affect ways of finding, capturing, and processing food. Evolutionary changes in symmetry, body cavities, appendages, and segmentation have played key roles in enabling animals to obtain food from their environment, as well as helping them avoid becoming food for other animals.

31.3 How Do Animals Get Their Food?

As noted in Section 31.1, animals are heterotrophs, or “other feeders.” Although many animals rely on photosynthetic endosymbionts for nutrition (see Figures 5.14C and 27.8), most animals must actively obtain an outside source of nutrition, otherwise known as food. The need to locate food has favored the evolution of sensory structures that can provide animals with detailed information about their environment, as well as nervous systems that can receive, process, and coordinate that information.

To acquire food, most animals must expend energy, either to move through the environment to where food is located or to move the environment and the food it contains to them. Animals that can move from one place to another are **motile**; animals that stay in one place are **sessile**.

The principal feeding strategies that animals use fall into five broad categories:

- **Filter feeders** capture small organisms delivered to them by their environment.
- **Herbivores** eat plants or parts of plants.
- **Predators** capture and eat other animals that typically are relatively large.
- **Parasites** live in or on other, generally much larger, organisms from which they obtain energy and nutrients.
- **Detritivores** actively feed on dead organic material.

Each of these strategies can be found in many different animal groups, and none of them is limited to a single group. In

addition, individuals of some species may employ more than one feeding strategy, and some animals employ different feeding strategies at different points in their life cycle. The constant and ongoing need to obtain food, the variety of nutrient sources available in any given environment, and the necessity of competing with other animals to obtain food means that a variety of feeding strategies can be found among all the major animal groups.

Filter feeders capture small prey

Air and water often contain small organisms and organic molecules that are potential food for animals. Moving air and water may carry those items to an animal that positions itself in a good location. These **filter feeders** then use some kind of straining device to filter the food from the environment. Many sessile aquatic animals rely on water currents to bring prey to them (**Figure 31.6A**).

(A) *Spirobranchus* sp.

(B) *Phoenicopterus ruber*

Motile filter feeders bring the nutrient-containing medium to them. Flamingos, for example, use their serrated beak to filter small organisms out of the muddy mixture they pick up as they wade through shallow water (**Figure 31.6B**). Blue whales—the largest animals that have ever lived—are filter feeders that strain tiny crustaceans from the water column as they swim.

Some sessile filter feeders expend energy to move water past their food-capturing devices. Sponges, for example, bring water into their body by beating the flagella of their specialized feeding cells, called **choanocytes** (**Figure 31.7**). These flagellated feeding cells of sponges are similar in structure to protists known as choanoflagellates, which provides evidence for the close relationship of choanoflagellates to animals (see Section 27.5).

Herbivores eat plants

Animals that eat plants are called **herbivores**. An individual plant has many different structures—leaves, wood, sap, flowers, fruits, nectar, and seeds—that animals can consume. Not surprisingly, then, many different kinds of herbivores may feed on a single kind of plant, consuming different parts of the plant or eating the same part in different ways. An individual animal that is captured by a predator is likely to die, but herbivores often feed on plants without killing them.

Animals do not need to expend energy subduing and killing plants. However, they do need to digest them, and animals must expend energy to detoxify plants' defensive chemicals. Digestion can pose challenges to terrestrial herbivores because the dominant land plants tend to have several different kinds of tissues, many of which are tough or fibrous. Herbivorous animals typically have long, complex guts to accomplish the tasks involved in digesting plants (see Section 51.2).

Predators capture and subdue large prey

Predators possess features that enable them to capture and subdue relatively large animals (referred to as their **prey**). Many vertebrate predators have sensitive sensory organs that enable them to locate prey, as well as sharp teeth or claws that allow them to capture and subdue large prey (**Figure 31.8**). Predators may stalk and pursue their prey, or wait (often camouflaged) for their prey to come to them.

Another weapon of predators (as well as of prey) is toxins. We are all aware of the dangers of encountering the toxins of a venomous snake. Toxins often have both a defensive role as well as a role in the capture and sometimes the digestion of prey. Cnidarians (jellyfishes and their relatives) are one of many animal groups that use toxins to capture and subdue prey. The cnidarians' tentacles are covered with specialized cells that con-

31.6 Filter-Feeding Strategies (A) Sessile marine filter feeders such as this “Christmas tree worm,” a polychaete, allow the ocean currents to bring their food—plankton—to them. (B) The greater flamingo of South America is a motile filter feeder, using its appendages (legs) to stir up mud as it wades through ocean lagoons and salty lakes. The bird then uses its beak (close-up) to strain small organisms out of the muddy mixture.

31.7 Even Sessile Filter Feeders Expend Energy (A) A sponge moves food-containing water through its body by beating the flagella of its choanocytes—specialized feeding cells. Water enters through small pores and passes into water canals or an open atrium, where the choanocytes capture food particles from the water. Spicules are supportive, skeletal structures. (B) The similarity of this choanoflagellate protist (see Section 27.5) to sponge choanocytes visualizes a clear evolutionary link between a protist lineage and the animals.

tain stinging organelles called **nematocysts**, which inject toxins into the prey (**Figure 31.9**).

Omnivores are animals, such as raccoons and humans, that eat both plants and other animals. The diet of some omnivores differs at different life stages; many songbirds, for example, eat fruit or seeds as adults but feed insects to their young.

31.8 Tooth and Claw (A) The teeth of the predatory gray wolf are adapted for killing prey and shearing meat. (B) The appendages (legs and wings) of the bald eagle, along with its strong beak, are adaptations to the life of a predatory hunter.

(A) *Canis lupus*

(B) *Haliaeetus leucocephalus*

Parasites live in or on other organisms

Parasites are animals that live in or on another organism—called a *host*—and obtain their nutrients from that host. Some parasites consume parts of the host itself (such as ticks that suck body fluids); others hijack nutrients the host would otherwise consume (such as tapeworms that may live in our intestines). Most animal parasites are much smaller than their hosts, and many parasites can consume parts of their host without killing it. To reside within a host, a parasite must first overcome the host's defenses. Parasites often have complex life cycles that rely on multiple hosts, as we detail in Section 31.4.

31.9 Nematocysts Are Potent Weapons The tentacles of the Portuguese man-of-war, a cnidarian, are rife with specialized cells that contain stinging organelles called nematocysts, which inject toxin into prey. The Portuguese man-of-war is a colonial organism, composed of many physiologically integrated individuals with specialized functions.

ducted many interesting experiments to establish how quickly earthworms break down organic matter and build up rich soils.

31.3 RECAP

Animals have many ways of acquiring food. Filter feeders strain food particles from the water or air. Herbivores have digestive adaptations that allow them to eat plants, whereas predators are physically adapted to capture and subdue other animals (prey) and consume them. Parasites obtain their nutrition from a host organism. Detritivores consume decaying organic matter and make important nutrients available for use by other organisms.

- What adaptations are necessary for animals that eat plants? What adaptations are needed for a predatory lifestyle? **See pp. 652–653**
- Looking at the brief overview of some of the diverse feeding modes of animals presented here, and using whatever you already know about different animals, how useful do you think feeding behavior would be as a criterion for grouping animals into phylogenetic categories?

Parasites that live inside their hosts are called *endoparasites*, and they are often morphologically very simple. They can often function without a digestive system because they absorb food directly from the host's gut or bodily tissues. Many flatworms are endoparasites of humans and other mammals, as described in Chapter 32.

Parasites that live outside their hosts are called *ectoparasites*, and they are generally more complex morphologically than endoparasites. Ectoparasites have digestive tracts and mouthparts that enable them to pierce the host's tissues or suck on their body fluids. Fleas and ticks are widely known ectoparasitic arthropods that many humans have unfortunately experienced.

Detritivores live off the remains of other organisms

Detritivores feed on decomposing organic matter, or *detritus*. In so doing, they perform an important ecosystem function by returning nutrients to the environment in a state that can be used by other organisms. Detritivores are common in any soil with high organic content, as well as on the ocean floors. Well-known detritivores include earthworms and other annelids, millipedes, and many insects and crustaceans.

Charles Darwin became fascinated with the action of earthworms, and wrote a book called *The Formation of Vegetable Mould Through the Action of Worms*. He was particularly impressed by the importance of earthworms in soil formation. Darwin con-

As an animal grows from a single cell into a larger, more complex adult, its body structure, its diet, and the environment in which it lives may all change. In the next section we describe some animal life cycles and discuss why they are so varied.

31.4 How Do Life Cycles Differ among Animals?

The **life cycle** of an animal encompasses its embryonic development, birth, growth to maturity, reproduction, and death. During its life an individual animal ingests food, grows, interacts with other individuals of the same and other species, and reproduces.

In some groups of animals, newborns bear many similarities to adults (a pattern called *direct development*). Newborns of most species, however, differ dramatically from adults. Consider, for example a **larva** (plural *larvae*), the immature life stage that some organisms take early in their life cycle before assuming an adult form. Some of the most striking life cycle changes are found among insects such as beetles, flies, moths, butterflies, and bees, which undergo radical changes (called *metamorphosis*) between their larval and adult stages (**Figure 31.10**). In these animals, one stage may be specialized for feeding and the other for reproduction. Adults of most moth species, for example, do not eat. In some animals species, individuals eat during all life cycle stages, but what they eat changes with the stage. For exam-

31.10 A Life Cycle with Metamorphosis (A) The larval stage (caterpillar) of the monarch butterfly (*Danaus plexippus*) is specialized for feeding. (B) The pupa is the stage during which the transformation to the adult form occurs. (C) The adult butterfly is specialized for dispersal and reproduction.

ple, butterfly larvae, known as *caterpillars*, eat leaves and flowers, whereas most adult butterflies eat only nectar. Having different life cycle stages that are specialized for different activities may increase the efficiency with which an animal performs particular tasks.

Most animal life cycles have at least one dispersal stage

At some time during its life, an animal moves, or is moved, so few animals die exactly where they were born. Movement of organisms from a parent organism or from an existing population is called **dispersal**.

Animals that are sessile as adults typically disperse as eggs or larvae. Most sessile marine animals discharge their small eggs and sperm into the water, where fertilization takes place. A larva

soon hatches and floats freely in the plankton, where it filters small prey from the water.

Many animals that live on the seafloor, including polychaete worms and mollusks, have a radially symmetrical larval form known as a **trochophore** (Figure 31.11A); others, such as crustaceans, have a bilaterally symmetrical larval form called a **nauplius** (Figure 31.11B). Both types of larvae feed for some time in the plankton before settling on a substratum and transforming into adults.

Although the main dispersal phase of many animals occurs early in the life cycle, some species that are motile as adults disperse when they are mature. A caterpillar, for example, may spend its entire larval stage feeding on a single plant, but after it metamorphoses into a flying adult—a butterfly—it may fly to and lay eggs on other plants located far from the one where it spent its caterpillar days. In some species, individuals disperse during several different life cycle stages.

No life cycle can maximize all benefits

The common saying “a jack-of-all-trades is master of none” suggests why there are constraints on the evolution of life cycles. The characteristics an animal has in any one life cycle stage may improve its performance in one activity but reduce its performance in another—a situation known as a *trade-off*. An animal that is good at filtering small food particles from the water, for example, probably cannot capture large prey. Similarly, energy devoted to building protective structures such as shells cannot be used for growth.

Some major trade-offs can be seen in animal reproduction. Some animals produce large numbers of small eggs, each with

31.11 Planktonic Larval Forms of Marine Animals (A) The trochophore (“wheel-bearer”) is a distinctive larval form found in several marine animal clades with spiral cleavage, most notably the polychaete worms and the mollusks. (B) This nauplius larva will mature into a crustacean with a segmented body and jointed appendages.

(A) *Rana sylvatica*(B) *Pygoscelis papua*

31.12 Many Small or Few Large Allocation of energy to eggs requires trade-offs. (A) This wood frog has divided her reproductive energy among a large number of small eggs. (B) This gentoo penguin invested all of her reproductive energy in one large egg.

a small energy store (**Figure 31.12A**). Other animals produce a small number of large eggs, each with a large energy store (**Figure 31.12B**). With a fixed amount of available energy, a female animal can produce many small eggs or a few large eggs, but she cannot produce many large eggs. Thus there is a trade-off between the number of offspring produced and the energy resources each offspring receives from its mother.

The larger the energy store in an egg, the longer an offspring can develop before it must either find its own food or be fed by its parents. Birds of all species lay relatively small numbers of relatively large eggs, but incubation periods vary. In some

species, eggs hatch when the young are still helpless (**Figure 31.13A**). Such *altricial* young must be fed and cared for until they can feed themselves; parents can provide for only a small number of altricial offspring. In contrast, some bird species incubate their eggs longer, and the hatchlings are developed to a point that they are able to forage for themselves almost immediately (**Figure 31.13B**). The young of such species are called *precocial*.

Parasite life cycles evolve to facilitate dispersal and overcome host defenses

Animals that live as internal parasites are bathed in the nutritious tissues of their host or in the digested food that fills their host's digestive tract. Thus they may not need to exert much energy to obtain food, but to survive they must overcome the host's defenses. Furthermore, either they or their offspring must disperse to new hosts while their host is still living, because they die when their host dies.

The fertilized eggs of some parasites are voided with the host's feces and later ingested directly by other host individuals. Most parasite species, however, have complex life cycles involving one or more intermediate hosts and several larval stages (**Figure 31.14**). Some intermediate hosts transport individual parasites directly between other hosts. Others house and support the parasite until another host ingests it. Complex life cycles may thus facilitate the transfer of individual parasites among hosts.

Colonial organisms are composed of genetically identical, physiologically integrated individuals

Most people tend to view the distinction between individuals and populations as clear-cut. However, in several groups of animals, asexual reproduction without fission can lead to colonies

(A) *Parus caeruleus*(B) *Branta canadensis*

31.13 Helpless or Independent

(A) The altricial young of the blue tit are essentially helpless when they hatch. Their parents feed and care for them for several weeks. (B) Canada goose hatchlings are precocial, ready to swim and feed independently almost immediately after hatching.

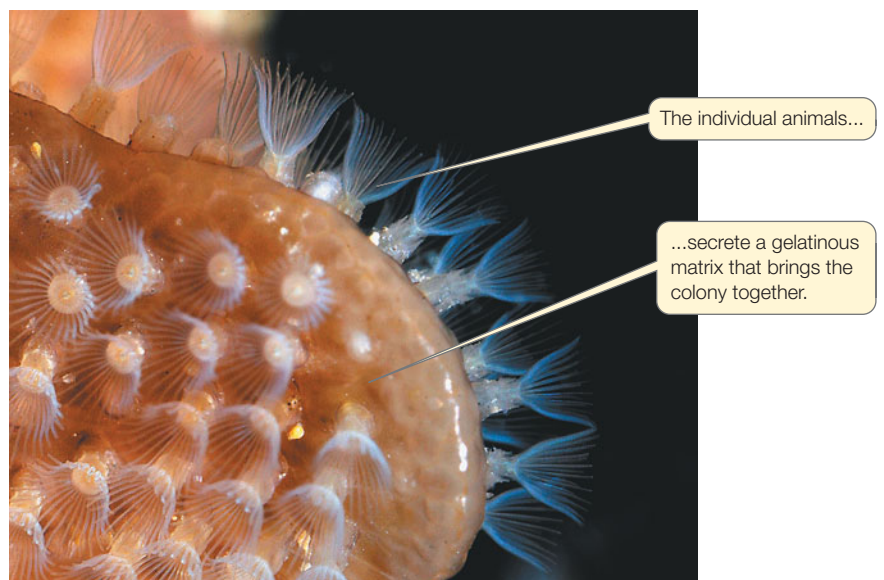

31.14 Reaching a New Host by a Complex Route

The broad fish tapeworm (*Diphyllobothrium latum*) must pass through the bodies of a copepod (a type of crustacean) and at least one fish before it can reinfect its primary host, a mammal. Such complex life cycles assist the parasite's colonization of new host individuals, but they also provide opportunities for humans to break the cycle with hygienic measures.

of organisms composed of many physiologically integrated individuals, which at first appearance may look much like a single integrated organism. The individuals in a colony are clonal copies of one another, so they are genetically homogeneous. Coloniality has arisen several times among animal groups, with widely varying levels of integration and specialization among the individuals. In some species, colonies are composed of loosely connected but integrated individuals that all function alike (**Figure 31.15**). In other colonial species, the individuals may become specialized for different functions, just as different cell types in multicellular organisms have different functions. The Portuguese man-of-war (see Figure 31.9) is an example of such a colonial animal, as it is composed of many individuals of four specialized body forms, all integrated and functioning together. The individuals in the colony are themselves multicellular, however, unlike the cells of a single multicellular organism.

Diaperoecia californica

31.15 Colonial Animals This colonial bryozoan consists of many asexually reproducing, genetically homogeneous, physiologically interacting individuals. The colony looks much like a single individual with many parts, but in fact it is many individuals acting together.

31.4 RECAP

Many animals have a larval stage that clearly differs from the adult in morphology. In some animals, the larval form is a dispersal stage; in other species, the adults are more likely to disperse than are larvae. In several groups of organisms, asexual reproduction without fission leads to coloniality.

- How do trade-offs constrain the evolution of life cycles? See pp. 655–656
- Do you understand the differences between a single multicellular organism and coloniality? See p. 657 and Figure 31.15

31.5 What Are the Major Groups of Animals?

Variations in body symmetry, body cavity structure, life cycles, patterns of development, and survival strategies differentiate millions of animal species. In the remainder of this chapter and in Chapters 32 and 33, we become acquainted with the

(A) *Xestospongia testudinaria*(B) *Euplectella aspergillum*(C) *Leucilla nuttingi*

major animal groups and learn how the general characteristics described in this chapter apply to each of them.

Table 31.1 summarizes the living members of the major animal groups. **Bilateria** is a large monophyletic group embracing all animals other than sponges, placozoans, ctenophores, and cnidarians. Some major traits that support the monophyly of bilaterians (in addition to genomic analyses) are the presence of three distinct cell layers in embryos (triploblasty) and the presence of at least seven Hox genes (see Chapters 19 and 20). Although bilateral symmetry is often viewed as a synapomorphy of bilaterians (and the trait gives the group its name), some groups of cnidarians are also bilaterally symmetrical. Recent studies have shown that the genetic basis of bilateral symmetry is the same in bilaterians and cnidarians that have bilateral symmetry, so this feature was likely present in the ancestor of these two groups.

Bilaterian animals comprise the two major categories mentioned earlier in this chapter, the protostomes and the deuterostomes (see Figure 31.1). These two groups have been evolving separately for more than 500 million years—since the early Cambrian or the late Precambrian. We describe the protostomes in Chapter 32 and the deuterostomes in Chapter 33.

The remainder of this chapter describes those animal groups that are not bilaterians. The simplest animals, the sponges, have no distinct tissue types. Placozoans have four cell types and weakly differentiated tissue layers. All other animals groups, including the bilaterians, are known as **eumetazoans**. The eumetazoans have obvious body symmetry, a gut, a nervous system, and tissues organized into distinct organs (although there have been secondary losses of some of these structures in some eumetazoans). Sponges and placozoans lack all of these features.

Sponges are loosely organized animals

Sponges are the simplest animals.

Although they have some specialized cells, they have no distinct embryonic cell layers and no true organs. Early naturalists thought sponges were plants because they were sessile and lacked body symmetry.

Sponges have hard skeletal elements called **spicules**, which may be small and simple or large and complex. There are three major groups of sponges, which separated soon after the split between sponges and the rest of the animals. Members of two groups (*glass sponges* and *demosponges*) have skeletons composed of siliceous spicules made of hydrated silicon dioxide (**Figure 31.16A,B**). These spicules are remarkable in having greater flexibility and toughness than synthetic glass rods of similar length. Members of the third group, the *calcareous sponges*, take their name

31.16 Sponge Diversity (A) The great majority of sponge species are demosponges, such as these Pacific barrel sponges. The system of pores and water canals “typical” of the sponge body plan is apparent. (B) The supporting structures of both demosponges and glass sponges are siliceous spicules, seen here in the skeleton of a glass sponge. (C) The skeletons of calcareous sponges are made of calcium carbonate.

TABLE 31.1

Summary of Living Members of the Major Animal Groups

APPROXIMATE NUMBER OF LIVING SPECIES DESCRIBED			APPROXIMATE NUMBER OF LIVING SPECIES DESCRIBED		
MAJOR GROUPS			MAJOR GROUPS		
Sponges	9,000	Demosponges, glass sponges, calcareous sponges	Ecdysozoans		
Placozoans	2		Kinorhynchs	150	
Ctenophores	150		Loriciferans	100	
Cnidarians	11,000	Anthozoans: Corals, sea anemones	Priapulids	16	
		Hydrozoans: Hydras and hydroids	Horsehair worms	320	
		Scyphozoans: Jellyfishes	Nematodes	25,000	
PROTOSTOMES			Onychophorans	150	
Arrow worms	100		Tardigrades	800	
Lophotrochozoans			Arthropods:		
Bryozoans	4,500		Crustaceans	52,000	Crabs, shrimps, lobsters, barnacles, copepods
Flatworms	25,000	Free-living flatworms; flukes and tapeworms (all parasitic); monogeneans (ectoparasites of fishes)	Hexapods	1,000,000	Insects and relatives
			Myriapods	14,000	Millipedes, centipedes
Rotifers	1,800		Chelicerates	98,000	Horseshoe crabs, arachnids (scorpions, harvestmen, spiders, mites, ticks)
Ribbon worms	1,000		DEUTEROSTOMES		
Phoronids	20		Echinoderms	7,000	Crinoids (sea lilies and feather stars); brittle stars; sea stars; sea daisies; sea urchins; sea cucumbers
Brachiopods	335		Hemichordates	100	Acorn worms and pterobranchs
Annelids	16,500	Polychaetes (all marine)	Urochordates	3,000	Ascidians (sea squirts)
		Clitellates: Earthworms, freshwater worms, leeches	Cephalochordates	30	Lancelets
Mollusks	100,000	Monoplacophorans	Vertebrates	62,000	Hagfish; lampreys
		Chitons			Cartilaginous fishes
		Bivalves: Clams, oysters, mussels			Ray-finned fishes
		Gastropods: Snails, slugs, limpets			Coelacanths; lungfishes
		Cephalopods: Squids, octopuses, nautiloids			Amphibians
					Reptiles (including birds)
					Mammals

from their calcium carbonate skeletons (**Figure 31.16C**). There is some question about the monophyly of sponges. Analyses of some gene sequences suggest that calcareous sponges are actually more closely related to the eumetazoans than to the other groups of sponges. However, genomic analyses that combine information from many genes do support the monophyly of sponges.

The body plan of sponges of all three groups—even large ones, which may reach a meter or more in length—is an aggregation of cells built around a water canal system. Water, along with any food particles it contains, enters the sponge by way of small pores and passes into the water canals or a central atrium, where choanocytes capture food particles (see Figure 31.7).

A skeleton of simple or branching spicules, and often a complex network of elastic fibers, supports the body of most

sponges. Sponges also have an extracellular matrix, composed of collagen, adhesive glycoproteins, and other molecules, that holds the cells together. Most species are filter feeders; a few species are carnivores that trap prey on hook-shaped spicules that protrude from the body surface.

Most of the 9,000 species of sponges are marine animals; only about 50 species live in fresh water. Sponges come in a wide variety of sizes and shapes that are adapted to different movement patterns of water. Sponges living in intertidal or shallow subtidal environments with strong wave action are firmly attached to the substratum. Most sponges that live in slowly flowing water are flattened and are oriented at right angles to the direction of current flow. They intercept water and the prey it contains as it flows past them.

Sponges reproduce both sexually and asexually. In most species, a single individual produces both eggs and sperm, but individuals do not self-fertilize. Water currents carry sperm from one individual to another. Asexual reproduction is by budding and fragmentation.

Placozoans are abundant but rarely observed

As discussed in the opening of this chapter, **placozoans** are structurally very simple animals with only a few distinct cell types (see the photograph on p. 645). Individuals in the mature, asymmetrical life stage are usually observed adhering to surfaces (such as the glass of aquariums, where they were first discovered, or to rocks and other hard substrates in nature). Their structural simplicity—they have no mouth, gut, or nervous system—initially led biologists to suspect they might be the sister group of all other animals. Most phylogenetic analyses have not supported this hypothesis, however, and some aspects of the placozoans' structural simplicity may be secondarily derived. They are generally considered to have a diploblastic body plan, with upper and lower epithelial (surface) layers that sandwich a layer of contractile fiber cells.

Recent studies have found that placozoans have a pelagic (open-ocean) stage that is capable of swimming (**Figure 31.17**), but the life history of placozoans is incompletely known. Most studies have focused on the larger adherent stages that are usually found in aquariums, where they appear after being inadvertently collected with other marine organisms. The transparent nature and small size of placozoans make them very difficult to observe in nature. Nonetheless, it is known that placozoans can reproduce both asexually as well as sexually, although the details of their sexual reproduction are mostly unknown. As we

31.17 A Swimming Stage in the Life of a Placozoan Placozoans are tiny and transparent, and thus difficult to observe in nature. Recent studies have found a small, weakly swimming pelagic stage of placozoan to be abundant in many warm tropical and subtropical seas.

noted in the opening story, placozoans have mostly been studied in aquariums, although we now know that pelagic-stage placozoans are abundant in warm seas around the world.

Ctenophores are radially symmetrical and diploblastic

Ctenophores, also known as *comb jellies*, lack most of the Hox genes found in all other eumetazoans. Ctenophores have a radially symmetrical, diploblastic body plan. The two cell layers are separated by an inert, gelatinous extracellular matrix called **mesoglea**. Ctenophores have a *complete gut*: food enters through a mouth, and wastes are eliminated through two anal pores.

Ctenophores move by beating cilia rather than muscular contractions. Most of the 150 known species have eight comblike rows of cilia-bearing plates, called **ctenes** (**Figure 31.18**). The feeding tentacles of ctenophores are covered with cells that discharge adhesive material when they contact prey. After capturing its prey, a ctenophore retracts its tentacles to bring the food to its mouth. In some species, the entire surface of the body is coated with sticky mucus that captures prey. Most ctenophores

(B) *Mnemiopsis* sp.

Mouth

31.18 Comb Jellies Feed with Tentacles (A) The body plan of a typical ctenophore. The long, sticky tentacles sweep through the water, efficiently harvesting small prey. (B) This comb jelly, photographed in Sydney Harbor, Australia, has short tentacles.

31.19 The Cnidarian Life Cycle Typically Has Two Stages The life cycle of a scyphozoan (jellyfish) exemplifies the typical cnidarian body forms: the sessile, asexual polyp; and the motile, sexual medusa. Some species of cnidarians have life cycles that lack polyps or medusae.

eat small planktonic organisms, although some eat other ctenophores. They are common in open seas and can become abundant in protected bodies of water, where large populations of ctenophores can damage local ecosystems.

Ctenophore life cycles are uncomplicated. Gametes are released into the body cavity and then discharged through the mouth or the anal pores. Fertilization takes place in open seawater. In nearly all species, the fertilized egg develops directly into a miniature ctenophore that gradually grows into an adult.

Cnidarians are specialized carnivores

The **cnidarians** (jellyfishes, sea anemones, corals, and hydrozoans) may be the sister group of the ctenophores, although some biologists think they are more closely related to the bilaterians. The mouth of a cnidarian is connected to a blind sac called the **gastrovascular cavity** (a cnidarian thus does not have a complete gut). The gastrovascular cavity functions in digestion, circulation, and gas exchange, and it also acts as a hydrostatic skeleton. The single opening serves as both mouth and anus.

The life cycle of many cnidarians has two distinct stages, one sessile and the other motile (Figure 31.19), although one or the other of these stages is absent in some groups. In the sessile

polyp stage, a cylindrical stalk is attached to the substratum. The motile **medusa** (plural *medusae*) is a free-swimming stage shaped like a bell or an umbrella. It typically floats with its mouth and feeding tentacles facing downward. Mature polyps produce medusae by asexual budding. Medusae then reproduce sexually, producing eggs or sperm by meiosis and releasing the gametes into the water. A fertilized egg develops into a free-swimming, ciliated larva called a **planula**, which eventually settles to the bottom and develops into a polyp.

yourBioPortal.com

GO TO Animated Tutorial 31.1 • Life Cycle of a Cnidarian

Cnidarians have epithelial cells with muscle fibers whose contractions enable the animals to move, as well as simple *nerve nets* that integrate their body activities. They also have specialized structural molecules (collagen, actin, and myosin). They are specialized carnivores, using the toxin in their nematocysts to capture relatively large and complex prey (see Figure 31.9). Some cnidarians, including many corals and anemones, gain additional nutrition from photosynthetic endosymbionts that live in their tissues. Cnidarians, like ctenophores, are largely made up of inert mesoglea. They have low metabolic rates and can survive in environments where they encounter prey only infrequently.

Of the roughly 11,000 living cnidarian species, all but a few live in the oceans (Figure 31.20). The smallest cnidarians can hardly be seen without a microscope. The largest known jellyfish is 2.5 meters in diameter, and some colonial siphonophores

(C) *Gonionemus vertens*(D) *Polyorchis penicillatus*

ondary polyps differentiate into feeding polyps; in some species, other secondary polyps differentiate to circulate water through the colony.

The common names of coral groups—brain corals, staghorn corals, and organ pipe corals, among others—often describe their appearance (Figure 31.21A). Corals are sessile and colonial. The polyps of

(which include the Portuguese man-of-war; see Figure 31.9) can reach lengths in excess of 30 meters. Here we describe three clades of cnidarians that have many species: anthozoans, scyphozoans, and hydrozoans.

ANTHOZOANS Members of the **anthozoan** clade include sea anemones, sea pens, and corals. Sea anemones (see Figure 31.20A), all of which are solitary, are widespread in both warm and cold ocean waters. Sea pens (see Figure 31.20B), by contrast, are colonial. Each colony consists of two or more different kinds of polyps. The primary polyp has a lower portion anchored in the bottom sediment and a branched upper portion that projects above the substratum. Along the upper portion, the primary polyp produces smaller secondary polyps by budding. Some of these sec-

(A) *Diploria labyrinthiformis*

31.21 Corals (A) The descriptive common name of this Caribbean coral is “brain coral.” (B) Many different coral species form this reef in the Red Sea between Egypt and the Arabian Peninsula.

31.22 Hydrozoans Often Have Colonial Polyps

The polyps in a hydrozoan colony may differentiate to perform specialized tasks. In the species whose life cycle is diagrammed here, the medusa is the sexual reproductive stage, producing eggs and sperm in organs called gonads.

SCYPHOZOANS The several hundred species of scyphozoans are all marine. The mesoglea of their medusae is thick and firm, giving rise to their common name—jellyfishes or sea jellies. The medusa rather than the polyp dominates the life cycle of scyphozoans. An individual medusa is male or female, releasing eggs or sperm into the open sea. The fertilized egg develops into a small planula larva that quickly settles on a substratum and develops into a small polyp. This polyp feeds and grows and may produce additional polyps by budding. After a period of growth, the polyp begins to bud off small medusae, which feed, grow, and transform into adult medusae (see Figures 31.19 and 31.20C).

most species form a skeleton by secreting a matrix of organic molecules on which they deposit calcium carbonate, which forms the eventual skeleton of the coral colony. As the colony grows, old polyps die but their calcium carbonate skeletons remain. Living corals form a layer on top of a growing bank of skeletal remains, eventually forming chains of islands and reefs (**Figure 31.21B**). The Great Barrier Reef along the northeastern coast of Australia is a system of coral formations more than 2,000 kilometers long—about the distance from New York City to St. Louis. A single coral reef in the Red Sea has been calculated to contain more material than all the buildings in the major cities of North America combined.

Corals flourish in clear, nutrient-poor tropical waters. They grow well in such environments because unicellular photosynthetic dinoflagellates live endosymbiotically within their cells. These dinoflagellates provide the corals with products of photosynthesis; the corals, in turn, provide the dinoflagellates with nutrients and a place to live. This endosymbiotic relationship explains why reef-forming corals are restricted to clear surface waters, where light levels are high enough to support photosynthesis.

Coral reefs throughout the world are threatened both by global warming, which is raising the temperatures of shallow tropical ocean waters, and by polluted runoff from development on adjacent shorelines. Warming can lead to the loss of coral endosymbionts (*coral bleaching*; see Figure 27.8A), and an overabundance of nitrogen in runoff gives an advantage to algae, which overgrow and eventually smother the corals.

HYDROZOANS Hydrozoans have diverse life cycles. The polyp typically dominates the life cycle, but some species have only medusae and others have only polyps. Most hydrozoans are colonial (see Figure 31.20D). A single larval planula eventually gives rise to a colony of many polyps, all interconnected and sharing a continuous gastrovascular cavity (**Figure 31.22**). Within such a colony, some polyps have tentacles with many nematocysts; they capture prey for the colony. Other individuals lack tentacles and are unable to feed but are specialized for the asexual production of medusae. Still others are fingerlike and defend the colony with their nematocysts.

31.5 RECAP

Bilateria animals are in one of two major clades, protostomes or deuterostomes. The non-bilateria animals—the sponges, placozoans, ctenophores, and cnidarians—have diverse life cycles, feeding strategies, and growth forms.

- Why are sponges considered to be animals, even though they lack the complex body structures found among most other animal groups? **See pp. 658–659 and Figure 31.7**
- Describe some major features of the following groups: sponges, placozoans, ctenophores, and cnidarians. **See pp. 658–663 and Figures 31.16–31.19**

CHAPTER SUMMARY

31.1 What Characteristics Distinguish the Animals?

- Animals share a set of derived traits not found in other groups of organisms. These traits include similarities in the sequences of many of their genes, the structure of their cell junctions, and the components of their extracellular matrix.
- Patterns of embryonic development provide clues to the evolutionary relationships among animals. **Diploblastic** animals develop two embryonic cell layers; **triploblastic** animals develop three cell layers.
- Differences in their patterns of early development characterize two major clades of triploblastic animals, the **protostomes** and the **deuterostomes**.

31.2 What Are the Features of Animal Body Plans?

- Animal **body plans** can be described in terms of **symmetry**, **body cavity** structure, **segmentation**, and type of appendages.
- A few animals have no symmetry, but most animals have either **radial symmetry** or **bilateral symmetry**. **Review Figure 31.3**
- Most animals with radial symmetry move slowly or not at all, whereas most animals with bilateral symmetry are able to move more rapidly. Many bilaterally symmetrical animals exhibit **cephalization**, with sensory and nervous tissues in an anterior head.
- On the basis of their body cavity structure, animals can be described as **acoelomates**, **pseudocoelomates**, or **coelomates**. **Review Figure 31.4**
- Segmentation, which takes many forms, improves control of movement, especially if the animal also has appendages.

31.3 How Do Animals Get Their Food?

- **Motile** animals can move to find food; **sessile** animals stay in one place and capture food by filter feeding or through interaction with endosymbionts.
- **Filter feeders** strain small organisms and organic molecules from their environment.
- **Predators** have morphological features such as sharp teeth, beaks, and claws that enable them to capture and subdue animal **prey**.
- **Herbivores** consume plants, usually without killing them.
- **Parasites** live in or on other organisms and obtain nutrition from these host individuals.
- **Detritivores** consume decaying organic matter and return nutrients to the ecosystem.

31.4 How Do Life Cycles Differ among Animals?

- The stages of an animal's **life cycle** may be specialized for different activities. An immature stage that is dramatically different from the adult stage is called a **larva**.
- Most animal life cycles have at least one **dispersal** stage, so that the animal does not die in the same place where it was born. Many sessile marine animals can be grouped by the presence of one of two distinct larval dispersal stages: **trochophore** or **nauplius**.
- Parasites have complex life cycles that may involve one or more hosts and several larval stages. **Review Figure 31.14**
- A characteristic of an animal or a life cycle stage may improve the animal's performance in one activity but reduce its performance in another, a situation known as a trade-off.
- Colonial organisms are composed of groups of genetically homogeneous individuals produced through clonal reproduction without subsequent fission.

31.5 What Are the Major Groups of Animals?

- All animals other than sponges, placozoans, ctenophores, and cnidarians belong to a large monophyletic group called the **Bilateria**. **Eumetazoans**, which have tissues organized into distinct organs, include all animals other than sponges and placozoans.
- **Sponges** are simple animals that lack differentiated cell layers and true organs. They have skeletons made up of siliceous or calcareous **spicules**. They create water currents and capture food with flagellated feeding cells called choanocytes. Choanocytes are an evolutionary link between the animals and the choanoflagellate protists. **Review Figure 31.7**
- **Placozoans** have only a few cell types and lack true organs, although their simplicity may be secondarily derived. They are abundant in warm seas of the world, but their transparent form and small size make them difficult to observe.
- **Ctenophores** and many **cnidarians** are radially symmetrical, although some cnidarians are bilaterally symmetrical. The mature adherent stage of placozoans is asymmetrical.
- The two cell layers of ctenophores are separated by an inert extracellular matrix called **mesoglea**.
- Ctenophores move by beating fused plates of cilia called **ctenes**. **Review Figure 31.18**
- The life cycle of most cnidarians has two distinct stages: a sessile **polyp** stage and a motile **medusa**. A fertilized egg develops into a free-swimming larval **planula**, which settles to the bottom and develops into a polyp. **Review Figures 31.19 and 31.22, ANIMATED TUTORIAL 31.1**

SEE WEB ACTIVITIES 31.1 and 31.2 for a concept review of this chapter.

SELF-QUIZ

- The body plan of an animal is
 - its general structure.
 - the integrated functioning of its parts.
 - its general structure and the integrated functioning of its parts.
 - its general structure and its evolutionary history.
 - the integrated functioning of its parts and its evolutionary history.
- A bilaterally symmetrical animal can be divided into mirror images by
 - any plane through the midline of its body.
 - any plane from its anterior to its posterior end.
 - any plane from its dorsal to its ventral surface.
 - any plane through the midline of its body from its anterior to its posterior end.
 - a single plane through the midline of its body from its dorsal to its ventral surface.

3. Among protostomes, cleavage of the fertilized egg is
 - a. delayed while the egg continues to mature.
 - b. always radial.
 - c. spiral, radial, or idiosyncratic.
 - d. triploblastic.
 - e. diploblastic.
4. Many parasites evolved complex life cycles because
 - a. they are too simple to disperse readily.
 - b. they are poor at recognizing new hosts.
 - c. they were driven to it by host defenses.
 - d. complex life cycles increase the probability of a parasite's transfer to a new host.
 - e. their ancestors had complex life cycles and they simply retained them.
5. Bilateral symmetry
 - a. is found only among bilaterians.
 - b. is characteristic of all sponges.
 - c. is characteristic of all ctenophores.
 - d. is characteristic of all cnidarians.
 - e. none of the above
6. In the common ancestor of protostomes and deuterostomes, the pattern of early cleavage was
 - a. spiral.
 - b. radial.
 - c. biradial.
 - d. deterministic.
 - e. haphazard.
7. A fluid-filled body cavity can function as a hydrostatic skeleton because
 - a. fluids are moderately compressible.
 - b. fluids are highly compressible.
 - c. fluids are incompressible at physiological pressures.
 - d. fluids have the same density as body tissues.
 - e. fluids can be moved by ciliary action.
8. Which of the following is *not* a feature that enables some animals to capture large prey?
 - a. Sharp teeth
 - b. Claws
 - c. Toxins
 - d. A filtering device
 - e. Tentacles with stinging cells
9. The sponge body plan is characterized by
 - a. a mouth and digestive cavity but no muscles or nerves.
 - b. muscles and nerves but no mouth or digestive cavity.
 - c. a mouth, digestive cavity, and spicules.
 - d. muscles and spicules but no digestive cavity or nerves.
 - e. the lack of a mouth, digestive cavity, muscles, or nerves.
10. The endosymbiotic dinoflagellates present in many corals
 - a. provide the corals with the products of photosynthesis.
 - b. allow corals to grow rapidly in clear, nutrient-poor tropical waters
 - c. can be lost when environmental conditions change.
 - d. all of the above
 - e. none of the above

FOR DISCUSSION

1. Differentiate among the members of each of the following sets of related terms:
 - a. radial symmetry/bilateral symmetry
 - b. protostome/deuterostome
 - c. diploblastic/triploblastic
 - d. coelomate/pseudocoelomate/acelomate
2. In this chapter we listed some of the traits shared by all animals that convince most biologists that all animals are descendants of a single common ancestral lineage. In your opinion, which of these traits provides the most compelling evidence that animals are monophyletic? If morphological and molecular data do not agree, should one type of evidence be given greater weight? If so, which one?
3. Describe some features that allow animals to capture prey that are larger and more complex than they themselves are.
4. Why is bilateral symmetry strongly associated with cephalization, the concentration of sensory organs in an anterior head?
5. How does a slow metabolic rate enable an animal to live in an unproductive environment?

ADDITIONAL INVESTIGATION

The discoveries that pelagic (swimming in open ocean) stages of placozoans are abundant in warm seas, and that the mature stages settle onto smooth surfaces, suggest how these organisms

might be collected and surveyed. What sampling procedures might you use to discover whether placozoans occur at a particular location along a coast?

WORKING WITH DATA (GO TO yourBioPortal.com)

Reconstructing Animal Phylogeny In this exercise, you will analyze a subset of protein sequences that provide evidence about the evolutionary relationships of some major animal

groups. Using the parsimony method described in Chapter 22, you will build a phylogenetic tree of some of the major animal lineages depicted in Figure 31.1.

Tiny parasites exert mind control

Most people have never heard of strepsipterans, and even those who *have* heard of them have probably never seen one. They don't know what they are missing! These tiny insects—there are some 600 species of them—parasitize hundreds of other insect species, including bees, wasps, ants, grasshoppers, and cockroaches. Males and females of most strepsipteran species parasitize the same host species, although in one clade males parasitize ants whereas females parasitize grasshoppers.

Strepsipteran males and females are often so different that even determining that they are members of the same species requires DNA analysis.

They also have some of the strangest life cycles of any animals. Once grown to maturity within their hosts (whose internal organs they consume), the males of most species emerge looking like a “typical” insect. The females also consume the host from within, but they usually remain inside the host. A mature female extrudes her head and part of her body from the body of her host. The extruded body part contains an opening that receives sperm from a male. Much later, this opening becomes an exit for the strepsipteran larvae. The host insects are left dead or severely damaged and produce no offspring of their own.

Strepsipterans dramatically change the behavior of their hosts in ways that help them complete their life cycles at the expense of their hosts' reproduction. For

example, when wasps—a typical host—are parasitized by strepsipterans, the parasites generate signals that induce the wasps to leave their nest and form a mating aggregation. This aggregation, however, serves the strepsipterans, not the wasps. Once the wasps aggregate, the male strepsipterans emerge from their hosts to search for and mate with female strepsipterans, whose heads are now poking out of the bodies of other wasps.

Adult male strepsipterans live only a few hours, during which they must find a female and mate. Because the protruding part of a female's body is barely visible, the males have unusually large eyes,

Same Parasite, Different Lifestyles

Strepsipterans are parasitic insects that grow to maturity within host insects. Most male strepsipterans look insectlike upon reaching maturity, when they leave their host to find and mate with a very different-looking female strepsipteran. Females remain inside their host.

A Host Insect Strepsipterans parasitize many different insect species; wasps of the genus *Polistes* (paper wasps) are common hosts. Three female strepsipterans (arrows) can be seen on this *P. dorsalis* individual.

and about 75 percent of their brain cells are allocated to vision. This highly developed sensory system evolved as an adaptation to help the male find a female.

Strepsipterans and their hosts are all insects, and insects account for more than half of all described species on Earth. Other protostome groups, such as mollusks, nematodes, crabs, spiders, and ticks, are also species-rich. Many protostome species are parasites. Parasites often live within their hosts and absorb nutrients through their body walls. Some parasites, including the strepsipterans, can more technically be described as *parasitoids*, which consume the host's tissues as they develop from eggs laid on or in the host's body, ultimately killing the host.

IN THIS CHAPTER we will describe the characteristics of protostome animals and describe the members of two major protostome clades, the lophotrochozoans and the ecdysozoans. We will give particular attention to the arthropods, a species-rich group of ecdysozoans with rigid exoskeletons and jointed appendages.

CHAPTER OUTLINE

32.1 What Is a Protostome?

32.2 What Features Distinguish the Major Groups of Lophotrochozoans?

32.3 What Features Distinguish the Major Groups of Ecdysozoans?

32.4 Why Are Arthropods So Diverse?

32.1 What Is a Protostome?

You may recall from Chapter 31 that the embryos of diploblastic animals have two cell layers: an outer ectoderm and an inner endoderm (see Section 31.1). Sometime after the origin of the diploblastic animals (the placozoans, ctenophores, and cnidarians), a third embryological germ layer evolved—the mesoderm, which lies between the ectoderm and the endoderm. Mesoderm is found in the two major triploblastic animal clades, the protostomes and the deuterostomes. If we were to judge solely on the basis of numbers, both of species and of individuals, the protostomes would emerge as by far the more successful of the two groups.

As noted in Chapter 31, the name *protostome* means “mouth first.” In protostomes that have an embryonic blastopore, this opening becomes the mouth as the animal develops. In contrast, in deuterostomes (“mouth second”), the blastopore becomes the anal opening of the digestive tract (see Figure 31.2). The protostomes can be further divided into two major clades—the *lophotrochozoans* and the *ecdysozoans*—largely on the basis of DNA sequence analysis (**Figure 32.1**).

The protostomes are extremely varied, but they are all bilaterally symmetrical animals whose bodies exhibit two major derived traits:

- An anterior *brain* that surrounds the entrance to the digestive tract
- A ventral *nervous system* consisting of paired or fused longitudinal nerve cords

Other aspects of protostome body organization differ widely from group to group (**Table 32.1**). Although the common ancestor of the protostomes had a *coelom*, subsequent modifications of the coelom distinguish many protostome lineages. In at least one protostome lineage (the flatworms), the coelom has been lost (that is, the flatworms reverted to an *acoelomate* state). Some lineages are characterized by a *pseudocoelom*, which you may recall is a body cavity lined with mesoderm in which the internal organs are suspended (see Figure 31.4). In two of the most prominent protostome clades, the coelom has been highly modified:

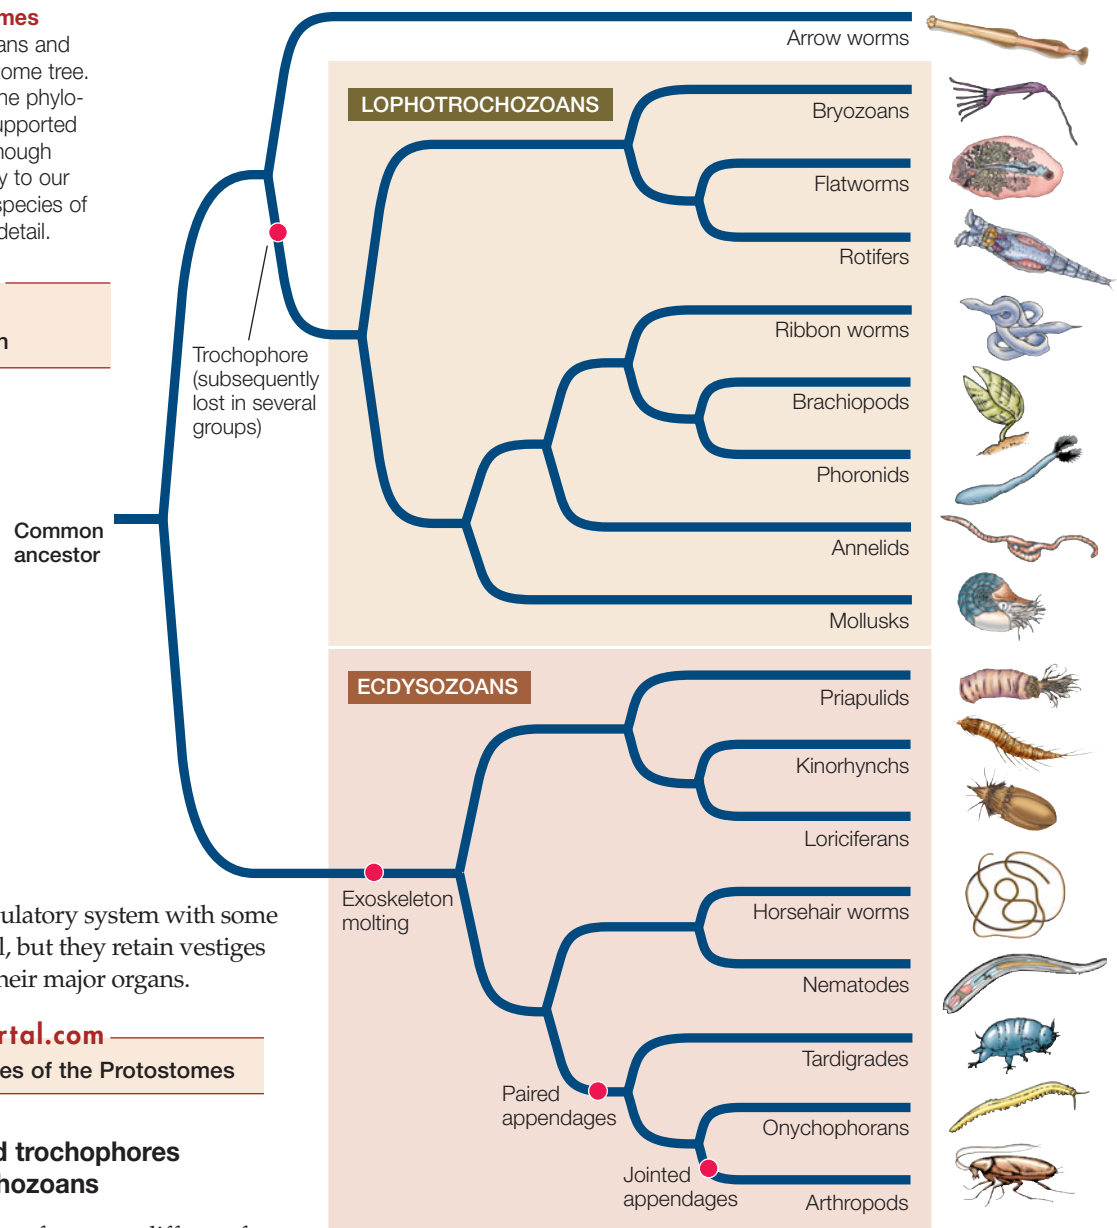

- The *arthropods* lost the ancestral condition of the coelom over the course of evolution. Their internal body cavity has become a *hemocoel*, or “blood chamber,” in which fluid from an open circulatory system bathes the internal organs before returning to blood vessels.

32.1 Phylogenetic Tree of Protostomes

Two major lineages, the lophotrochozoans and the ecdysozoans, dominate the protostome tree. Some small groups are not included. The phylogenetic relationships shown here are supported mostly by genomic sequence data. Although genomic studies are contributing greatly to our knowledge of animal phylogeny, most species of protostomes have yet to be studied in detail.

yourBioPortal.com

GO TO Web Activity 32.1
Protostome Classification

- Most *mollusks* have an open circulatory system with some of the attributes of the hemocoel, but they retain vestiges of an enclosed coelom around their major organs.

yourBioPortal.com

GO TO Web Activity 32.2 • Features of the Protostomes

Cilia-bearing lophophores and trochophores evolved among the lophotrochozoans

Lophotrochozoans derive their name from two different features that involve cilia: a feeding structure known as a *lophophore* and a free-living larva known as a *trochophore*. Neither a lophophore nor a trochophore is universal for all lophotrochozoans, however.

Several distantly related groups of lophotrochozoans (including bryozoans, brachiopods, and phoronids) have a **lophophore**, a circular or U-shaped ring of ciliated, hollow tentacles around the mouth (**Figure 32.2**). This complex structure is an organ for both food collection and gas exchange. Biologists once grouped taxa that have lophophores together as *lophophorates*, but it is now clear that they are not one another's closest relatives. The lophophore appears to have evolved independently several times, or else it is an ancestral feature of lophotrochozoans and has been lost in many groups. Nearly all animals with a lophophore are sessile as adults. They use the tentacles and cilia of the lophophore to capture small floating organisms from the water. Other sessile lophotrochozoans use less well-developed tentacles for the same purpose.

Some lophotrochozoans, especially in their larval form, use cilia for locomotion. The larval form known as a **trochophore** moves by beating a band of cilia (see Figure 31.11A). This movement of cilia also brings plankton closer to the larva, where the plankton can be captured and ingested (similar in function to the cilia of the lophophore). Trochophore larvae are found among many of the major groups of lophotrochozoans, including the mollusks, annelids, ribbon worms, and bryozoans. This larval form was probably present in the common ancestor of lophotrochozoans, although it has been subsequently lost in several lineages.

As discussed Chapter 31, some lophotrochozoans (including flatworms, ribbon worms, annelids, and mollusks) exhibit a form of cleavage in early development known as *spiral cleavage*. Some biologists group these taxa together as *spiralian*s, although phylogenetic analyses of gene sequences do not support the

TABLE 32.1

Anatomical Characteristics of Some Major Protostome Groups^a

GROUP	BODY CAVITY	DIGESTIVE TRACT	CIRCULATORY SYSTEM
Arrow worms	Coelom	Complete	None
LOPHOTROCHOZOANS			
Flatworms	None	Dead-end sac	None
Rotifers	Pseudocoelom	Complete	None
Bryozoans	Coelom	Complete	None
Brachiopods	Coelom	Complete in most	Open
Phoronids	Coelom	Complete	Closed
Ribbon worms	Coelom	Complete	Closed
Annelids	Coelom	Complete	Closed or open
Mollusks	Reduced coelom	Complete	Open except in cephalopods
ECDYSOZOANS			
Horsehair worms	Pseudocoelom	Greatly reduced	None
Nematodes	Pseudocoelom	Complete	None
Arthropods	Hemocoel	Complete	Open

^aNote that all protostomes have bilateral symmetry.

species with spiral cleavage as monophyletic. Nonetheless, spiral cleavage may have been present in the lophotrochozoan ancestor, with several subsequent losses of this cleavage pattern.

Many lineages of lophotrochozoans are *wormlike*, which means they are bilaterally symmetrical, legless, soft-bodied, and at least several times longer than they are wide. A wormlike body form enables animals to burrow efficiently through marine sediment or soil. However, as we will describe later in this chapter, the *mollusks*—the most familiar of the lophotrochozoans to many people—have a very different body organization.

Ecdysozoans must shed their cuticles

Ecdysozoans have an external covering, or **cuticle**, which is secreted by the underlying *epidermis* (the outermost cell layer). The cuticle provides these animals with both protection and support. Once formed, however, the cuticle cannot grow. How, then, can ecdysozoans increase in size? They do so by shedding, or **molting**, the cuticle and replacing it with a new, larger one. This molting process gives the clade its name (Greek *ecdysis*, “to get out of”).

A recently discovered fossil of a Cambrian soft-bodied arthropod, preserved in the process of molting, shows that molting evolved more than 500 million years ago (**Figure 32.3A**). An increasingly rich array of molecular and genetic evidence, including a set of Hox genes shared by all ecdysozoans, suggests they have a single common ancestor. Thus molting of a cuticle is a trait that may have evolved only once during animal evolution.

Before an ecdysozoan molts, a new cuticle is already forming underneath the old one. Once the old cuticle is shed, the new one expands and hardens. Until it has hardened, though, the animal is vulnerable to its enemies, both because its outer surface is easy to penetrate and because an animal with a soft cuticle moves slowly or not at all (**Figure 32.3B**).

In many ecdysozoans that have wormlike bodies, the cuticle is relatively thin and flexible; it offers the animal some protection but provides only modest body support. A thin cuticle allows the exchange of gases, minerals, and water across the body surface, but it restricts the animal to moist habitats. Many species of ecdysozoans with thin cuticles live in marine sediments from which they obtain prey, either by ingesting sediments and extracting organic material from them, or by capturing larger prey using a toothed *pharynx* (a muscular organ at the anterior end of the digestive tract). Some freshwater species absorb nutrients directly through their thin cuticles, as do parasitic species that live within their hosts. Many wormlike ecdysozoans are predators, eating protists and small animals.

The cuticles of other ecdysozoans, mainly arthropods, function as external skeletons, or **exoskeletons**. These exoskeletons are thickened by layers of protein and a strong, waterproof polysaccharide called **chitin**. An animal with a rigid, chitin-reinforced exoskeleton can neither move in a wormlike manner nor use cilia for locomotion. A hard exoskeleton also impedes the passage of oxygen and nutrients into the animal, presenting new

32.2 Bryozoans Use Their Lophophore to Feed The extended lophophore dominates the anatomy of the colonial bryozoans. This species inhabits fresh water, although most bryozoans are marine. Bryozoan colonies can grow to contain more than a million individuals, all stemming from the asexual reproduction of the colony's founder.

(A)

(B) *Phrynos parvulus*

32.3 Molting: Past and Present (A) This 500-million-year-old fossil from the Cambrian captured an individual of a long-extinct arthropod species in the process of molting and shows that the molting process is an evolutionarily ancient trait. (B) This whip spider has just emerged from its discarded exoskeleton and will be highly vulnerable until its new cuticle has hardened.

challenges in other areas besides growth. New mechanisms of locomotion and gas exchange evolved in those ecdysozoans with hard exoskeletons.

To move rapidly, an animal with a rigid exoskeleton must have body extensions that can be manipulated by muscles. Such *appendages* evolved in the late Precambrian, leading to the **arthropod** (“jointed foot”) clade. Arthropod appendages exist in an amazing variety of forms. They serve many functions, including walking and swimming, gas exchange, food capture and manipulation, copulation, and sensory perception. Arthropods grasp food with their mouths and associated appendages and digest it internally. Their muscles are attached to the inside

32.4 Arthropod Skeletons Are Rigid and Jointed This cross section through a thoracic segment of a generalized arthropod illustrates the arthropod body plan, which is characterized by a rigid exoskeleton with jointed appendages.

of the exoskeleton. Each segment has muscles that operate that segment and the appendages attached to it (**Figure 32.4**).

The arthropod exoskeleton has had a profound influence on the evolution of these animals. Encasement within a rigid body covering provides support for walking on dry land, and the waterproofing provided by chitin keeps the animal from dehydrating in dry air. Aquatic arthropods were, in short, excellent candidates to invade terrestrial environments. As we will see, they did so several times.

Arrow worms retain some ancestral developmental features

Nearly all triploblastic animal groups can be readily classified as either protostomes or deuterostomes, but the evolutionary relationships of one small group, the **arrow worms**, were debated for many years. Although the early development of arrow worms seems similar to that of deuterostomes, it is now known that arrow worms merely retain developmental features that are ancestral to triploblastic animals in general. Recent studies of gene sequences clearly identify arrow worms as protostomes. There is still some question as to whether they are the closest relatives of the lophotrochozoans (as shown in Figure 32.1), or possibly the sister group of all other protostomes.

The arrow worm body is divided into three compartments: head, trunk, and tail (**Figure 32.5**). The body is transparent or translucent. Most arrow worms swim in the open sea. A few species live on the seafloor. Their abundance as fossils indicates that they were common more than 500 million years ago. The 100 or so living species of arrow worms are small enough—ranging from 3 millimeters to less than 12 centimeters in length—that their gas-exchange and waste-excretion requirements are met by diffusion through the body surface. They lack a circulatory system; wastes and nutrients are moved around the body in the coelomic fluid, which is propelled by cilia that line the coelom. There is no distinct larval stage. Miniature adults hatch directly from eggs that are fertilized internally following elaborate courtship between two hermaphroditic in-

32.5 An Arrow Worm Arrow worms have a three-part body organization. Their fins and grasping spines are adaptations for a predatory lifestyle. Individuals are hermaphroditic, producing both eggs and sperm (ovary and testis).

dividuals (each arrow worm produces both male and female gametes).

Arrow worms are stabilized in the water by means of one or two pairs of lateral fins and a tail fin. They are major predators of planktonic organisms in the open ocean, ranging in size from small protists to young fish as large as the arrow worms themselves. An arrow worm typically lies motionless in the water until water movement signals the approach of prey. The arrow worm then darts forward and uses the stiff spines adjacent to its mouth to grasp its prey.

32.1 RECAP

The shared derived traits of protostomes include a blastopore that develops into a mouth, as well as the structure of the anterior brain and ventral nervous system. Several lophotrochozoan groups are characterized by a filter-feeding structure known as a lophophore and/or by cilia-bearing larvae known as trochophores. Ecdysozoans, which have a body covering known as a cuticle, must molt periodically in order to grow.

- How does an animal's body covering influence the way it breathes, feeds, and moves? **See pp. 669–670**
- What features made arthropods well adapted for colonizing terrestrial environments? **See p. 670**

32.2 What Features Distinguish the Major Groups of Lophotrochozoans?

Lophotrochozoans come in a variety of sizes and shapes, ranging from relatively simple animals with a blind gut (that is, a gut with only one opening) and no internal transport system to animals with a complete gut (having separate entrance and exit openings) and a complex internal transport system. They include some highly species-rich groups, such as flatworms, annelids, and mollusks. A number of these groups exhibit worm-like bodies, but the lophotrochozoans encompass a wide diversity of morphologies, including a few groups with external shells. Some lophotrochozoan groups have only recently been discovered by biologists.

Bryozoans live in colonies

The 4,500 species of **bryozoans** (“moss animals”) are colonial animals that live in a “house” made of material secreted by the external body wall. Almost all bryozoans are marine, although a few species occur in fresh or brackish water. A bryozoan colony consists of many small (1–2 mm) individuals

connected by strands of tissue along which nutrients can be moved (**Figure 32.6**). The colony is created by the asexual reproduction of its founding member, and a single colony may contain as many as 2 million individuals. Rocks in coastal regions in many parts of the world are covered with luxuriant growths of bryozoans. Some bryozoans create miniature reefs in shallow waters. In some species, the individual colony members are differentially specialized for feeding, reproduction, defense, or support.

Sertella septentrionalis

32.6 A Bryozoan Colony The rigid orange tissue of this bryozoan colony connects and supplies nutrients to thousands of individual animals (see Figure 32.2).

Individual bryozoans in a colony are able to oscillate their lophophore to increase contact with prey. They can also retract it into their “house” (see Figure 32.2). Bryozoans can reproduce sexually by releasing sperm into the water, which carries the sperm to other individuals. Eggs are fertilized internally; developing embryos are brooded before they exit as larvae to seek suitable sites for attachment to the substratum.

Flatworms and rotifers are structurally diverse relatives

Flatworms and rotifers compose a structurally diverse group, and only recently have their relationships to one another been hypothesized. Before gene sequences were available for phylogenetic analysis, biologists considered the structure of the body cavity to be a critical feature in animal classification. If recent genomic studies prove correct, however, this monophyletic animal group includes both acoelomate subgroups (e.g., the flatworms) and pseudocoelomate subgroups (e.g., the rotifers), and yet the closest relatives of these two groups—the bryozoans—are coelomate. Thus, systematists today conclude that body cavity forms have undergone considerable convergence in the course of animal evolution (see Table 32.1).

Flatworms lack specialized organs for transporting oxygen to their internal tissues. Lacking a gas transport system, each cell must be near a body surface, a requirement met by the dorsoventrally flattened body form. The digestive tract of a flatworm consists of a mouth opening into a blind sac. The sac is often highly branched, forming intricate patterns that increase the surface area available for the absorption of nutrients. Some

small free-living flatworms are cephalized, with a head bearing chemoreceptor organs, two simple eyes, and a tiny brain composed of anterior thickenings of the longitudinal nerve cords. Free-living flatworms glide over surfaces, powered by broad bands of cilia (**Figure 32.7A**).

Although many flatworms are free-living, most of the species are parasites. Of the parasitic species, most are internal parasites. There are also flatworms that feed externally on animal tissues (living or dead), and some graze on plants. A likely evolutionary transition was from feeding on dead organisms to feeding on the body surfaces of dying hosts to invading and consuming parts of healthy hosts.

Most of the 25,000 species of living flatworms are *tapeworms* and *flukes*; members of these two groups are internal parasites, particularly of vertebrates (**Figure 32.7B**). Because they absorb digested food from the digestive tracts of their hosts, many parasitic flatworms lack digestive tracts of their own. Some cause serious human diseases, such as schistosomiasis, which is common in parts of Asia, Africa, and South America. The species that causes this devastating disease has a complex life cycle involving both freshwater snails and mammals as hosts. Members of another flatworm group, the *monogeneans*, are external parasites of fishes and other aquatic vertebrates. The *turbellarians* include most of the free-living species.

Most **rotifers** are tiny (50–500 μm long)—smaller than some ciliate protists—but they have specialized internal organs (**Figure 32.8**). A complete gut passes from an anterior mouth to a posterior anus; the body cavity is a pseudocoel that functions as a hydrostatic skeleton. Rotifers typically propel themselves through the water by means of rapidly beating cilia rather than by muscular contraction.

The most distinctive organ of rotifers is a conspicuous ciliated organ called the *corona*, which surmounts the head of many species. Coordinated beating of the cilia sweeps particles of

(A) *Eurylepta californica*, a free-living flatworm

(B) Diagram of a typical parasitic flatworm

32.7 Flatworms May Live Freely or Parasitically

(A) Some flatworm species, such as this Pacific marine flatworm, are free-living. (B) The fluke diagrammed here lives parasitically in the gut of sea urchins and is representative of parasitic flatworms. Because their hosts provide all the nutrition they need, these internal parasites do not require elaborate feeding or digestive organs and can devote most of their bodies to reproduction.

(A) *Philodina roseola*(B) *Stephanoceros fimbriatus*

32.8 Rotifers (A) The individual diagrammed here reflects the general structure of many rotifers. (B) A micrograph reveals the internal complexity of a rotifer that has ingested photosynthetic protists. This species, one of the larger rotifers, is found in the Great Lakes of North America.

organic matter from the water into the animal's mouth and down to a complicated structure called the *mastax*, in which food is ground into small pieces. By contracting muscles around the pseudocoel, a few rotifer species that prey on protists and small animals can protrude the mastax through their mouth and seize small objects with it.

Most of the 1,800 known species of rotifers live in fresh water. Some species rest on the surfaces of mosses or lichens in a desiccated, inactive state until it rains. When rain falls, they absorb water and become mobile, feeding in the films of water that temporarily cover the plants. Most rotifers live no longer than a few weeks.

Both males and females are found in some species of rotifers, but only females are known among the *bdelloid rotifers* (the *b* in *bdelloid* is silent). Biologists have concluded that the bdelloid rotifers may have existed for tens of millions of years without regular sexual reproduction. In general, lack of genetic recombination leads to the buildup of deleterious mutations, so long-term asexual reproduction typically leads to extinction (see Section 21.4). Recent studies, however, have indicated that bdelloid rotifers may avoid this problem by picking up fragments of genes from their environment during the desiccation–rehydration cycle, which allows genetic recombination among individuals in the absence of direct sexual exchange.

Ribbon worms have a long, protrusible feeding organ

Ribbon worms (nemerteans) have simple nervous and excretory systems similar to those of flatworms. Unlike flatworms, however, they have a complete digestive tract with a mouth at one end and an anus at the other. Small ribbon worms move slowly by beating their cilia. Larger ones employ waves of muscle contraction to move over the surface of sediments or to burrow into them.

Within the body of nearly all of the 1,000 species of ribbon worms is a fluid-filled cavity called the *rhynchocoel*, within which lies a hollow, muscular *proboscis*. The proboscis, which is the worm's feeding organ, may extend much of the length of the body. Contraction of the muscles surrounding the rhynchocoel causes the proboscis to evert explosively through an anterior pore (Figure 32.9A). The proboscis may be armed with sharp stylets that pierce prey and discharge paralysis-causing toxins into the wound.

(B) *Tubulanus sexlineatus*

32.9 Ribbon Worms (A) The proboscis is the ribbon worm's feeding organ. (B) This large marine nemertean is found in harbors and bays along the Pacific Coast of North America. Its proboscis is not everted in this photograph.

Ribbon worms are largely marine, although there are species that live in fresh water or on land. Most species are less than 20 centimeters long, but individuals of some species reach 20 meters or more. Some genera feature species that are conspicuous and brightly colored (Figure 32.9B). Recent molecular analyses suggest that ribbon worms may be most closely related to the phoronids and brachiopods.

Phoronids and brachiopods use lophophores to extract food from the water

Recall that the bryozoans use a lophophore to feed. Phoronids and brachiopods also feed using a lophophore, but this structure may have evolved more than once among these groups. Although neither the phoronids nor the brachiopods are represented by many living species, the brachiopods (which have shells and thus leave an excellent fossil record) are known to have been much more abundant during the Paleozoic and Mesozoic eras.

The 20 known species of **phoronids** are small (5–25 cm long), sessile worms that live in muddy or sandy sediments or attached to rocky substrata. Phoronids are found in marine waters, from the intertidal zone to about 400 meters deep. They secrete tubes made of chitin, within which they live (Figure 32.10).

32.10 Phoronids (A) The tentacles of this phoronid's lophophore form a spiral. (B) The phoronid gut is U-shaped, as seen in this generalized diagram.

Laqueus sp.

32.11 A Brachiopod's Lophophore The lophophore of this North Pacific brachiopod can be seen between the valves of its shell.

Their cilia drive water into the top of the lophophore, and the water exits through the narrow spaces between the tentacles. Suspended food particles are caught and transported to the mouth by ciliary action. Some species release eggs into the water, where they are fertilized, but other species produce large eggs that are fertilized internally and retained in the parent's body, where they are brooded until they hatch.

Brachiopods are solitary marine animals. They have a rigid shell that is divided into two parts connected by a ligament (Figure 32.11). The two halves can be pulled shut to protect the soft body. Brachiopods superficially resemble bivalve mollusks, but shells have evolved independently in the two groups. The two halves of the brachiopod shell are dorsal and ventral, rather than lateral as in bivalves. The lophophore is located within the shell. The beating of cilia on the lophophore draws water into the slightly opened shell. Food is trapped in the lophophore and directed to a ridge, along which it is transferred to the mouth. Most brachiopods are 4–6 centimeters long.

Brachiopods live attached to a solid substratum or embedded in soft sediments. Most species are attached by means of a short, flexible stalk that holds the animal above the substratum. Gases are exchanged across body surfaces, especially the tentacles of the lophophore. Most brachiopods release their gametes into the water, where they are fertilized. The larvae remain among the plankton for only a few days before they settle and develop into adults.

Brachiopods reached their peak abundance and diversity in Paleozoic and Mesozoic times. More than 26,000 fossil species have been described. Only about 335 species survive, but they remain common in some marine environments.

Annelids have segmented bodies

The bodies of **annelids** are clearly segmented. As discussed in Section 31.2, segmentation allows an animal to move different parts of its body independently of one another, giving it much better control of its movement. The earliest segmented worms, preserved as fossils from the middle Cambrian, were burrowing marine annelids.

32.12 Annelids Have Many Body Segments

The segmented structure of the annelids is apparent both externally and internally. Many organs of this earthworm are repeated serially.

In most large annelids, the coelom in each segment is isolated from those in other segments (Figure 32.12). A separate nerve center called a *ganglion* controls each segment; nerve cords that connect the ganglia coordinate their functioning. Most annelids lack a rigid external protective covering; instead, they have a thin, permeable body wall that serves as a general surface for gas exchange. Most annelids are thus restricted to moist environments because they lose body water rapidly in dry air. The approximately 16,500 described species live in marine, freshwater, and moist terrestrial environments.

POLYCHAETES More than half of all annelid species are commonly known as *polychaetes* (“many hairs”), although this is a descriptive term rather than the name of a single clade. Most polychaetes are marine, and many live in burrows in soft sediments. Most of them have one or more pairs of eyes and one or more pairs of tentacles, with which they capture prey or filter food from the surrounding water, at the anterior end of the body (Figure 32.13A; see also Figure 31.6A). In some species, the body wall of most segments extends laterally as a series of

thin outgrowths called *parapodia*. The parapodia function in gas exchange, and some species use them to move. Stiff bristles called *setae* protrude from each parapodium, forming temporary contact with the substratum and preventing the animal from slipping backward when its muscles contract. Recent molecular studies indicate that polychaetes are paraphyletic with respect to the remaining annelids.

Members of one polychaete clade, the *pogonophorans*, secrete tubes made of chitin and other substances, in which they live (Figure 32.13B). Pogonophorans have lost their digestive tract (they have no mouth or gut). So how do they obtain nutrition? Part of the answer is that pogonophorans can take up dissolved organic matter directly from the sediments in which they live or from the surrounding water. Much of their nutrition, however, is provided by endosymbiotic bacteria that live in a specialized organ known as the *trophosome*. These bacteria

oxidize hydrogen sulfide and other sulfur-containing compounds, fixing carbon from methane in the process. The uptake of the hydrogen sulfide, methane, and oxygen used by the bacteria is facilitated by hemoglobin in the pogonophorans’ tentacles. It is this hemoglobin that gives the tentacles their red coloration (see Figure 32.13B).

Pogonophorans were not discovered until early in the twentieth century, when the first species were discovered at depths of up to a few hundred meters. In recent decades, deep-sea explorers have found them living many thousands of meters below the ocean surface. In these deep oceanic sediments, they may reach densities of many thousands per square meter. About 160 species have been described. The largest and most remarkable pogonophorans are 2 meters or more in length and live near deep-sea *hydrothermal vents*—volcanic openings in the seafloor through which hot, sulfide-rich water pours. The methane and hydrogen sulfide from these vents provide the raw materials for carbon fixation by the pogonophorans’ endosymbiotic bacteria.

CLITELLATES The approximately 3,000 described species of this well-supported clade within the annelids are found in freshwater, marine, or terrestrial environments. The clitellates appear to be phylogenetically nested among various groups of polychaetes, although the exact relationships are not yet clear. There are two major groups of clitellates, the oligochaetes and the leeches.

Oligochaetes (“few hairs”) have no parapodia, eyes, or anterior tentacles, and they have only four pairs of setae bundles per segment. Earthworms—the most familiar oligochaetes—burrow in and ingest soil, from which they extract food particles. All oligochaetes are *hermaphroditic*; that is, each individual is both male and female. Sperm are exchanged simultaneously between two copulating individuals (Figure 32.13C). Eggs and sperm are deposited in a cocoon outside the adult’s body. Fertilization occurs within the cocoon after it is shed, and when development is complete, miniature worms emerge and immediately begin independent life.

(A) *Eudistylia* sp.(C) *Lumbricus terrestris*(B) *Riftia* sp.(D) *Hirudo medicinalis***32.13 Diversity among the**

Annelids (A) “Fan worms” or “feather duster worms” are sessile marine polychaetes that grow in masses, filtering food from the water with their tentacles. This individual has been removed from its chitinous tube. (B) Pogonophorans live around hydrothermal vents deep in the ocean. Their tentacles can be seen protruding from their chitinous tubes. (C) Earthworms are hermaphroditic; when they copulate, each individual donates and receives sperm. (D) The medicinal leech has been a tool of physicians and healers for centuries. Even today, leeches have uses in modern clinical practice.

Leeches, like oligochaetes, lack parapodia and tentacles. The coelom of leeches is not divided into compartments; the coelomic space is largely filled with undifferentiated tissue. Groups of segments at each end of the body are modified to form suckers, which serve as temporary anchors that aid the leech in movement. With its posterior sucker attached to a substratum, the leech extends its body by contracting its circular muscles. The anterior sucker is then attached, the posterior one detached, and the leech shortens itself by contracting its longitudinal muscles. Leeches live in freshwater or terrestrial habitats.

A leech makes an incision in its host, from which blood flows. It can ingest so much blood in a single feeding that its body may enlarge several-fold. The leech secretes an anticoagulant into the wound that keeps the host’s blood flowing. For centuries, medical practitioners employed leeches to draw blood to treat diseases they believed were caused by an excess of blood or by “bad blood.” Although most leeching practices (such as inserting a leech in a person’s throat to alleviate swollen tonsils) have been abandoned, *Hirudo medicinalis* (the medicinal leech; **Figure 32.13D**) is used today to reduce fluid pressure and prevent blood clotting in damaged tissues, to eliminate pools of coagulated blood, and to prevent scarring. The anticoagulants of certain other leech species that also contain anesthetics and blood vessel dilators are being studied for possible medical uses.

Mollusks have undergone a dramatic evolutionary radiation

Mollusks are the most diverse group of lophotrochozoans, both in numbers of species and in environments they occupy. Although the major groups of mollusks differ dramatically in morphology, they all share the same three major body components: a foot, a visceral mass, and a mantle (**Figure 32.14**).

- The molluscan *foot* is a large, muscular structure that originally was both an organ of locomotion and a support for the internal organs. In squids and octopuses, the foot has been modified to form arms and tentacles borne on a head with complex sensory organs. In other groups, such as clams, the foot is a burrowing organ. In some groups the foot is greatly reduced.
- The heart and the digestive, excretory, and reproductive organs are concentrated in a centralized, internal *visceral mass*.
- The *mantle* is a fold of tissue that covers the organs of the visceral mass. The mantle secretes the hard, calcareous shell that is typical of many mollusks.

In most mollusks, the mantle extends beyond the visceral mass to form a *mantle cavity*. Within this cavity lie *gills* that are used for gas exchange. When cilia on the gills beat, they create a cur-

Generalized molluscan body plan**Chitons****Gastropods****Bivalves****Cephalopods**

32.14 Organization of Molluscan Bodies The major molluscan groups display different variations on a general body plan that includes three major components: a foot, a visceral mass of internal organs, and a mantle. The mantle may secrete a calcareous shell, as in the gastropods and bivalves.

rent of water. The tissue of the gills, which is highly *vascularized* (containing many blood vessels), takes up oxygen from the water and releases carbon dioxide. Many mollusk species use their gills as filter-feeding devices, whereas others feed using a rasping structure known as the *radula* to scrape algae from rocks. In some mollusks, such as the marine cone snails, the radula has been modified into a drill or poison dart.

Molluscan blood vessels do not form a closed system. Blood and other fluids empty into a large, fluid-filled *hemocoel*, through which fluids move around the animal and deliver oxygen to the internal organs. Eventually, the fluids reenter the blood vessels and are moved by a heart.

Monoplacophorans were the most abundant mollusks during the Cambrian period, 500 million years ago, but only a few species survive today. Unlike in all other living mollusks, in monoplacophorans the gas exchange organs, muscles, and excretory pores are repeated over the length of the body.

Figure 32.15 illustrates the four major clades of living mollusks: chitons, bivalves, gastropods, and cephalopods. The species shown here are a tiny sample of the approximately 100,000 living species of mollusks.

CHITONS Eight overlapping calcareous plates, surrounded by a structure known as the girdle, protect the internal organs and muscular foot of **chitons** (Figure 32.15A). The chiton body is bilaterally symmetrical, and the internal organs, particularly the digestive and nervous systems, are relatively simple. Most chitons are marine omnivores that scrape algae, bryozoans, and other organisms from rocks with their sharp radula. An adult chiton spends most of its life clinging tightly to rock surfaces with its large, muscular, mucus-covered foot. It moves slowly by means of rippling waves of muscular contraction in the foot. Fertilization in most chitons takes place in the water, but in a few species fertilization is internal and embryos are brooded within the body. There are approximately 1,000 living species of chitons.

BIVALVES Clams, oysters, scallops, and mussels are all familiar **bivalves**. The 30,000 living species are found in both marine and freshwater environments. Bivalves have a very small head and a hinged, two-part shell that extends over the sides of the body as well as the top (Figure 32.15B). Many clams use their foot to burrow into mud and sand. Bivalves feed by taking in water through an opening called an *incurrent siphon* and filtering food from the water with their large gills, which are also the main sites of gas exchange. Water and gametes exit through the *excurrent siphon*. Fertilization takes place in open water in most species.

GASTROPODS **Gastropods** are the most species-rich and widely distributed mollusks, with nearly 70,000 living species. Snails, whelks, limpets, slugs, nudibranchs (sea slugs), and abalones

(A) *Tonicella lineata*(B) *Tridacna gigas*(C) *Flabellina iodinea*(D) *Oxychilus draparnaudi*(E) *Octopus bimaculoides*(F) *Nautilus belauensis*

32.15 Diversity among the Mollusks (A) Chitons are common in the intertidal zone of temperate-zone coasts. (B) The giant clam of Indonesia is among the largest of the bivalve mollusks. (C) This shell-less nudibranch ("naked gills"), or sea slug, is brightly colored, a signal of its toxicity. (D) Pulmonate land snails, such as this dark-bodied glass snail, have a vascularized lung that allows them to survive in terrestrial environments. (E) Cephalopods such as the octopuses are active predators. (F) The boundaries of chambers are clearly visible on the outer surfaces of this shelled cephalopod, one of the chambered nautiluses.

are all gastropods. Most species move by gliding on their muscular foot, but in a few species—the sea butterflies and heteropods—the foot is a swimming organ with which the animal moves through open ocean waters. Nudibranchs have lost their protective shell over the course of evolution. Their sometimes brilliant coloration is *aposematic*, meaning it serves to warn

potential predators of toxicity (**Figure 32.15C**). Other nudibranch species exhibit camouflaged coloration.

Shelled gastropods have one-piece shells. The only mollusks that live in terrestrial environments—land snails and slugs—are gastropods (**Figure 32.15D**). In these terrestrial species, the mantle tissue is modified into a highly vascularized lung.

CEPHALOPODS The **cephalopods**—squids, octopuses, and nautiluses—first appeared near the beginning of the Cambrian period. By the Ordovician period a variety of types were present. Today there are about 800 living species.

In the cephalopods, the excurrent siphon is modified to allow the animal to control the water content of the mantle cavity. The modification of the mantle into a device for forcibly ejecting water from the cavity through the siphon enables these animals to move rapidly by “jet propulsion” through the water. With their greatly enhanced mobility, cephalopods became the major predators in the open waters of the Devonian oceans. They remain important marine predators today.

Cephalopods capture and subdue prey with their tentacles; octopuses also use their tentacles to move over the substratum (**Figure 32.15E**). As is typical of active, rapidly moving predators, cephalopods have a head with complex sensory organs, most notably eyes that are comparable to those of vertebrates in their ability to resolve images. The head is closely associated with a large, branched foot that bears the tentacles and a siphon. The large, muscular mantle provides a solid external supporting structure. The gills hang in the mantle cavity. Many cephalopods have elaborate courtship behavior, which may involve striking color changes.

Many early cephalopods had a chambered shell divided by partitions penetrated by tubes through which gases and liquids could be moved to control the animal’s buoyancy. Nautiluses (genus *Nautilus*) are the only surviving cephalopods that have such external chambered shells (**Figure 32.15F**).

32.2 RECAP

Lophotrochozoans include animals with diverse body types. Wormlike forms include some flatworms, ribbon worms, phoronids, and annelids. There has been convergent evolution of lophophores (in bryozoans versus brachiopods and phoronids) and of external two-part shell coverings (in brachiopods versus bivalve mollusks).

- Can you explain how flatworms can survive without a gas transport system? **See p. 672 and Figure 32.7**
- Do you know why most annelids are restricted to moist environments? **See p. 675**
- Briefly describe how the basic body organization of mollusks has been modified to yield a wide diversity of animals. **See pp. 676–679 and Figure 32.14**

The second of the two major protostome clades, the ecdysozoans, contains the vast majority of Earth’s animal species. What evolutionary innovations led to this massive diversity?

32.3 What Features Distinguish the Major Groups of Ecdysozoans?

Many ecdysozoans are wormlike in form, although the *arthropods*, *onychophorans*, and *tardigrades* have limbs. In this section we will look at the two clades of wormlike ecdysozoans: the priapulids, kinorhynchs, and loriciferans in one group, and the horsehair worms and nematodes in the other. Section 32.4 is devoted to the most diverse ecdysozoans—the arthropods and their relatives—and the many forms their appendages take.

Several marine groups have relatively few species

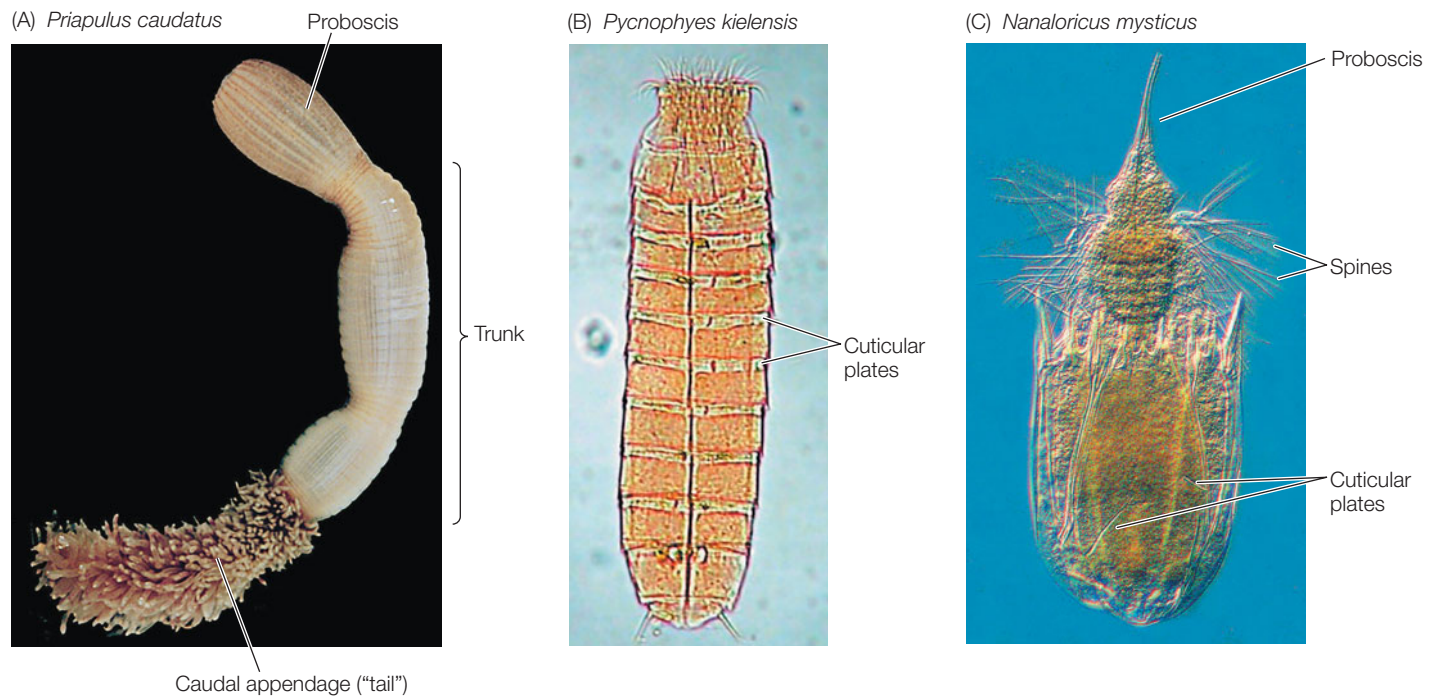

Members of several species-poor groups of wormlike marine ecdysozoans—the priapulids, kinorhynchs, and loriciferans—have relatively thin cuticles that are molted periodically as the animals grow to full size. In 2004, embryos of a fossil species related to these ecdysozoans were discovered in sediments laid down in China about 500 million years ago. This remarkable discovery shows that the ancestors of these animals developed directly from an egg to the adult form, as their modern descendants do.

The 16 species of **priapulids** are cylindrical, unsegmented, wormlike animals with a three-part body plan consisting of a proboscis, trunk, and caudal appendage (“tail”). It should be clear from their appearance why they were named after the Greek fertility god Priapus (**Figure 32.16A**). Priapulids range in length from 0.5 millimeters to 20 centimeters. They burrow in fine marine sediments and prey on soft-bodied invertebrates such as polychaetes, which they capture with a toothed, muscular pharynx that they evert through their mouth and then withdraw into their body together with the grasped prey. Fertilization is external, and most species have a larval form that also lives in the mud.

About 150 species of **kinorhynchs** have been described. They live in marine sands and muds and are virtually microscopic; no kinorhynchs are longer than 1 millimeter. Their bodies are divided into 13 segments, each with a separate cuticular plate (**Figure 32.16B**). These plates are periodically molted during growth. Kinorhynchs feed by ingesting sediments through their retractable proboscis (the name means “movable snout”). They then digest the organic material found in the sediment, which may include living algae as well as dead matter. Kinorhynchs have no distinct larval stage; fertilized eggs develop directly into juveniles, which emerge from their egg cases with 11 of the 13 body segments already formed.

Loriciferans are also minute animals less than 1 millimeter long. They were not discovered until 1983. About 100 living species are known to exist, although many of these are still being described. The body is divided into a head, neck, thorax, and abdomen and is covered by six plates, from which the loriciferans get their name (Latin *lorica*, “corset”). The plates around the base of the neck bear anterior-directed spines of unknown

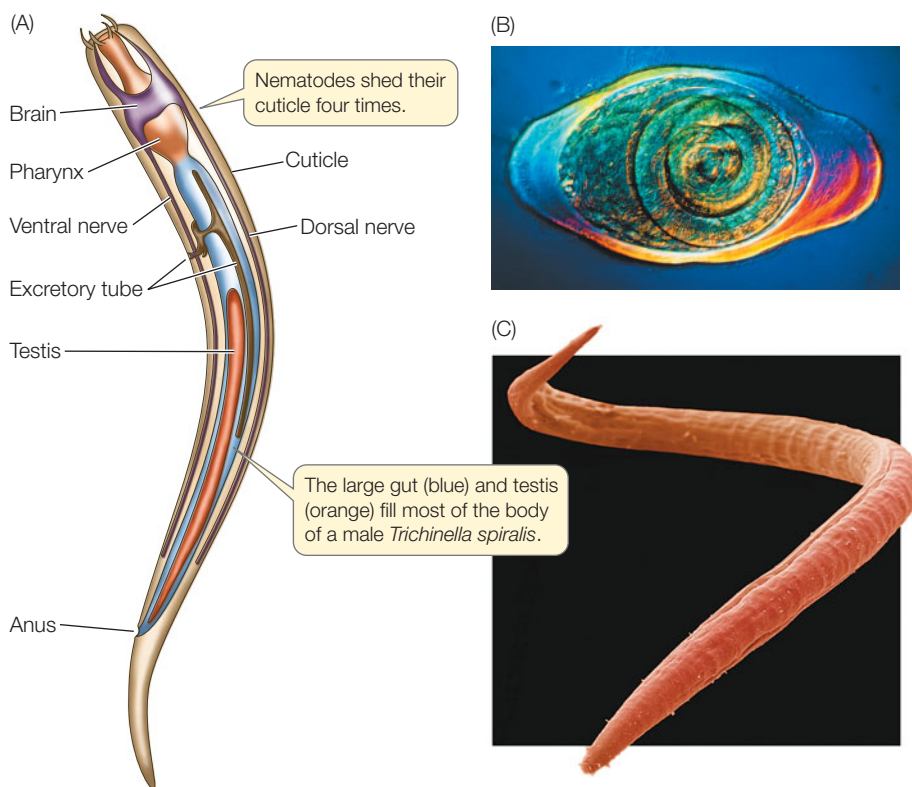

32.16 Wormlike Marine Ecdysozoans Members of these groups are marine bottom-dwellers. (A) Most priapulid species live in burrows on the ocean floor, extending the proboscis for feeding. (B) Kinorhynchs are virtually microscopic. The cuticular plates that cover their bodies are molted periodically. (C) Six cuticular plates form a “corset” around the minute loriciferan body.

function (Figure 32.16C). Loriciferans live in coarse marine sediments. Little is known about what they eat, but some species apparently eat bacteria.

Nematodes and their relatives are abundant and diverse

Nematodes (roundworms) have a thick, multilayered cuticle that gives their unsegmented body its shape (Figure 32.17). As a nematode grows, it sheds its cuticle four times. Nematodes exchange oxygen and nutrients with their environment through both the cuticle and the gut, which is only one cell layer thick. Materials are moved through the gut by rhythmic contraction of a highly muscular organ, the *pharynx*, at the worm’s anterior end. Nematodes move by contracting their longitudinal muscles.

Nematodes are probably the most abundant and universally distributed of all animal groups. Many are microscopic; the largest known nematode, which reaches a length of 9 meters, is a parasite in the placentas of sperm whales. About 25,000 species have been described, but the actual number of living species may be more than a million. Countless nematodes live as scavengers in the upper layers of the soil, on the bottoms of lakes and streams, and in marine sediments. The topsoil of rich farmland may contain from 3 to 9 billion nematodes per acre. A single rotting apple may contain as many as 90,000 individuals.

32.17 Nematodes (A) *Trichinella spiralis*, a parasitic nematode that causes trichinosis. (B) This polarized light micrograph shows a cyst of *T. spiralis* in the muscle tissue of a host. (C) This free-living nematode lives in freshwater environments.

One soil-inhabiting nematode, *Caenorhabditis elegans*, serves as a model organism in the laboratories of geneticists and developmental biologists. It is ideal for such research because it is easy to cultivate, matures in 3 days, and has a fixed number of body cells. Its genome has been completely sequenced.

Many nematodes are predators, feeding on protists and small animals (including other roundworms). Most significant to humans, however, are the many species that parasitize plants and animals. The nematodes that parasitize humans (causing serious diseases such as trichinosis, filariasis, and elephantiasis), domestic animals, and economically important plants have been studied intensively in an effort to find ways of controlling them.

The structure of parasitic nematodes is similar to that of free-living species, but the life cycles of many parasitic species have special stages that facilitate the transfer of individuals among hosts. *Trichinella spiralis*, the species that causes the human disease trichinosis, has a relatively simple life cycle. A person may become infected by eating the flesh of an animal (usually a pig) that has *Trichinella* larvae encysted in its muscles (see Figure 32.17B). The larvae are activated in the person's digestive tract, emerge from their cysts, and attach to the intestinal wall, where they feed. Later, they bore through the intestinal wall and are carried in the bloodstream to muscles, where they form new cysts. If present in great numbers, these cysts can cause severe pain or death.

About 320 species of the unsegmented **horsehair worms** have been described. As their name implies, these animals are extremely thin in diameter; horsehair worms range from a few millimeters up to a meter in length. Most adult worms live in fresh water, among leaf litter and algal mats near the edges of streams and ponds. A few species live in damp soil.

Horsehair larvae are internal parasites of freshwater crayfish and of terrestrial and aquatic insects (**Figure 32.18**). An adult

32.18 Horsehair Worm Larvae Are Parasitic Like the strepsipteran insects described at the start of this chapter, the larvae of this horsehair worm (*Paragordius tricuspidatus*) can manipulate its host's behavior. The hatching worm causes the cricket to jump into water, where the worm can continue its life cycle as a free-living adult. The insect, having delivered its parasitic burden, drowns.

horsehair worm has no mouth, and its gut is greatly reduced and probably nonfunctional. Some species may feed only as larvae, absorbing nutrients from their hosts across the body wall. But other species continue to grow after they have left their hosts, shedding their cuticles, suggesting that adult worms may also absorb nutrients from their environment.

32.3 RECAP

Priapulids, kinorhynchans, and loriciferans are relatively small, poorly known groups of wormlike marine ecdysozoans. Horsehair worms and nematodes are also wormlike. Nematodes are probably the most abundant and universal animal group. The biology of some nematodes has been studied extensively, particularly that of *Caenorhabditis elegans*, which serves as a model laboratory organism.

- Describe at least three different ways in which nematodes have a significant impact on humans. **See pp. 680–681**

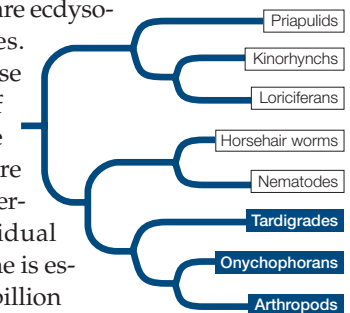

We now turn to the animals that not only dominate the ecdysozoan clade but are also the most diverse animals on Earth.

32.4 Why Are Arthropods So Diverse?

Arthropods and their relatives are ecdysozoans with paired appendages. Arthropods are the most diverse group of animals in numbers of species (about a million have been described, and many more remain to be discovered). Furthermore, the number of individual arthropods alive at any one time is estimated to be about 10^{18} , or a billion billion. Among the animals, only the nematodes are thought to exist in greater numbers.

Several key features have contributed to the success of the arthropods. Their bodies are segmented, and their muscles are attached to the inside of their rigid exoskeletons. Each segment has muscles that operate that segment and the jointed appendages attached to it (see Figure 32.4). Jointed appendages permit complex movements, and different appendages are specialized for different functions. Encasement of the body within a rigid exoskeleton provides the animal with support for walking in the water or on dry land and provides some protection against predators. The waterproofing provided by chitin keeps the animal from dehydrating in dry air.

Representatives of the four major arthropod groups living today are all species-rich: the *crustaceans* (including shrimps, crabs, and barnacles), *hexapods* (insects and their relatives), *myriapods* (millipedes and centipedes), and *chelicerates* (including the arachnids—spiders, scorpions, mites, and their relatives). Phylogenetic relationships among arthropod groups are currently being

reexamined in light of a wealth of new information, much of it based on gene sequences. These studies show close relationships between the myriapods and chelicerates in one clade and between the crustaceans and hexapods in another, with strong support for the monophyly of arthropods as a whole.

The jointed appendages of arthropods gave the clade its name, from the Greek words *arthron*, “joint,” and *podos*, “foot” or “limb.” Arthropods evolved from ancestors with simple, unjointed appendages. The exact forms of those ancestors are unknown, but some arthropod relatives with segmented bodies and unjointed appendages survive today. Before we describe the modern arthropods, we will discuss those arthropod relatives, as well as an early clade that went extinct but left an important fossil record.

Arthropod relatives have fleshy, unjointed appendages

Until fairly recently, biologists debated whether the **onychophorans** (velvet worms) were more closely related to annelids or arthropods, but molecular evidence clearly links them to the latter. Indeed, with their soft, fleshy, unjointed, claw-bearing legs, onychophorans may be similar in appearance to the ancestors of arthropods (**Figure 32.19A**). The 150 species of onychophorans live in leaf litter in humid tropical environments. They have soft,

segmented bodies that are covered by a thin, flexible cuticle that contains chitin. They use their fluid-filled body cavities as hydrostatic skeletons. Fertilization is internal, and the large, yolk eggs are brooded within the body of the female.

Tardigrades (water bears) also have fleshy, unjointed legs and use their fluid-filled body cavities as hydrostatic skeletons (**Figure 32.19B**). Tardigrades are extremely small (0.1–0.5 millimeters long) and lack both a circulatory system and gas-exchange organs. The 800 known extant species live in marine sands and on temporary water films on plants. When these films dry out, the animals also lose water and shrink to small, barrel-shaped objects that can survive for at least a decade in a dormant state. Tardigrades have been found in densities as high as 2 million per square meter of moss.

Jointed appendages first appeared in the trilobites

The **trilobites** flourished in Cambrian and Ordovician seas, but they disappeared in the great Permian extinction at the close of the Paleozoic era (251 mya). Because they had heavy exoskeletons that readily fossilized, they left behind an abundant record of their existence (**Figure 32.20**). About 10,000 species have been described.

The body segmentation and appendages of trilobites followed a relatively simple, repetitive plan, but some of their

Acanthopyge sp.

32.20 A Trilobite The relatively simple, repetitive segments of the now-extinct trilobites are illustrated by a fossil trilobite from the shallow seas of the Devonian period, some 400 million years ago.

jointed appendages were modified for different functions. This specialization of appendages is a theme in the continuing evolution of the arthropods.

Myriapods have many legs

Members of two arthropod groups, the myriapods and the chelicerates, have a body with just two regions: a head and a trunk. This contrasts with the hexapods and crustaceans, most of which have a three-part body, with a head, thorax, and abdomen.

The **myriapods** comprise the centipedes, millipedes, and their close relatives. Centipedes and millipedes have a well-formed head and a long, flexible, segmented trunk that bears many pairs of legs (**Figure 32.21**). Centipedes, which have one pair of legs per segment, prey on insects and other small animals. In millipedes, two adjacent segments are fused so that each fused segment has two pairs of legs. Millipedes scavenge and eat plants. More than 3,000 species of centipedes and 11,000 species of millipedes have been described; many more species probably remain unknown. Although most myriapods are less than a few centimeters long, some tropical species are ten times that size.

Most chelicerates have four pairs of legs

In the two-part body of **chelicerates**, the head bears two pairs of appendages modified to form mouthparts. In addition, many chelicerates have four pairs of walking legs. The 98,000 de-

scribed species are usually placed in three major clades: pycnogonids, horseshoe crabs, and arachnids.

The *pycnogonids*, or sea spiders, are a poorly known group of about 1,000 marine species (**Figure 32.22A**). Most are small, with leg spans less than 1 centimeter, but some deep-sea species have leg spans up to 60 centimeters. A few pycnogonids eat algae, but most are carnivorous, eating a variety of small invertebrates.

There are four living species of *horseshoe crabs*, but many close relatives are known from fossils. Horseshoe crabs, which have changed very little morphologically during their long fossil history, have a large horseshoe-shaped covering over most of the body. They are common in shallow waters along the eastern

32.21 Myriapods (A) Centipedes have modified appendages that function as poisonous fangs for capturing active prey and one pair of legs per segment. (B) Millipedes, which are scavengers and plant eaters, have smaller jaws and legs than centipedes do. They have two pairs of legs per segment.

(A) *Endeis* sp.

(B) *Limulus polyphemus*

32.22 Two Small Chelicerate Groups (A) Although they are not spiders, it is easy to see why sea spiders were given their common name. (B) This spawning aggregation of horseshoe crabs was photographed on a sandy beach of Delaware Bay. Horseshoe crabs are an ancient group that has changed very little in morphology over time; such species are sometimes referred to as “living fossils.”

coast of North America and the southern and eastern coasts of Asia, where they scavenge and prey on bottom-dwelling animals. Periodically they crawl into the intertidal zone in large numbers to mate and lay eggs (**Figure 32.22B**).

Arachnids are abundant in terrestrial environments. Most arachnids have a simple life cycle in which miniature adults hatch from internally fertilized eggs and begin independent lives almost immediately. Some arachnids retain their eggs during development and give birth to live young.

The most species-rich and abundant arachnids are the spiders, scorpions, harvestmen, mites, and ticks (**Figure 32.23**). More than 50,000 described species of mites and ticks live in soil, leaf litter, mosses, and lichens, under bark, and as parasites of plants and animals. Mites are vectors for wheat and rye mosaic viruses; they cause mange in domestic animals and skin irritation in humans.

32.23 Arachnid Diversity (A) “Tarantulas” encompass many free-living species as well as several hundred species of hairy, ground-dwelling spiders, some of which can grow to the size of a dinner plate. Their venomous bite, although painful, is not usually dangerous to humans. (B) Scorpions are nocturnal predators. (C) Harvestmen, also called daddy longlegs, are scavengers. (D) Mites include many free-living species as well as blood-sucking external parasites.

(A) *Poecilotheria metallica*

(C) *Leiobunum rotundum*

Spiders, of which 38,000 species have been described, are important terrestrial predators. Some have excellent vision that enables them to chase and seize their prey. Others spin elaborate webs made of protein threads in which they snare prey. The threads are produced by modified abdominal appendages connected to internal glands that secrete the proteins, which solidify on contact with air. The webs of different groups of spiders are strikingly varied, and this variation enables the spiders to position their snares in many different environments for many different types of prey.

Crustaceans are diverse and abundant

Crustaceans are the dominant marine arthropods today, and they are also common in freshwater and some terrestrial environments. The most familiar crustaceans are the shrimps, lobsters, crayfishes, and crabs (all *decapods*; **Figure 32.24A**) and the sow bugs (*isopods*; **Figure 32.24B**). Additional species-rich groups of crustaceans include *amphipods*, *ostracods*, and *branchiopods* (**Figure 32.24C**), all of which are found in freshwater and marine environments. (Don't confuse the branchiopods with the similarly named brachiopods, described in Section 32.2.) *Krill* are small but abundant oceanic crustaceans that are important food items for a variety of large vertebrates, including baleen whales. (E) *Lepas pectinata*

32.24 Crustacean Diversity (A) This decapod crustacean, a purple sand crab, is also referred to as a “globe crab” based on its globelike body shape. (B) Isopods are sometimes referred to as “rock lice,” a name derived from their preferred habitat. (C) This tadpole shrimp, a branchiopod, is common in seasonal pools of the southwestern United States. Molecular studies suggest that branchiopods may be more closely related to hexapods than to other crustaceans. (D) This minute copepod from a freshwater pond is brooding eggs. (E) Gooseneck barnacles attach to a substratum by their muscular stalks and feed by protruding and retracting their feeding appendages.

included in the crustacean clade are the small *copepods* (Figure 32.24D), which are also abundant in the open oceans.

Barnacles are unusual crustaceans that are sessile as adults (Figure 32.24E). Adult barnacles look more like mollusks than like other crustaceans, but as the zoologist Louis Agassiz remarked more than a century ago, a barnacle is “nothing more than a little shrimp-like animal, standing on its head in a limestone house and kicking food into its mouth.”

Recent molecular studies suggest that crustaceans may not be monophyletic. In analyses of DNA sequences, the branchiopods (which include brine shrimp, fairy shrimp, water fleas, and tadpole shrimp; see Figure 32.24D) appear to be more closely related to the hexapods than to other crustaceans.

Most of the 52,000 described species of crustaceans have a body that is divided into three regions: head, thorax, and abdomen (Figure 32.25). The segments of the head are fused together, and the head bears five pairs of appendages. Each of the multiple thoracic and abdominal segments usually bears one pair of appendages. The appendages on different parts of the body are specialized for different functions, such as gas exchange, chewing, capturing food, sensing, walking, and swimming. In some cases, the appendages are branched, with different branches

32.25 Crustacean Body Plan The bodies of crustaceans are divided into three regions: the head, thorax, and abdomen. Each region bears specialized appendages, and a shell-like carapace covers the head and thorax.

TABLE 32.2
The Major Insect Groups^a

GROUP	APPROXIMATE NUMBER OF DESCRIBED LIVING SPECIES
Jumping bristletails (Archaeognatha)	300
Silverfish (Thysanura)	370
PTERYGOTE (WINGED) INSECTS (PTERYGOTA)	
Mayflies (Ephemeroptera)	2,000
Dragonflies and damselflies (Odonata)	5,000
Neopterans (Neoptera)^b	
Ice-crawlers (Grylloblattodea)	25
Gladiators (Mantophasmatodea)	15
Stoneflies (Plecoptera)	1,700
Webspinners (Embioptera)	300
Angel insects (Zoraptera)	30
Earwigs (Dermaptera)	1,800
Grasshoppers and crickets (Orthoptera)	20,000
Stick insects (Phasmida)	3,000
Cockroaches (Blattodea)	3,500
Termites (Isoptera)	2,750
Mantids (Mantodea)	2,300
Booklice and barklice (Psocoptera)	3,000
Thrips (Thysanoptera)	5,000
Lice (Phthiraptera)	3,100
True bugs, cicadas, aphids, leafhoppers (Hemiptera)	80,000
Holometabolous neopterans (Holometabola)^c	
Ants, bees, wasps (Hymenoptera)	125,000
Beetles (Coleoptera)	375,000
Strepsipterans (Strepsiptera)	600
Lacewings, ant lions, dobsonflies (Neuropterida)	4,700
Scorpionflies (Mecoptera)	600
Fleas (Siphonaptera)	2,400
True flies (Diptera)	120,000
Caddisflies (Trichoptera)	5,000
Butterflies and moths (Lepidoptera)	250,000

^a The hexapod relatives of insects include the springtails (Collembola; 3,000 spp.), two-pronged bristletails (Diplura; 600 spp.), and proturans (Protura; 10 spp.). All are wingless and have internal mouthparts.
^b Neopteran insects can tuck their wings close to their bodies
^c Holometabolous insects are neopterans that undergo complete metamorphosis.

serving different functions. In many species, a fold of the exoskeleton, the *carapace*, extends dorsally and laterally back from the head to cover and protect some of the other segments.

The fertilized eggs of most crustacean species are attached to the outside of the female’s body, where they remain during their early development. At hatching, the young of some species are

released as larvae; those of other species are released as juveniles that are similar in form to the adults. Still other species release eggs into the water or attach them to an object in the environment. The typical crustacean larva, called a *nauplius*, has three pairs of appendages and one central eye (see Figure 31.11B).

Insects are the dominant terrestrial arthropods

During the Devonian period, more than 400 million years ago, some arthropods colonized terrestrial environments. Of the several groups that successfully colonized the land, none is more prominent today than the six-legged *hexapods*: the **insects** and their relatives (**Table 32.2**). Insects are abundant and diverse in terrestrial and freshwater environments; only a few live in salt water.

Insects, like crustaceans, have a body with three regions—head, thorax, and abdomen. In addition, insects have a unique mechanism for gas exchange in air: a system of air sacs and tubular channels called *tracheae* (singular *trachea*) that extend from external openings called *spiracles* inward to tissues throughout the body. Insects have a single pair of antennae on the head and three pairs of legs attached to the thorax (**Figure 32.26**). Unlike the other arthropods, insects have no appendages growing from their abdominal segments. Insects can be distinguished from other hexapods by their external mouthparts and paired antennae that contain a motion-sensitive receptor called *Johnston’s organ*.

The wingless relatives of the insects—the springtails (**Figure 32.27**), two-pronged bristletails, and proturans—are probably the most similar of living forms to insect ancestors. These relatives of insects have a simple life cycle; they hatch from eggs as miniature adults. They differ from insects in having inter-

32.26 Body Plan of an Insect Insects, like crustaceans, have a three-part body plan with a head, thorax, and abdomen. The middle region, the thorax, bears three pairs of legs and, in most groups, two pairs of wings. Unlike other arthropods, the abdomen of an insect bears no appendages (see Figure 20.8).

Sminthurides aquaticus

32.27 Wingless Hexapods The wingless hexapods, such as this springtail, have a simple life cycle. They hatch looking like miniature adults, then grow by successive molts of the cuticle.

nal mouthparts. Springtails can be extremely abundant (up to 200,000 per square meter) in soil, leaf litter, and on vegetation, and are the most abundant hexapods in the world in terms of number of individuals (rather than number of species).

Insects use nearly all species of plants and many species of animals as food. Herbivorous insects can consume massive amounts of plant matter. Gypsy moth caterpillars, for example, have been known to denude entire forests of their hardwood tree leaves, and the cyclical depredations wrought by locust hordes can be of biblical proportions. Many insects are predatory, feeding on small animals or on other insects. *Detritivorous* insects such as dung beetles are important in the recycling of chemicals through ecosystems. Some insects are internal parasites of plants or animals; others suck their host's blood or consume surface body tissues.

As recently as the 1980s, most biologists thought that about half of existing insect species had been described, but today they think that the approximately 1 million species of described insects are a small fraction of the total number of living species. Why did they change their minds?

A simple but important field study published in 1988 suggested that the number of existing insect species had been significantly underestimated. Knowing that the insects of tropical forests (the most species-rich habitat on Earth) were poorly known, entomologist Terry Erwin decided to make a comprehensive sample of beetles in the canopies of a single species of tropical forest tree, *Luehea seemannii*. Erwin fogged the canopies of 19 large *L. seemannii* trees with a pesticide and collected the insects that fell from the trees in collection nets (**Figure 32.28**). His sample contained about 1,000 species of beetles—many of them undescribed—from this one species of tree. He then used a set of assumptions to estimate the total number of insect species in tropical evergreen forests. Erwin's assumptions included estimates of the number of species of host trees in these forests, the proportion of beetles that specialized on a specific species of host tree, the proportion of beetles relative to other insect groups, and the proportion of beetles that live in trees versus leaf litter, among several other factors. From this and similar studies, Erwin estimated that there may be as many as 50 million species of insects on Earth! This estimate was surpris-

ing to many biologists, since it is about 50 times higher than the known species diversity of insects.

The assumptions Erwin used to make his calculations are open to debate, and Erwin did not intend for his calculations to provide more than a rough estimate of undiscovered biodiversity. If different assumptions are used, estimates of the number of species of insects change dramatically. For example, one of Erwin's assumptions involved an estimate of the proportion of insect species thought to be *specialists*—species that specialize on a particular host plant (in this case, *Luehea seemannii*). If the proportion of specialist species was overestimated, then the total number of species was likely overestimated; if the proportion of specialists was underestimated, the total number of species may have been underestimated. Erwin's extrapolations also assumed that his samples were representative of other forest trees, and that his sampling areas were representative of other tropical forests, among many other assumptions. But even if his estimates were off by several fold, Erwin's pioneering study highlighted the fact that we live on a poorly known planet, most of whose species have yet to be named and described.

Two groups of insects—the jumping bristletails and silverfish—are wingless and have simple life cycles, like the springtails and other close insect relatives. The remaining insects are the *pterygote insects*. Pterygotes have two pairs of wings, except in

32.28 Erwin's Research Project In an important study, entomologist Terry Erwin fogged tree canopies in a Panamanian rainforest with insecticide. Using the number of species represented among the fallen insects as a base, he extrapolated to estimate the total number of insect species on Earth.

(A) *Libellula semifasciata*(B) *Brachystola magna*(C) *Lygaeus kalmii*(D) *Limnephilus* sp. (larva)(E) *Eupholus magnificus*(F) *Argema mittrei*(G) *Phaenicia sericata*(H) *Vespula vulgaris*

some groups where one or both pairs of wings have been secondarily lost. Secondarily wingless groups include the parasitic lice and fleas, some beetles, and the worker individuals in many ants.

Hatchling pterygote insects do not look like adults, and they undergo substantial changes at each molt. The immature stages of insects between molts are called **instars**. As Section 31.4 describes, a substantial change that occurs between one developmental stage and another is called **metamorphosis**. If the changes between its instars are gradual, an insect is said to have **incomplete metamorphosis**. If the change between at least some instars is dramatic, an insect is said to have **complete metamorphosis**.

The most familiar examples of species with complete metamorphosis are butterflies (see Figure 31.10). The wormlike butterfly larva, called a *caterpillar*, transforms itself during a specialized phase, the **pupa**, in which larval tissues are broken down and the adult form develops. In many insects with complete metamorphosis, the different life stages are specialized for dif-

32.29 Diverse Winged Insects (A) Unlike most flying insects, a dragonfly cannot fold its wings over its back. (B) The plains lubber, a grasshopper, is an orthopteran. (C) Milkweed bugs are true bugs (hemipterans). The plants they feed on (*Asclepias* spp.) are toxic to many species; its coloring serves as a signal to predators that the bug also toxic. (D–H) Holometabolous insects undergo complete metamorphosis. (D) A larval caddisfly (right) emerges from its dark pupal case. (E) Coleopterans (beetles) such as this New Guinean weevil account for more than half of all holometabolous species and are the largest insect group. (F) The comet moth of Madagascar is a lepidopteran. (G) Flies such as this green bottle fly are dipterans. (H) Many hymenopteran genera, such as these yellow-jacket wasps, are social.

ferent environments and use different food sources. In many species, the larvae are adapted for feeding and growing, whereas the adults are specialized for reproduction and dispersal.

Pterygote insects were the first animals in evolutionary history to achieve the ability to fly. Flight opened up many new lifestyles and feeding opportunities that only the insects could

exploit, and it is almost certainly one of the reasons for the remarkable numbers of insect species and individuals, and for their unparalleled evolutionary success.

The adults of most flying insects have two pairs of stiff, membranous wings attached to the thorax. True flies, however, have one pair of wings and a pair of stabilizers called *halteres*. In winged beetles, one pair of wings—the forewings—forms heavy, hardened wing covers. Flying insects are important pollinators of flowering plants.

Two groups of pterygotes, the mayflies and dragonflies (**Figure 32.29A**), cannot fold their wings against their bodies. This is the ancestral condition for pterygote insects, and these two groups are not closely related to one another. Members of these groups have predatory or herbivorous aquatic larvae that transform into flying adults after they crawl out of the water. Dragonflies (and their relatives the damselflies) are active predators as adults. In contrast, adult mayflies lack functional digestive tracts. Mayflies live only about a day, just long enough to mate and lay eggs.

All other pterygote insects—the *neopterans*—can tuck their wings out of the way upon landing and crawl into crevices and other tight places. Some neopteran groups undergo incomplete metamorphosis, so hatchlings of these insects are sufficiently similar in form to adults to be recognizable. Examples include the grasshoppers (**Figure 32.29B**), roaches, mantids, stick insects, termites, stoneflies, earwigs, thrips, true bugs (**Figure 32.29C**), aphids, cicadas, and leafhoppers. They acquire adult organ systems, such as wings and compound eyes, gradually through several juvenile instars.

More than 80 percent of all insects belong to a subgroup of the neopterans called the *holometabolous* insects (see Table 32.2),

which undergo complete metamorphosis (**Figure 32.29D**). The many species of beetles account for almost half of this group (**Figure 32.29E**). Also included are lacewings and their relatives; caddisflies; butterflies and moths (**Figure 32.29F**); sawflies; true flies (**Figure 32.29G**); and bees, wasps, and ants, some species of which display unique and highly specialized social behaviors (**Figure 32.29H**).

Molecular data suggest that insects began to diversify about 450 million years ago, about the time of the appearance of the first land plants. These early hexapods evolved in a terrestrial environment that lacked any other similar organisms, which in part accounts for their remarkable success. But the success of the insects is also due to their wings. Homologous genes control the development of insect wings and crustacean appendages, suggesting that the insect wing evolved from a dorsal branch of a crustacean-like limb (**Figure 32.30**). The dorsal limb branch of crustaceans is used for gas exchange. Thus the insect wing probably evolved from a gill-like structure that had a gas exchange function.

32.4 RECAP

All arthropods have segmented bodies. Muscles in each segment operate that segment and the appendages attached to it. These jointed, specialized appendages permit complex patterns of movement, including, in insects, the ability to fly. With flight, insects took advantage of new feeding and lifestyle opportunities, which contributed to the unparalleled evolutionary success of this group.

- What features have contributed to making arthropods among the most abundant animals on Earth, both in number of species and number of individuals? **See p. 681**
- Describe the difference between incomplete and complete metamorphosis. **See p. 688**
- Can you think of some possible reasons why there are so many species of insects? **See pp. 688–689**

32.30 The Origin of Insect Wings? Insect wings may have evolved from an ancestral appendage similar to that of modern crustaceans. (A) A diagram of the ancestral, multibranched arthropod limb. (B, C) The *pdm* gene, a Hox gene, is expressed throughout the dorsal limb branch and walking leg of the thoracic limb of a crayfish (B) and in the wings and legs of *Drosophila* (C).

The protostomes encompass the majority of Earth's animal species, so it is not surprising that the different protostome groups display a huge variety of different characteristics.

An Overview of Protostome Evolution

The myriad species of protostomes encompass a staggering number of different body forms and life styles. The following aspects of protostome evolution have contributed to this enormous diversity:

- The evolution of *segmentation* permitted some groups of protostomes to move different parts of the body independently of one another. Species in some groups gradually evolved the ability to move rapidly over and through the substratum, through water, and through air.

- *Complex life cycles* with dramatic changes in form between one stage and another allow individuals of different stages to specialize on different resources.
- *Parasitism* has evolved repeatedly, and many protostome groups parasitize plants and animals.
- The evolution of *diverse feeding structures* allowed protostomes to specialize on many different food sources. Specialization on food sources undoubtedly contributed to species isolation and further diversification.
- Predation was a major selection pressure favoring the development of *hard external body coverings* (exoskeletons and

shells). Such coverings evolved independently in many lophotrochozoan and ecdysozoan groups. In addition to providing protection, these coverings became key elements in the development of new systems of locomotion.

- *Better locomotion* permitted prey to escape from predators, but also allowed predators to pursue their prey more effectively. Thus the evolution of animals has been, and continues to be, a complex “arms race” among predators and prey.

Many major evolutionary trends among the protostomes are shared by the deuterostomes, which includes the chordates, the group to which humans belong. We turn to the deuterostomes in the next chapter.

CHAPTER SUMMARY

32.1 What Is a Protostome?

- Protostomes (“mouth first”) are bilaterally symmetrical animals with an anterior brain that surrounds the entrance to the digestive tract and a ventral nervous system. The blastopore of protostomes (when present in development) develops into a mouth. Protostomes comprise two major clades, the lophotrochozoans and the ecdysozoans. **Review Figure 32.1, WEB ACTIVITIES 32.1 and 32.2**
- **Lophotrochozoans** include a wide diversity of animals. Within this group evolved **lophophores** (a complex organ for both food collection and gas exchange), free-living **trochophore** larvae, and spiral cleavage. Some of these features were subsequently lost in some lineages.
- **Ecdysozoans** have a body covering known as the **cuticle**, which they must **molt** in order to grow. Some ecdysozoans have a relatively thin cuticle. Others, especially the **arthropods**, have a rigid cuticle reinforced with **chitin**. This rigid cuticle functions as an **exoskeleton**. New mechanisms of locomotion and gas exchange evolved among the arthropods. **Review Figure 32.4**

32.2 What Features Distinguish the Major Groups of Lophotrochozoans?

- Lophotrochozoans range from animals having only one entrance to the digestive tract and no oxygen transport system to animals with complete digestive tracts and complex internal transport systems.
- Lophophores, wormlike body forms, and external shells are each found in many unrelated groups of lophotrochozoans.
- The most species-rich groups of lophotrochozoans are the **flatworms**, **annelids**, and **mollusks**.
- Annelids are a diverse group of segmented worms that live in moist terrestrial and aquatic environments. **Review Figure 32.12**
- Mollusks underwent a dramatic evolutionary radiation based on a body plan consisting of three major components: a foot, a mantle, and a visceral mass. The four major living molluscan clades—**chitons**, **bivalves**, **gastropods**, and **cephalopods**—demonstrate the diversity that evolved from this three-part body plan. **Review Figure 32.14**

32.3 What Features Distinguish the Major Groups of Ecdysozoans?

- Many ecdysozoan groups are wormlike in form. Members of several species-poor groups of wormlike marine ecdysozoans—**priapulids**, **kinorhynchs**, and **loriciferans**—have thin cuticles.
- **Horsehair worms** are extremely thin; many are internal parasites as larvae.
- **Nematodes**, or roundworms, have a thick, multilayered cuticle. Nematodes are among the most abundant and universally distributed of all animal groups. **Review Figure 32.17**
- One major ecdysozoan clade, the arthropods, has evolved jointed, paired appendages that have a wide diversity of functions. Collectively, arthropods are the dominant animals on Earth in number of described species, and among the most abundant in number of individuals.

32.4 Why Are Arthropods So Diverse?

- Encasement within a rigid exoskeleton provides arthropods with support for walking as well as some protection from predators. The waterproofing provided by chitin keeps arthropods from dehydrating in dry air.
- Jointed appendages permit complex movement patterns. Each arthropod segment has muscles attached to the inside of the exoskeleton that operate that segment and the appendages attached to it.
- Two groups of arthropod relatives, the **onychophorans** and the **tardigrades**, have simple, unjointed appendages. **Trilobites** were early marine arthropods that disappeared in the Permian extinction.
- The bodies of **myriapods** have only two regions, a head, and a long trunk with many segments, each of which carries appendages. **Chelicerates** also have a two-part body; most chelicerates have four pairs of walking legs.
- **Crustaceans** are the dominant marine arthropods, and are also found in many freshwater and some terrestrial environments. Their segmented bodies are divided into three regions (head, thorax, and abdomen) with different, specialized appendages in each region. **Review Figure 32.25**
- Hexapods—**insects** and their relatives—are the dominant terrestrial arthropods. They have the same three body regions as crustaceans, but no appendages form in their abdominal segments. Wings and the ability to fly first evolved among the insects, allowing them to exploit new lifestyles. **Review Figure 32.26**

SELF-QUIZ

- Members of which groups have lophophores?
 - Phoronids, brachiopods, and nematodes
 - Phoronids, brachiopods, and bryozoans
 - Brachiopods, bryozoans, and flatworms
 - Phoronids, rotifers, and bryozoans
 - Rotifers, bryozoans, and brachiopods
- Which of the following is *not* part of the molluscan body plan?
 - Mantle
 - Foot
 - Radula
 - Visceral mass
 - Jointed skeleton
- Nautilus control their buoyancy by
 - adjusting salt concentrations in their blood.
 - forcibly expelling water from the mantle.
 - pumping water and gases in and out of internal chambers.
 - using the complex sensory organs in their heads.
 - swimming rapidly.
- The outer covering of ecdysozoans
 - is always hard and rigid.
 - is always thin and flexible.
 - is hard and rigid in larvae but thin in adults.
 - ranges from very thin to hard and rigid depending on the species.
 - grows throughout life to accommodate a growing body.
- Nematodes are abundant and diverse because
 - they are both parasitic and free-living and eat a wide variety of foods.
 - they are able to molt their exoskeleton.
 - their thick cuticle enables them to move in complex ways.
 - their body cavity is a pseudocoelom.
 - their segmented body enables them to live in many different places.
- The arthropod exoskeleton is composed of a
 - mixture of several kinds of polysaccharides.
 - mixture of several kinds of proteins.
 - single complex polysaccharide called chitin.
 - single complex protein called arthropodin.
 - mixture of layers of proteins and a polysaccharide called chitin.
- Which groups are arthropod relatives with unjointed legs?
 - Trilobites and onychophorans
 - Onychophorans and tardigrades
 - Trilobites and tardigrades
 - Onychophorans and chelicerates
 - Tardigrades and chelicerates
- The body plan of insects is composed of which of the three following regions?
 - Head, abdomen, and trachea
 - Head, abdomen, and cephalothorax
 - Cephalothorax, abdomen, and trachea
 - Head, thorax, and abdomen
 - Abdomen, trachea, and mantle
- Insects whose hatchlings are sufficiently similar in form to adults to be recognizable are said to have
 - instars.
 - neopterous development.
 - accelerated development.
 - incomplete metamorphosis.
 - complete metamorphosis.
- Factors that may have contributed to the remarkable evolutionary success of insects include
 - the lack of any other similar organisms in the terrestrial environments colonized by insects.
 - the ability to fly.
 - complete metamorphosis.
 - a new mechanism for delivering oxygen to their internal tissues.
 - all of the above

FOR DISCUSSION

- Segmentation has either arisen several times during animal evolution, or else it arose early in animal evolution and was subsequently lost multiple times. What advantages does segmentation provide? Given these advantages, why might some animals have lost their segmentation?
 - Major structural novelties have arisen only infrequently during the course of evolution. Which of the features of protostomes do you think are major evolutionary novelties?
- Can you think of morphological features that may have led to major evolutionary radiations?
- There are more described and named species of insects than of all other species on Earth combined. However, only a very few insect species live in marine environments, and those species are restricted to the intertidal zone or the ocean surface. What factors may have contributed to this lack of success by the insects in the oceans?

ADDITIONAL INVESTIGATION

If you were given funding to carry out studies to improve our understanding of Earth's biodiversity, how would you spend it? How would your investigation differ if you targeted particular

major groups of animals, such as insects or nematodes? Which animal groups do you think should receive highest priority for such studies, and why?

WORKING WITH DATA (GO TO yourBioPortal.com)

Estimating the Number of Species of Insects In this exercise based on the study illustrated in Figure 32.28, you will use the data collected by Terry Erwin to estimate the number of insects in a hectare (10,000 m²) of Panamanian rainforest, as well as to

estimate the number of insect species found on Earth. You will also examine Erwin's assumptions and consider how they might be modified and tested.

Good parents, or cannibals?

Why would a frog swallow its own offspring? That may not sound like a good parenting skill, but female gastric brooding frogs of Australia shut down their digestive system to brood their tadpoles in their stomach. This provides the tadpoles with a safe haven from predators, making it much more likely that they will survive to metamorphosis. That was the case, at least, until gastric brooding frogs went extinct in the early 1980s, after humans introduced pathogenic fungi into their native range.

Not all frogs are as involved in raising their young as were gastric brooding frogs, however. Bullfrogs, for example, lay thousands of eggs each year and provide no parental care for their offspring. The eggs are fertilized by a male bullfrog and are then left to develop on their own. The eggs hatch into tadpoles and transform into tiny frogs—if they aren't eaten first; most of these offspring don't survive. In the water, the tadpoles are eaten by

many species of fishes, turtles, birds, snakes, aquatic insects, and other predators. As the young tadpoles transform into frogs, they are likely to be eaten by predators hunting at the margins of the pond. Out of the tens of thousands of tadpoles an adult bullfrog produces in its lifetime, an average of only two offspring are expected to survive to reproduce themselves.

In many species of frogs, complex behaviors associated with parental care change these long odds. Rather than producing huge numbers of offspring, each with a minimal chance of surviving, some frogs invest more energy in each offspring and care for the young as they grow. This increases the chances that any one offspring will survive and reproduce—but it also means far fewer offspring can be produced, because of the greater parental investment per offspring.

Strategies for parental care include many behaviors in addition to gastric brooding. The females of many species

guard a terrestrial egg clutch until it hatches. Other females carry their developing embryos or tadpoles around with them on their backs, or even in special brood pouches (as in the marsupial frogs of South America). Parental care often involves males as well. Males of many frog species guard egg masses or carry young, sometimes in unusual ways. In Darwin's frog

Eating One's Offspring? Young frogs emerge from the digestive tract of a female *Rheobatrachus silus*, one of the now-extinct gastric brooding frogs of Australia. In this unique form of gestation, eggs hatch and tadpoles develop within the protected environment of the mother's stomach.

Riding Piggyback The young of this female *Flectonotus pygmaeus* are developing within a pouch on her back. The marsupial frogs of South America take their name from another vertebrate group—marsupial mammals such as kangaroos—whose females also protect their developing young in pouches.

of southern South America, for example, the tadpoles develop within the male's vocal sacs.

Parental care can extend beyond protection to feeding the young. Some female dart-poison frogs of the tropical Americas carry each individual tadpole to one of the tiny pools of water that collect in bromeliad plants growing on the trees. The female then returns to each bromeliad "pond" and lays unfertilized eggs as food for the single tadpole developing there.

Frogs and other vertebrates constitute one of the major groups of deuterostome animals. Although there are far fewer species of deuterostomes than of protostomes, deuterostomes are of particular interest to biologists because of their importance in many ecosystems, their often complex behaviors, and their widespread use as models in developmental biology and genetics.

IN THIS CHAPTER we will introduce the deuterostomes and describe the principal animal groups: the echinoderms, hemichordates, and chordates. We will then discuss the evolution of the vertebrates within the chordates, including the features that allowed vertebrates to colonize most habitats on Earth. We will look especially closely at the primate lineage, which includes our own species.

CHAPTER OUTLINE

- 33.1** What Is a Deuterostome?
- 33.2** What Are the Major Groups of Echinoderms and Hemichordates?
- 33.3** What New Features Evolved in the Chordates?
- 33.4** How Did Vertebrates Colonize the Land?
- 33.5** What Traits Characterize the Primates?

33.1 What Is a Deuterostome?

It may surprise you to learn that both you and a sea urchin are deuterostomes. Adult sea stars, sea urchins, and sea cucumbers—the most familiar echinoderms—look so different from adult vertebrates (fishes, frogs, lizards, birds, and mammals) that it may be difficult to believe all these animals are closely related. The evidence that all deuterostomes share a common ancestor that is not shared with the protostomes includes common early developmental patterns and phylogenetic analysis of gene sequences, factors that are not apparent in the forms of the adult animals.

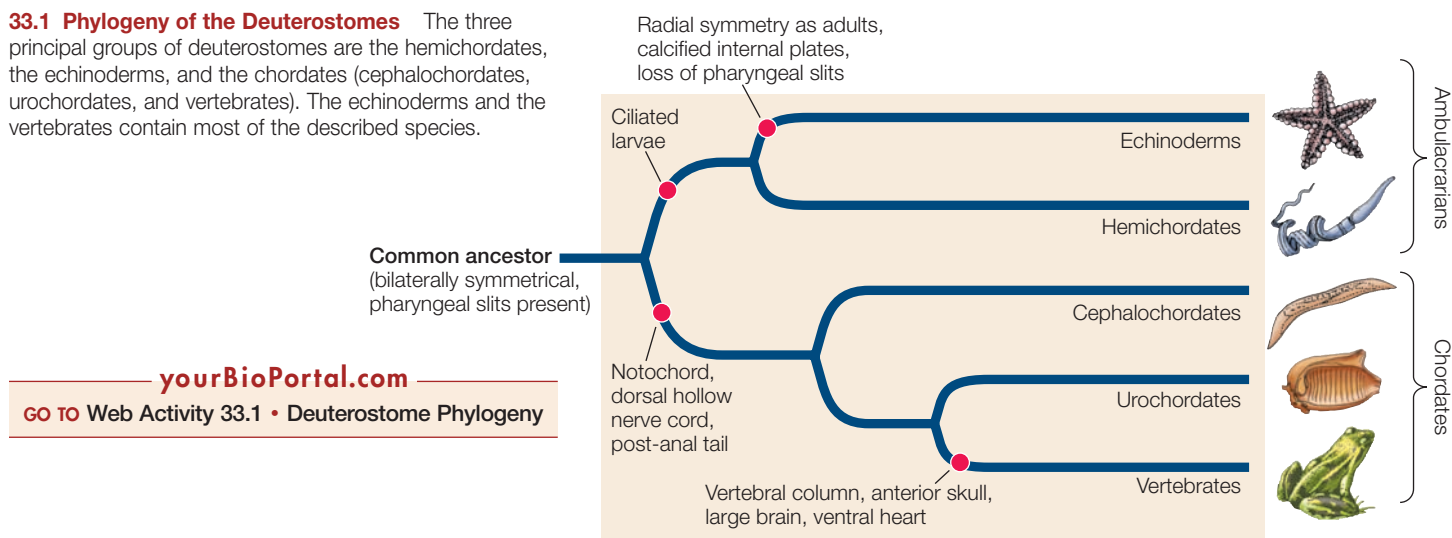

Historically, the deuterostomes were characterized by three early developmental patterns:

- Radial cleavage
- Formation of the mouth at the opposite end of the embryo from the blastopore (the pattern that gives the deuterostomes their name); in deuterostomes, the blastopore develops into the anus (see Figure 31.2)
- Development of a coelom from mesodermal pockets that bud off from the cavity of the gastrula rather than by splitting of the mesoderm, as occurs among protostomes

Radial cleavage is not exclusive to deuterostomes, and as noted in Chapter 31, it is now thought to be the ancestral condition for bilaterians. In fact, some of the groups now known to be protostomes were once thought to be deuterostomes because they have developmental patterns similar to those of echinoderms and chordates. The development of the blastopore into an anus may also be the ancestral condition for bilaterians, rather than a derived feature of deuterostomes. Today, the strongest support for the shared evolutionary relationships of echinoderms, hemichordates, and chordates (the groups that now compose the deuterostomes) comes from phylogenetic analyses of DNA sequences of many different genes.

Although there are far fewer species of deuterostomes than of protostomes (see Table 31.1), we have a special interest in deuterostomes, in part because we are members of that clade. The deuterostomes are also of interest because they include many large animals that strongly influence the characteristics of ecosystems. Many deuterostome species have been intensively studied in all fields of biology. Complex behaviors, such as the parenting behaviors described in the opening of this chapter, are especially well developed among some deuterostomes.

33.1 Phylogeny of the Deuterostomes The three principal groups of deuterostomes are the hemichordates, the echinoderms, and the chordates (cephalochordates, urochordates, and vertebrates). The echinoderms and the vertebrates contain most of the described species.

Living deuterostomes comprise three distinct clades (**Figure 33.1**):

- **Echinoderms:** sea stars, sea urchins, and their relatives
- **Hemichordates:** acorn worms and pterobranchs
- **Chordates:** sea squirts, lancelets, and vertebrates

All deuterostomes are triploblastic, coelomate animals (see **Figure 31.4C**). Skeletal support features, where present, are internal rather than external. Some species have segmented bodies, but the segments are less obvious than those of annelids and arthropods.

Scientists are learning much about the ancestors of modern deuterostomes from fossils recently discovered in 520-million-year-old rocks in China. Some of these early deuterostomes had a skeleton similar to that of a modern echinoderm, but they had pharyngeal slits and bilateral symmetry. Another group of early

deuterostomes, the *yunnanozoans*, were discovered in China's Yunnan Province. These well-preserved animals had a large mouth, six pairs of external gills, and a segmented posterior body section bearing a light cuticle (**Figure 33.2**).

The features of these fossil animals support the findings from phylogenetic analyses of living species in showing that the earliest deuterostomes were bilaterally symmetrical, segmented animals with a pharynx that had slits through which water flowed. Echinoderms evolved their adult forms with unique symmetry (in which the body parts are arranged along five radial axes) much later, whereas other deuterostomes retained the ancestral bilateral symmetry.

33.1 RECAP

The deuterostomes include the echinoderms, hemichordates, and chordates. The common ancestry of these groups is supported by developmental similarities and by phylogenetic analyses of DNA sequences.

- What are three developmental patterns the earliest deuterostomes had in common? **See p. 693**
- Why is radial cleavage no longer considered to be evidence for the monophyly of deuterostomes? **See p. 693**

Yunnanozoon lividum

33.2 Ancestral Deuterostomes Had External Gills The extinct yunnanozoans may be ancestral to all deuterostomes. This fossil, which dates from the Cambrian, shows the six pairs of external gills and segmented posterior body that characterized these animals.

33.2 What Are the Major Groups of Echinoderms and Hemichordates?

About 13,000 species of echinoderms in 23 major groups have been described from their fossil remains. They are probably only a small fraction of those that actually lived. Only 6 of the 23 major groups known from fossils are represented by species that survive today; many clades became extinct during the periodic mass extinctions that have occurred throughout Earth's history. Nearly all of the 7,000 extant species of echinoderms live only in marine environments. There are far fewer species of living hemichordates, with only about 100 known species.

33.3 Echinoderms Are Bilaterally Symmetrical as Larvae but Radially Symmetrical as Adults

(A) The ciliated larva of a sea star has bilateral symmetry. Hemichordates have a similar larval form. (B) The radially symmetrical adult sea star displays the canals and tube feet of the echinoderm water vascular system, as well as the calcified internal skeleton. The body's orientation is oral–aboral rather than anterior–posterior.

The echinoderms and hemichordates (together known as *ambulacrarians*) have a bilaterally symmetrical, ciliated larva (**Figure 33.3A**). Adult hemichordates also are bilaterally symmetrical. Echinoderms, however, undergo a radical change in form as they develop into adults (**Figure 33.3B**), changing from a bilaterally symmetrical larva to an adult with **pentaradial symmetry** (symmetry in five or multiples of five). As is typical of animals with radial symmetry, echinoderms have no head, and they move slowly and equally well in many directions. Rather than having an anterior–posterior (head–tail) and dorsal–ventral (back–belly) body organization, echinoderms have an *oral* side (containing the mouth) and an opposite *aboral* side (containing the anus).

Echinoderms have unique structural features

In addition to having pentaradial symmetry, adult echinoderms have two unique structural features. One is a system of calcified internal plates covered by thin layers of skin and some muscles. The calcified plates of most echinoderms are thick, and they fuse inside the entire body, forming an *internal skeleton*. The other unique feature is a **water vascular system**, a network of water-filled canals leading to extensions called **tube feet**. This system functions in gas exchange, locomotion, and feeding (see Figure 33.3B). Seawater

enters the system through a perforated structure called a *madreporite*. A calcified canal leads from the madreporite to the *ring canal*, which surrounds the *esophagus* (the tube leading from the mouth to the stomach). *Radial canals* branch off from the ring canal, extending through the arms (in species that have arms) and connecting with the tube feet. Echinoderms use their tube feet in many different ways to move and to capture prey. These structural innovations have been modified in many ways, resulting in a striking array of very different animals.

Members of one major extant echinoderm clade, the *crinoids* (sea lilies and feather stars), were more abundant and species-rich 300 to 500 million years ago than they are today. There are some 80 described living sea lily species, most of which are sessile organisms attached to the substratum by a stalk. Feather stars (**Figure 33.4A**) grasp the substratum with flexible appendages that allow for limited movement. About 600 living species of feather stars have been described.

Unlike the mostly sessile crinoids, most surviving echinoderms are motile. The two main groups of motile echinoderms are the *echinozoans* (sea urchins and sea cucumbers) and *asterozoans* (sea stars and brittle stars). Sea urchins are hemispherical in shape and lack arms (**Figure 33.4B**). They are covered with spines that are attached to the underlying skeleton with ball-and-socket joints. These joints enable the spines to be moved so they can converge toward a point that has been touched. The spines vary in size and shape and can be used for locomotion; a few produce toxic substances. They provide effective protection for the urchin, as many a scuba diver has found out the hard way. Sand dollars are flattened, disc-shaped relatives of sea urchins.

Sea cucumbers also lack arms, and their bodies are oriented in an atypical manner for an echinoderm (**Figure 33.4C**). The mouth is anterior and the anus is posterior (front and rear), not oral and aboral (top and bottom) as in other echinoderms.

(A) *Oxycomanthus bennetti*(B) *Sphaerechinus granularis*(C) *Synaptula* sp.(D) *Asterias rubens*(E) *Ophiothrix spiculata*

33.4 Echinoderm Diversity (A) The flexible arms of this golden feather star are clearly visible. (B) Sea urchins are important grazers on algae in the intertidal zones of the world's oceans. (C) Sea cucumbers are unique among echinoderms in having an anterior–posterior rather than an oral–aboral orientation of the mouth and anus. (D) Sea stars are important predators on bivalve mollusks such as mussels and clams. Suction tips on its tube feet allow a sea star to grasp both shells of the bivalve and pull them open. (E) The arms of the brittle star are composed of hard but jointed plates.

Sea cucumbers use most of their tube feet primarily for attaching to the substratum rather than for moving.

Sea stars, popularly called starfish, are the most familiar echinoderms (**Figure 33.4D**). Their gonads and digestive organs are located in the arms, as seen in Figure 33.3B. Their tube feet serve as organs of locomotion, gas exchange, and attachment. Each tube foot of a sea star consists of an internal *ampulla* connected by a muscular tube to an external suction cup that can stick to the substratum. The tube foot is moved by expansion and contraction of the circular and longitudinal muscles of the tube. Brittle stars are similar in structure to sea stars, but their flexible arms are composed of jointed, hard plates (**Figure 33.4E**).

Echinoderms use their tube feet in a great variety of ways to capture prey. Sea lilies, for example, feed by orienting their arms in passing water currents. Food particles then strike and stick to the tube feet, which are covered with mucus-secreting

glands. The tube feet transfer these particles to grooves in the arms, where ciliary action carries the food to the mouth. Sea cucumbers capture food with their anterior tube feet, which are modified into large, feathery, sticky tentacles that can be protruded from the mouth. Periodically, a sea cucumber withdraws the tentacles, wipes off the material that has adhered to them, and digests it.

Many sea stars use their tube feet to capture large prey such as polychaetes, gastropod and bivalve mollusks, small crustaceans such as crabs, and fishes. With hundreds of tube feet acting simultaneously, a sea star can grasp a bivalve in its arms, anchor the arms with its tube feet, and by steady contraction of the muscles in its arms, gradually exhaust the muscles the bivalve uses to keep its shell closed (see Figure 33.4D). To feed on a bivalve, a sea star can push its stomach out through its mouth and then through the narrow space between the two halves of the bivalve's shell. The sea star's stomach then secretes enzymes that digest the prey.

Most sea urchins eat algae, which they catch with their tube feet from the plankton or scrape from rocks with a complex rasping structure. Most of the 2,000 species of brittle stars ingest particles from the upper layers of sediments and assimilate the organic material from them, although some species filter suspended food particles from the water and others capture small animals.

Hemichordates are wormlike marine deuterostomes

Hemichordates—acorn worms and pterobranchs—have a body organized in three major parts, consisting of a *proboscis*, a *collar* (which bears the mouth), and a *trunk* (which contains the other body parts). The 70 known species of *acorn worms* range up to 2 meters in length (Figure 33.5A). They live in burrows in muddy and sandy marine sediments. The digestive tract of an acorn worm consists of a mouth behind which are a muscular *pharynx* and an *intestine*. The pharynx opens to the outside through a number of *pharyngeal slits* through which water can exit. Highly vascularized tissue surrounding the pharyngeal slits serves as a gas-exchange apparatus. Acorn worms breathe by pumping water into the mouth and out through the pharyngeal slits. They capture prey with the large proboscis, which is coated with sticky mucus to which small organisms in the sediment stick.

33.5 Hemichordates (A) The proboscis of an acorn worm is modified for burrowing. (B) The structure of a colonial pterobranch.

The mucus and its attached prey are conveyed by cilia to the mouth. In the esophagus, the food-laden mucus is compacted into a ropelike mass that is moved through the digestive tract by ciliary action.

The 30 living species of *pterobranchs* are sedentary marine animals up to 12 millimeters long that live in a tube secreted by the proboscis. Some species are solitary; others form colonies of individuals joined together (Figure 33.5B). Behind the proboscis is a collar with anywhere from one to nine pairs of arms. The arms bear long tentacles that capture prey and function in gas exchange.

33.2 RECAP

Echinoderms have an internal skeleton of calcified plates and a unique water vascular system. Hemichordates have a bilaterally symmetrical body divided into three parts: proboscis, collar, and trunk.

- What are some of the ways that echinoderms use their tube feet to obtain food? [See p. 696](#)
- How do hemichordates obtain food? [See p. 697](#)

We have described the deuterostome groups that are most distantly related to us. Now we turn our attention to the chordates, the clade to which humans belong.

33.3 What New Features Evolved in the Chordates?

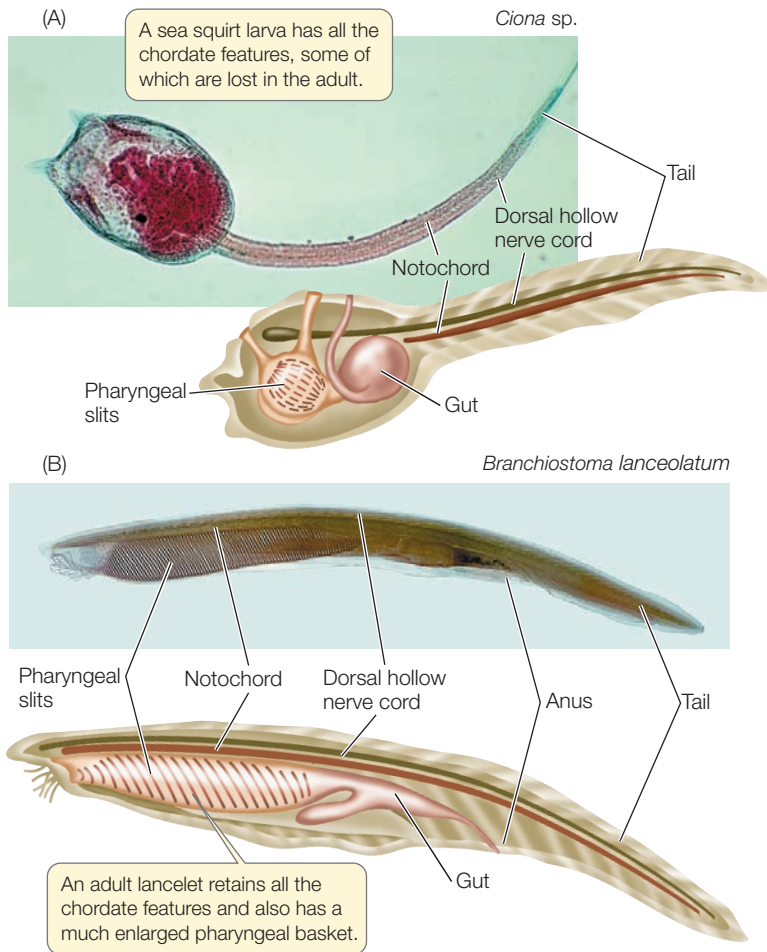

It is not obvious from examining adult animals that echinoderms and chordates share a common ancestor. The evolutionary relationships among some chordate groups are not immediately apparent, either. The features that reveal the evolutionary relationships both among the chordates and between chordates and echinoderms are seen primarily in the larvae—in other words, it is during the early developmental stages that their evolutionary relationships are evident.

There are three principal chordate clades: the **cephalochordates**, the **urochordates**, and the **vertebrates** (see Figure 33.1). There are about 3,000 living species of urochordates and 62,000 living species of vertebrates, but only about 30 living species of cephalochordates.

Adult chordates vary greatly in form, but all chordates display the following derived structures at some stage in their development (Figure 33.6):

- A dorsal hollow nerve cord
- A tail that extends beyond the anus
- A dorsal supporting rod called the notochord

The **notochord** is the most distinctive derived chordate trait. It is composed of a core of large cells with turgid fluid-filled vacuoles, which make it rigid but flexible. In the urochordates the notochord is lost during metamorphosis to the adult stage. In most vertebrate species, it is replaced during development by skeletal structures that provide support for the body.

33.6 The Key Features of Chordates Are Most Apparent in Early Developmental Stages The pharyngeal slits of both the urochordate sea squirt and the cephalochordate lancelet develop into a pharyngeal basket. (A) The sea squirt larva (but not the adult) has all three chordate features: dorsal hollow nerve cord, postanal tail, and a notochord. (B) All three chordate synapomorphies are retained in the adult lancelet.

The ancestral pharyngeal slits (not a derived feature of this group) are present at some developmental stage of chordates but are often lost in adults. The *pharynx*, which develops around the pharyngeal slits, functioned in chordate ancestors as the site for oxygen uptake and the elimination of carbon dioxide and water (as in acorn worms). The pharynx is much enlarged in some chordate species (as in the *pharyngeal basket* of the lancelet in Figure 33.6B) but has been lost in others.

Adults of most cephalochordates and urochordates are sessile

The 30 species of cephalochordates, or *lancelets*, are small animals that rarely exceed 5 centimeters in length. The notochord, which provides body support, extends the entire length of the body throughout their lives (see Figure 33.6B). Lancelets are found in shallow marine

and brackish waters worldwide. Most of the time they lie covered in sand with their head protruding above the sediment, but they can swim. They filter prey from the water with their pharyngeal basket. During the reproductive season, the gonads of the males and females greatly enlarge. At spawning, the walls of the gonads rupture, releasing eggs and sperm into the water column, where fertilization takes place.

All members of the three major urochordate groups—the ascidians, thaliaceans, and larvaceans—are marine animals. More than 90 percent of the known species of urochordates are *ascidians* (sea squirts). Individual ascidians range in length from less than 1 millimeter to 60 centimeters. Some ascidians form colonies by asexual budding from a single founder. Colonies may measure several meters across. The baglike body of an adult ascidian is enclosed in a tough tunic, leading to its alternate name of “tunicate” (Figure 33.7A). The tunic is composed of proteins and a complex polysaccharide secreted by epidermal cells. The ascidian pharynx is enlarged into a pharyngeal basket that filters prey from the water passing through it.

In addition to its pharyngeal slits, an ascidian larva has a dorsal hollow nerve cord and a notochord that is restricted mostly to the tail region (see Figure 33.6A). Bands of muscle that surround the notochord provide support for the body. After a short

(A) *Clavelina dellavallei*

(B) *Pegea socia*

33.7 Adult Urochordates (A) The transparent tunic and the pharyngeal basket are clearly visible in this ascidian (sea squirt, also known as a tunicate). (B) A chainlike colony of thaliaceans (salps) floats in tropical waters.

time swimming in the plankton, the larvae of most species settle on the seafloor and transform into sessile adults. The swimming, tadpolelike larvae suggest a close evolutionary relationship between ascidians and vertebrates (see Figure 22.6).

Thaliaceans (salps) can live singly or in chainlike colonies up to several meters long (Figure 33.7B). They float in tropical and subtropical oceans at all depths down to 1,500 meters. *Larvaceans* are solitary planktonic animals that retain their notochord and dorsal hollow nerve cord throughout their lives. Most larvaceans are less than 5 millimeters long, but some species that live near the bottom of deep ocean waters build delicate casings of mucus that may be more than a meter wide. They snare sinking organic particles (their primary food source) with elaborate filters built into their mucus “houses.” When the old “house” gets clogged with excess debris, the animals build a new one.

A dorsal supporting structure replaces the notochord in vertebrates

In one chordate group, a new dorsal supporting structure evolved. The **vertebrates** take their name from the jointed, dorsal **vertebral column** that replaces the notochord during early development as their primary supporting structure (Figure 33.8).

All of the non-vertebrate deuterostomes (the hemichordates, echinoderms, cephalochordates, and urochordates) are exclusively or primarily marine. The lineage that led to the vertebrates is also thought to have evolved in the oceans, although

probably in an estuarine environment (where fresh water meets salt water). Vertebrates have since radiated into marine, fresh-water, terrestrial, and aerial environments worldwide.

The *hagfishes* are thought by many biologists to be the sister group to the remaining vertebrates (as shown in Figure 33.8). Hagfishes (Figure 33.9A) have a weak circulatory system, with three small accessory hearts (rather than a single, large heart), a partial *cranium* or skull (containing no *cerebrum* or *cerebellum*, two main regions of the brain of other vertebrates), and no jaws or stomach. They also lack separate, jointed vertebrae and have a skeleton composed of cartilage. Thus, some biologists do not consider hagfishes vertebrates, and use instead the term *craniates* to refer collectively to the hagfishes and the vertebrates. Some analyses of gene sequences suggest, however, that hagfishes may be more closely related to the vertebrate lampreys (Figure 33.9B); in this phylogenetic arrangement, the two groups are collectively called the *cyclostomes* (“circle mouths”). If in fact the hagfishes and lampreys do form a monophyletic group, then hagfishes must have secondarily lost many of the major vertebrate morphological features during their evolution.

The 58 known species of hagfishes are unusual marine animals that produce copious quantities of slime as a defense. They are virtually blind and rely largely on the four pairs of sensory tentacles around their mouth to detect food. Although they have no jaws, hagfishes have a tonguelike structure equipped with toothlike rasps that they can use to tear apart dead organisms and to capture their principal prey, polychaete worms. Hagfishes have direct development (no larvae), and individuals may actually change sex from year to year (from male to female and vice versa).

The nearly 50 species of lampreys either live in fresh water, or they live in coastal salt water and move into fresh water to breed. Although the lampreys and hagfishes may look super-

33.8 Phylogeny of the Living Vertebrates This phylogenetic tree shows the evolution of some of the key innovations among the major groups of vertebrates.

33.9 Modern Jawless Fishes (A) Hagfishes burrow in the ocean mud, from which they extract small prey. They also scavenge on dead or dying fish. Hagfishes have degenerate eyes, which has led to their being misnamed “blind eels.” (B) Sea lampreys are ectoparasites that attach to the bodies of living fish and use their large, jawless mouths to suck blood and flesh. They can survive in both fresh and salt water, as this individual attached to a salmon returning to its spawning ground will do.

ficially similar (with elongate eel-like bodies and no paired fins), they differ greatly in their biology.

Lampreys have a complete braincase and distinct and separate (although rudimentary) vertebrae, all cartilaginous rather than bony. Lampreys undergo a complete metamorphosis from filter-feeding larvae known as *ammocoetes*, which are morphologically quite similar in general structure to adult lancelets. The adults of many species of lampreys are parasitic, although several lineages of lampreys evolved to become nonfeeding as adults. These nonfeeding adult lampreys survive only a few weeks after metamorphosis—just long enough to breed. In the species that are parasitic as adults, the round mouth is a rasping and sucking organ that is used to attach to their prey and rasp at the flesh (see Figure 33.9B). Some species of lampreys are critically endangered because of recent habitat changes and losses.

The vertebrate body plan can support large, active animals

Four key features characterize the vertebrates:

- An anterior *skull* with a large brain
- A rigid internal *skeleton* supported by the vertebral column
- Internal organs *suspended in a coelom*
- A well-developed *circulatory system*, driven by contractions of a ventral *heart*

This organization of the vertebrate body is exemplified by the bony fish diagrammed in **Figure 33.10**. Many kinds of jawless

Eptatretus stoutii

Petromyzon marinus

fishes were found in the seas, estuaries, and fresh waters of the Devonian period, but hagfishes and lampreys are the only jawless fishes that survived beyond the Devonian. During that period, the *gnathostomes* (Greek, “jaw mouths”) evolved jaws via modifications of the skeletal arches that supported the gills (**Figure 33.11A**). Jaws greatly improved feeding efficiency, as an animal with jaws can grasp, subdue, and swallow large prey.

33.10 The Vertebrate Body Plan A ray-finned fish is used here to illustrate the structural elements common to all vertebrates. In addition to the paired pelvic fins, these fishes have paired pectoral fins on the sides of their bodies (not seen in this cutaway view).

33.11 Jaws and Teeth Increased Feeding Efficiency (A) The diagrams illustrate one probable scenario for the evolution of jaws from the anterior gill arches of jawless fishes. (B) Jaws of the extinct giant shark (*Carcharodon megalodon*) display the teeth that indicate an extreme predatory lifestyle.

The earliest jaws were simple, but the evolution of *teeth* made predators more effective (**Figure 33.11B**). In predators, teeth function crucially both in grasping and in breaking up prey. In both predators and herbivores, teeth enable an animal to chew both soft and hard body parts of their food. Chewing also aids chemical digestion and improves an animal's ability to extract nutrients from its food, as we describe in Chapter 51. Vertebrates are remarkable in the diversity of their jaws and teeth.

Fins and swim bladders improved stability and control over locomotion

Paired fins stabilize the position of jawed fishes in water (and in some cases, help propel them). Most aquatic gnathostomes have a pair of pectoral fins just behind the gill slits, and a pair of pelvic fins anterior to the anal region (see Figures 33.10 and 33.12). Median dorsal and anal fins stabilize the fish, or may be used for propulsion in some species. In many fishes, the caudal fin helps propel the animal and enables it to turn rapidly.

Several groups of gnathostomes became abundant during the Devonian. Among them were the **chondrichthyans**—sharks, skates, and rays (940 living species) and chimaeras (40 living species). Like hagfishes and lampreys, these fishes have a skeleton composed entirely of firm but pliable cartilage. Their skin is flexible and leathery, sometimes bearing scales that give it the

consistency of sandpaper. Sharks move forward by means of lateral undulations of their body and caudal (tail) fin (**Figure 33.12A**). Skates and rays propel themselves by means of vertical undulating movements of their greatly enlarged pectoral fins (**Figure 33.12B**).

Most sharks are predators, but some feed by straining plankton from the water. Most skates and rays live on the ocean floor, where they feed on mollusks and other animals buried in the sediments. Nearly all cartilaginous fishes live in the oceans, but a few are estuarine or migrate into lakes and rivers. One group of stingrays is found in river systems of South America. The less familiar chimaeras (**Figure 33.12C**) live in deep-sea or cold waters.

In the ancestor of the bony vertebrates, gas-filled sacs supplemented the gas-exchange function of the gills by giving the animals access to atmospheric oxygen. These features enabled those fishes to live where oxygen was periodically in short supply, as it often is in freshwater environments. These lunglike sacs evolved into *swim bladders*, which are organs of buoyancy, as well as into the lungs of tetrapods. By adjusting the amount of gas in its swim bladder, a fish can control the depth at which it remains suspended in the water while expending very little energy to maintain its position.

Ray-finned fishes, and most remaining groups of vertebrates, have internal skeletons of calcified, rigid *bone* rather than flexible cartilage. The outer body surface of most species of ray-finned fishes is covered with flat, thin, lightweight scales that provide some protection or enhance movement through the wa-

ter. The gills of ray-finned fishes open into a single chamber covered by a hard flap, called an *operculum*. Movement of the operculum improves the flow of water over the gills, where gas exchange takes place.

Ray-finned fishes radiated extensively in the Tertiary. Today there are about 30,000 known living species, encompassing a remarkable variety of sizes, shapes, and lifestyles (**Figure 33.13**). The smallest are less than 1 centimeter long as adults; the largest weigh as much as 900 kilograms. Ray-finned fishes exploit nearly all types of aquatic food sources. In the oceans they filter plankton from the water, rasp algae from rocks, eat corals and other soft-bodied colonial animals, dig animals from soft sediments, and prey on virtually all kinds of other fishes. In fresh water they eat plankton, devour insects, eat fruits that fall into the water in flooded forests, and prey on other aquatic vertebrates and, occasionally, terrestrial vertebrates. Many ray-finned fishes are solitary, but in open water others form large aggregations called *schools*. Many species perform complicated behaviors to maintain schools, build nests, court and choose mates, and care for their young.

Although ray-finned fishes can readily control their position in open water using their fins and swim bladder, their eggs tend to sink. Some species produce small eggs that are buoyant enough to complete their development in the open water, but many marine fishes move to food-rich shallow waters to lay their eggs. That is why coastal waters and estuaries are so important in the life cycles of many marine fishes. Some, such as salmon, are *anadromous*; these species leave salt water when they breed, ascending rivers to spawn in freshwater streams and lakes (see **Figure 33.9B**).

33.3 RECAP

Chordates are characterized by a dorsal hollow nerve chord, a post-anal tail, and a dorsal supporting rod called a notochord at some point during the life cycle. Specialized structures for support (such as vertebrae), locomotion (such as fins), and feeding (such as jaws and teeth) evolved among the vertebrates, which allowed them to colonize and adapt to most of Earth's environments.

- What synapomorphies respectively characterize the chordates and the vertebrates? See pp. 697–700 and **Figures 33.6 and 33.10**
- How do the hagfishes differ from the lampreys in morphology and life history? Do you see why some biologists do not consider the hagfishes to be vertebrates? See p. 699

In some fishes, the lunglike sacs that gave rise to swim bladders became specialized for another purpose: breathing air. That adaptation set the stage for the vertebrates to move onto the land.

33.4 How Did Vertebrates Colonize the Land?

The evolution of lunglike sacs in fishes set the stage for the invasion of the land. Some early ray-finned fishes probably used those sacs to supplement their gills when oxygen levels in the water were low, as lungfishes and many groups of ray-finned fishes do today. But with their unjointed fins, those fishes could only flop around on land. Changes in the structure of the fins first allowed some fishes to support themselves better in shallow water and, later, to move better on land.

Jointed fins enhanced support for fishes

Two pairs of muscular, jointed fins evolved in the ancestor of the **sarcopterygians**, which include coelacanth, lungfishes, and tetrapods. Each of the jointed appendages of sarcopterygians is joined to the body by a single enlarged bone. The coelacanth flourished from the Devonian until about 65 million years ago, when they were thought to have become extinct. However, in 1938 a commercial fisherman caught a living coelacanth off South Africa. Since that time, hundreds of individuals of this extraordinary fish, *Latimeria chalumnae*, have been collected. A second species, *L. menadoensis*, was discovered in 1998 off the Indonesian island of Sulawesi. *Latimeria*, a predator of other fishes, reaches a length of about 1.8 meters and weighs up to 82 kilograms (**Figure 33.14A**). Its skeleton is composed mostly of cartilage, not bone. A cartilaginous skeleton is a derived feature in this clade because it had bony ancestors.

Lungfishes, which also have jointed fins that are connected to the body by a single enlarged bone, were important predators in shallow-water habitats in the Devonian, but most lineages died out. The six surviving species live in stagnant swamps and muddy waters in South America, Africa, and Australia (**Figure 33.14B**). Lungfishes have lungs derived from the lunglike sacs of their ancestors as well as gills. When ponds dry up, individuals of most species can burrow deep into the mud and survive for many months in an inactive state while breathing air.

It is believed that some early aquatic sarcopterygians began to use terrestrial food sources, became more fully adapted to life on land, and eventually evolved to become ancestral **tetrapods** (four-legged vertebrates).

How was the transition from an animal that swam in water to one that walked on land accomplished? Early in 2006, scientists reported the discovery of a Devonian fossil they believe represents an intermediate between the finned appendages of fishes and the limbs of terrestrial tetrapods (**Figure 33.14C**). It appears that limbs able to prop up a large fish with the front-to-rear movement necessary for walking evolved while the animals still lived in water. These limbs appear to have functioned in holding the animals upright in shallow water, perhaps even allowing them to hold their head above the water's surface. These same structures were then co-opted for movement on land, at first probably for foraging on brief trips out of water.

Amphibians adapted to life on land

During the Devonian, the first tetrapods arose from an aquatic ancestor. In this lineage, legs capable of movement on land evolved from the short, stubby fins of their aquatic ancestors. The basic elements of those legs have remained throughout the evolution of terrestrial vertebrates, although they have changed considerably in their form.

Most modern **amphibians** are confined to moist environments because they lose water rapidly through the skin when exposed to dry air. In addition, their eggs are enclosed within delicate membranous envelopes that cannot prevent water loss in dry conditions. In some amphibian species, adults live mostly on land but return to fresh water to lay their eggs, which are usually fertilized outside the body (**Figure 33.15**). The fertilized eggs

give rise to larvae that live in water until they undergo metamorphosis to become terrestrial adults. However, many amphibians (especially those in tropical and subtropical areas) have evolved a wide diversity of additional reproductive modes and types of parental care, as described in the opening of this chapter. Internal fertilization evolved many times among the amphibians.

33.15 In and Out of the Water

Most early stages in the life cycle of many amphibians take place in water. The aquatic tadpole transforms into a terrestrial adult through metamorphosis. Some species of amphibians, however, have direct development (with no aquatic larval stage), and others are aquatic throughout life.

yourBioPortal.com

GO TO Animated Tutorial 33.1 •
Life Cycle of a Frog

Many species develop directly into adultlike forms from fertilized eggs laid on land or carried by the parents. Other species of amphibians are entirely aquatic, never leaving the water at any stage of their lives, and many of these species retain a larval-like morphology.

The more than 6,500 known species of amphibians living on Earth today belong to three major groups: the wormlike, limbless, tropical, burrowing or aquatic *caecilians* (Figure 33.16A), the tail-less frogs and toads (collectively called *anurans*; Figure 33.16B), and the tailed *salamanders* (Figure 33.16C and D).

Anurans are most diverse in wet tropical and warm temperate regions, although a few are found at very high latitudes. There are far more anurans than any other amphibians, with about 5,800 described species and more being discovered every year. Some anurans have tough skins and other adaptations that enable them to live for long periods in very dry deserts, whereas others live in moist terrestrial and arboreal environments. Some species are completely aquatic as adults. All anurans have a very short vertebral column, with a strongly modified pelvic region that is modified for leaping, hopping, or propelling the body through water by kicking the hind legs.

The approximately 600 described species of salamanders are most diverse in temperate regions of the Northern Hemisphere, but many species are also found in cool, moist environments in the mountains of Central America, and a few species penetrate into the South American tropics. Many salamanders live in rotting logs or moist soil. One major group has lost lungs, and these species exchange gases entirely through the skin and

mouth lining—body parts that all amphibians use in addition to their lungs. Through *paedomorphosis* (retention of the juvenile state; see Chapter 20), a completely aquatic lifestyle has evolved several times among the salamanders (see Figure 33.16D). Most species of salamanders have internal fertilization, which is usually achieved through the transfer of a small jellylike, sperm-embedded capsule called a *spermatophore*.

Many amphibians have complex social behaviors. Most male anurans utter loud, species-specific calls to attract females of their own species (and sometimes to defend breeding territories), and they compete for access to females that arrive at the breeding sites. Many amphibians lay large numbers of eggs, which they abandon once they are deposited and fertilized. As described in the opening of this chapter, some amphibians lay only a few eggs, which are fertilized and then guarded in a nest, or carried on the backs, in the vocal pouches, or even in the stomachs of one of the parents. A few species of frogs, salamanders, and caecilians are *viviparous*, meaning they give birth to well-developed young that have received nutrition from the female during gestation.

(B) *Bufo periglenes*

(C) *Ambystoma mavortium*

(D) *Eurycea waterlooensis*

Amphibians are the focus of much attention today because populations of many species are declining rapidly, especially in mountainous regions of western North America, Central and South America, and northeastern Australia. Worldwide, about one-third of amphibian species are now threatened with extinction or have disappeared completely in the last few decades (as happened with the gastric brooding frogs described at the beginning of this chapter). Scientists are investigating several hypotheses to account for these population declines, including the adverse effects of habitat alteration by humans, increased solar radiation caused by destruction of Earth's ozone layer, pollution from urban and industrial areas and airborne agricultural pesticides and herbicides (see Chapter 1), and the spread of a pathogenic chytrid fungus that attacks amphibians. Scientists have documented the spread of the chytrid fungus through Central America, where many species of amphibians have become extinct (including Costa Rica's golden toad; see Figure 33.16B).

Amniotes colonized dry environments

Several key innovations contributed to the ability of members of one clade of tetrapods to exploit a wide range of terrestrial habitats. The animals that evolved these water-conserving traits are called **amniotes**.

The **amniote egg** (which gives the group its name) is relatively impermeable to water and allows the embryo to develop in a contained aqueous environment (Figure 33.17). The leathery or brittle, calcium-impregnated shell of the amniote egg retards evaporation of the fluids inside but permits passage of oxygen and carbon dioxide. The egg also stores large quantities of food in the form of *yolk*, allowing the embryo to attain a relatively advanced state of development before it hatches. Within the shell are *extraembryonic membranes* that protect the embryo from desiccation and assist its gas exchange and excretion of waste nitrogen.

In several different groups of amniotes, the amniote egg became modified, allowing the embryo to grow inside (and receive nutrition from) the mother. For instance, the mammalian egg lost its

33.17 An Egg for Dry Places The evolution of the amniote egg, with its water-retaining shell, four extraembryonic membranes, and embryo-nourishing yolk, was a major step in the colonization of the terrestrial environment.

yourBioPortal.com

GO TO Web Activity 33.2 • The Amniote Egg

shell while the functions of the extraembryonic membranes were retained and expanded; we examine the roles of these membranes in detail in Section 44.4.

Other innovations evolved in the organs of terrestrial adults. A tough, impermeable skin, covered with scales or modifications of scales such as hair and feathers, greatly reduced water loss. Adaptations of the vertebrate excretory organs, the kidneys, allowed amniotes to excrete concentrated urine, ridding the body of waste nitrogen without losing a large amount of water in the process (see Chapter 52).

During the Carboniferous, amniotes split into two major groups, the mammals and reptiles (Figure 33.18). More than

18,700 species of **reptiles** exist today, over half of which are *birds*. Birds are the only living members of the otherwise extinct *dinosaurs*, the dominant terrestrial predators of the Mesozoic.

Reptiles adapted to life in many habitats

The lineage leading to modern reptiles began to diverge from other amniotes about 250 million years ago. One reptilian group that has changed very little over the intervening millennia is the *turtles*. The dorsal and ventral bony plates of turtles form a shell into which the head and limbs can be withdrawn in many species (**Figure 33.19A**). The dorsal shell is an expansion of the ribs, and it is a mystery how the pectoral girdles evolved to be inside the ribs of turtles, making them unlike any other vertebrates. Most turtles live in aquatic environments, but several groups, such as tortoises and box turtles, are terrestrial. Sea turtles spend their entire lives at sea except when they come ashore to lay eggs. Human exploitation of sea turtles and their eggs has resulted in worldwide declines of these species, all of which are now endangered. A few species of turtles are strict herbivores or carnivores, but most species are omnivores that eat a variety of aquatic and terrestrial plants and animals.

The *lepidosaurs* constitute the second-most species-rich clade of living reptiles. This group is composed of the *squamates* (lizards, snakes, and amphisbaenians—the last a group of mostly

legless, wormlike, burrowing reptiles with greatly reduced eyes) and the *tuataras*, which superficially resemble lizards but differ from them in tooth attachment and several internal anatomical features. Many species related to the tuataras lived during the Mesozoic era, but today only two species, restricted to a few islands off New Zealand, survive (**Figure 33.19B**).

The skin of a lepidosaur is covered with horny scales that greatly reduce loss of water from the body surface. These scales, however, make the skin unavailable as an organ of gas exchange. Gases are exchanged almost entirely via the lungs, which are proportionally much larger in surface area than those of amphibians. A lepidosaur forces air into and out of its lungs by bellowslike movements of its ribs. The three-chambered lepidosaur heart partially separates oxygenated blood from the lungs from deoxygenated blood returning from the body. With this type of heart, lepidosaurs can generate high blood pressure and can sustain a relatively high metabolism.

Most lizards are insectivores, but some are herbivores; a few prey on other vertebrates. The largest lizard, which grows as

33.19 Reptilian Diversity (A) Green sea turtles are widely distributed in tropical oceans. (B) This tuatara represents one of only two surviving species in a lineage that diverged long ago. (C) *Eublepharis macularius*

(B) *Sphenodon punctatus*

(D) *Diadophis punctatus*

long as 3 meters and can weigh more than 150 kilograms, is the predaceous Komodo dragon of the East Indies. Most lizards walk on four limbs (**Figure 33.19C**), although limblessness has evolved repeatedly in the group, especially in burrowing and grassland species. One major group of limbless squamates is the snakes (**Figure 33.19D**). All snakes are carnivores, and many can swallow objects much larger than themselves. Several snake groups evolved venom glands and the ability to inject venom rapidly into their prey.

Crocodylians and birds share their ancestry with the dinosaurs

Another reptilian group, the *archosaurs*, includes the crocodilians, dinosaurs, and birds. *Dinosaurs* rose to prominence about 215 million years ago and dominated terrestrial environments for about 150 million years; only one group of dinosaurs, the *birds*, survived the mass extinction event at the Cretaceous–Tertiary boundary. During the Mesozoic, most terrestrial animals more than a meter long were dinosaurs. Many were agile and could run rapidly; they had special muscles that enabled the lungs to be filled and emptied while the limbs moved. We can infer the existence of such muscles in dinosaurs from the structure of the vertebral column in fossils. Some of the largest dinosaurs weighed as much as 70,000 kilograms.

Modern *crocodilians*—crocodiles, caimans, gharials, and alligators—are confined to tropical and warm temperate environments (**Figure 33.20A**). Crocodilians spend much of their time in water, but they build nests on land or on floating piles of vegetation. The eggs are warmed by heat generated by decaying organic matter that the female places in the nest. Typically, the female guards the eggs until hatching, and she often facilitates hatching. In some species, the female continues to guard and communicate with her offspring after they hatch. All crocodilians are carnivorous. They eat vertebrates of all kinds, including large mammals.

Biologists have long accepted the phylogenetic position of birds among the reptiles, although birds clearly have many unique, derived morphological features. In addition to the strong morphological evidence for the placement of birds among the reptiles, fossil and molecular data emerging over the last few decades have provided definitive supporting evidence. Birds are thought to have emerged among the *theropods*, a group of predatory dinosaurs that share such traits as bipedal stance, hollow bones, a *furcula* (“wishbone”), elongated metatarsals with three-fingered feet, elongated forelimbs with three-fingered hands, and a pelvis that points backward.

The living bird species fall into two major groups that diverged during the late Cretaceous, about 80 to 90 million years ago, from a flying ancestor. The few modern descendants of one lineage include a group of secondarily flightless and weakly flying birds, some of which are very large. This group, called the *palaeognaths*, includes the South and Central American tinamous and several large flightless birds of the southern continents—

(A) *Crocodylus porosus*

(B) *Struthio camelus*

33.20 Archosaurs (A) Crocodiles, alligators, and their relatives live in tropical and warm temperate climates. This crocodile lives in saltwater and estuarine environments along Australia's coast. (B) Birds are the other living archosaur group, represented here by the winged but flightless ostrich.

the rheas, emu, kiwis, cassowaries, and the world's largest bird, the ostrich (**Figure 33.20B**). The second lineage, the *neognaths*, has left a much larger number of descendants, most of which have retained the ability to fly.

The evolution of feathers allowed birds to fly

Fossil dinosaurs discovered recently in early Cretaceous deposits in Liaoning Province, in northeastern China, show that the scales of some small predatory dinosaurs were highly modified to form *feathers*. The feathers of one of these dinosaurs, *Microraptor gui*, were structurally similar to those of modern birds (**Figure 33.21A**).

During the Mesozoic era, about 175 million years ago, a lineage of theropods gave rise to the birds. The oldest known avian fossil, *Archaeopteryx*, which lived about 150 million years ago, had teeth, but it was covered with feathers that are virtually identical to those of modern birds (**Figure 33.21B**). It also had well-developed wings, a long tail, and a furcula to which some of the flight muscles were probably attached. *Archaeopteryx* had clawed fingers on its forelimbs, but it also had typical perching bird claws on its hindlimbs. It probably lived in trees and shrubs and used the fingers to assist it in clambering over branches.

The evolution of feathers was a major force for diversification. Feathers are lightweight but are strong and structurally complex (**Figure 33.22**). The large quills of the flight feathers on

33.21 Mesozoic Bird Relatives Fossil remains demonstrate the evolution of birds from other dinosaurs. (A) *Microraptor gui* was a feathered dinosaur from the early Cretaceous (about 140 mya). (B) Dating from roughly the same timeframe, *Archaeopteryx* is the oldest known birdlike fossil.

the wings arise from the skin of the forelimbs to create the flying surfaces. Other strong feathers sprout like a fan from the shortened tail and serve as stabilizers during flight. The feathers that cover the body, along with an underlying layer of down feathers, provide birds with insulation that helps them to survive in virtually all of Earth's climates.

The bones of theropod dinosaurs, including birds, are hollow with internal struts that increase their strength. Hollow bones would have made early theropods lighter and more mobile; later they facilitated the evolution of flight. The sternum (breastbone) of flying birds forms a large, vertical keel to which the flight muscles are attached.

Flight is metabolically expensive. A flying bird consumes energy at a rate about 15 to 20 times faster than a running lizard of the same weight. Because birds have such high metabolic rates, they generate large amounts of heat. They control the rate of heat loss using their feathers, which may be held close to the body or elevated to alter the amount of insulation they provide. The lungs of birds allow air to flow through unidirectionally rather than by pumping air in and out (see Section 49.2). This flow-through structure of the lungs increases the efficiency of gas exchange and thereby supports an increased metabolic rate.

There are about 10,000 species of living birds, which range in size from the 150-kilogram ostrich to a tiny hummingbird

33.22 Feathers Represent a Major Evolutionary Innovation The flight feathers of birds are attached to the forelimb (wing) bones by a hollow central shaft. Fine branches with interlocking hooks and barbs radiate from the shaft, creating a strong, lightweight surface that enables flight.

weighing only 2 grams. The teeth so prominent among other dinosaurs were secondarily lost in the ancestral birds, but birds nonetheless eat almost all types of animal and plant material. Insects and fruits are the most important dietary items for terrestrial species. Birds also eat seeds, nectar and pollen, leaves and buds, carrion, and other vertebrates. By eating the fruits and seeds of plants, birds serve as major agents of seed dispersal. **Figure 33.23** shows representatives of a few of the major groups of birds.

Mammals radiated after the extinction of dinosaurs

Small and medium-sized **mammals** coexisted with the dinosaurs for millions of years. After the non-avian dinosaurs disappeared during the mass extinction at the close of the Mesozoic era, mammals increased dramatically in numbers, diversity, and size. Today mammals range in size from tiny shrews and bats weighing only about 2 grams to the blue whale, the largest animal on Earth, which measures up to 33 meters long and can weigh as much as 160,000 kilograms. Mammals have far fewer, but more highly differentiated, teeth than do fishes, amphibians, or reptiles. Differences among mammals in the number, type, and arrangement of teeth reflect their varied diets (see Figure 51.6).

Four key features distinguish the mammals:

- **Sweat glands**, which secrete sweat that evaporates and thereby cools an animal
- **Mammary glands**, which in females secrete a nutritive fluid (milk) on which newborn individuals feed

33.23 Diversity among the Birds

(A) Perching, or passeriform, birds such as this cedar waxwing comprise the most species-rich of all bird groups. (B) This bright-plumaged male Mandarin duck is a member of the group that includes ducks, geese, and swans. (C) Great frigatebirds are among the ocean-going birds that are often found miles from shore. This male is in display mode, with an inflated pouch that advertises his presence to females. (D) This barn owl is a nighttime predator that can find prey using its sensitive auditory “sonar” system.

- *Hair*, which provides a protective and insulating covering
- A *four-chambered heart* that completely separates the oxygenated blood coming from the lungs from the deoxygenated blood returning from the body (this last characteristic is convergent with the archosaurs, including modern birds and crocodiles)

Mammalian eggs are fertilized within the female’s body, and the embryos undergo a period of development in the female’s body in an organ called the *uterus* prior to being born. Most mammals have a covering of hair (fur), which is luxuriant in some species but has been greatly reduced in others, including the cetaceans (whales and dolphins) and humans. Thick layers of insulating fat (blubber) replace hair as a heat-retention mechanism in the cetaceans; humans learned to use clothing for this purpose when they dispersed from warm tropical areas.

The approximately 5,000 species of living mammals are divided into two primary groups: the *prototherians* and the *therians*. Only five species of prototherians are known, and they are found only in Australia and New Guinea. These mammals, the duck-billed platypus and four species of echidnas, differ from other mammals in lacking a placenta, laying eggs, and having sprawling legs (**Figure 33.24**). Prototherians supply milk for their young, but they have no nipples on their mammary glands; the milk simply oozes out and is lapped off the fur by the offspring.

Most mammals are therians

Members of the *therian* clade are further divided into the *marsupials* and the *eutherians*. Females of most marsupial species have a ventral pouch in which they carry and feed their offspring (see Figure 33.25A). Gestation (pregnancy) in marsupials is brief; the young are born tiny but with well-developed forelimbs, with which they climb to the pouch. They attach to

(A) *Bombycilla cedrorum*

(B) *Ornithorhynchus anatinus*

33.24 Prototherians (A) The short-beaked echidna is one of the four surviving species of echidnas. (B) The duck-billed platypus is another surviving prototherian.

33.25 Marsupials (A) Australia's eastern gray kangaroo is among the largest living marsupials. This female carries her young offspring in the characteristic marsupial pouch. (B) The carnivorous Tasmanian devil is found only in Tasmania, an island off southern Australia. (C) This arboreal opossum is a South American marsupial.

a nipple but cannot suck. The mother ejects milk into the tiny offspring until it grows large enough to suckle. Once her offspring have left the uterus, a female marsupial may become sexually receptive again. She can then carry fertilized eggs that are capable of initiating development and can replace the offspring in her pouch should something happen to them.

At one time marsupials were found on all continents, but the approximately 350 living species are now restricted to Australasia (**Figure 33.25A and B**) and the Americas (especially South America; **Figure 33.25C**). One species, the Virginia opossum, is widely distributed in North America. Marsupials radiated to become herbivores, insectivores, and carnivores, but no marsupials live in the oceans. None can fly, although some *arboreal* (tree-dwelling) marsupials are gliders. The largest living marsupials are the kangaroos of Australia, which can weigh up to 90 kilograms. Much larger marsupials existed in Australia until humans exterminated them soon after reaching that continent about 40,000 years ago.

Eutherians include the majority of mammals. Eutherians are sometimes called *placental mammals*, but this name is inappropriate because some marsupials also have placentas. Eutherians are more developed at birth than are marsupials; no external pouch houses them after they are born.

The approximately 5,000 species of living eutherians are divided into 20 major groups (**Table 33.1**). The largest group is the rodents, with about 2,300 species. Rodents are traditionally defined by the unique morphology of their teeth, which are adapted for gnawing through substances such as wood. The next largest group comprises the approximately 1,100 bat species—the flying mammals. The bats are followed by the moles and shrews, with about 430 species. The relationships of the major groups of eutherians to one another have been difficult to determine, because most of the major groups diverged in a short period of time during an explosive adaptive radiation.

Eutherians are extremely varied in their form and ecology (**Figure 33.26**). The extinction of the non-avian dinosaurs at the end of the Cretaceous may have made it possible for them to diversify and radiate into a large range of ecological *niches*. Many eutherian species grew to become quite large in size, and some

(B) *Sarcophilus harrisii*

(A) *Macropus giganteus*

(C) *Marmosa murina*

assumed the role of dominant terrestrial predators previously occupied by the large dinosaurs. Among these predators, social hunting behavior evolved in several species, including members of the canid (dog), felid (cat), and primate lineages.

Grazing and browsing by members of several eutherian groups helped transform the terrestrial landscape. Herds of grazing herbivores feed on open grasslands, whereas browsers feed on shrubs and trees. The effects of herbivores on plant life favored the evolution of the spines, tough leaves, and difficult-to-eat growth forms found in many plants. In turn, adaptations to the teeth and digestive systems of many herbivore lineages allowed these species to consume many plants despite such defenses—a striking example of coevolution. A large animal can survive on food of lower quality than a small animal can, and large size evolved in several groups of grazing and browsing mammals (see **Figure 33.26C**). The evolution of large herbivores, in turn, favored the evolution of large carnivores able to attack and overpower them.

Several lineages of terrestrial eutherians subsequently returned to the aquatic environments their ancestors had left behind (see **Figure 33.26D**). The completely aquatic cetaceans—whales and dolphins—evolved from artiodactyl ancestors (whales are closely related to the hippopotamuses). The seals, sea lions, and walrus also returned to the marine environment, and their limbs became modified into flippers. Weasel-like otters retain their limbs but have also returned to aquatic environments, colonizing both fresh and salt water. The manatees and dugongs colonized estuaries and shallow seas.

(A) *Erithizon dorsatum*

(B) *Artibeus lituratus*

(C) *Rangifer tarandus*

33.26 Diversity among the Eutherians

(A) The North American porcupine, a large rodent covered with sharp, protective quills. Almost half of all eutherians are rodents. (B) Flight evolved in the ancestor of bats. This fruit-eating bat ranges from Central to South America. Virtually all bat species are nocturnal. (C) Large hoofed mammals are important herbivores in terrestrial environments. Although this bull is grazing by himself, caribou are usually found in huge herds. (D) Spinner dolphins are cetaceans, a cetartiodactyl group that returned to the marine environment.

(D) *Stenella longirostris*

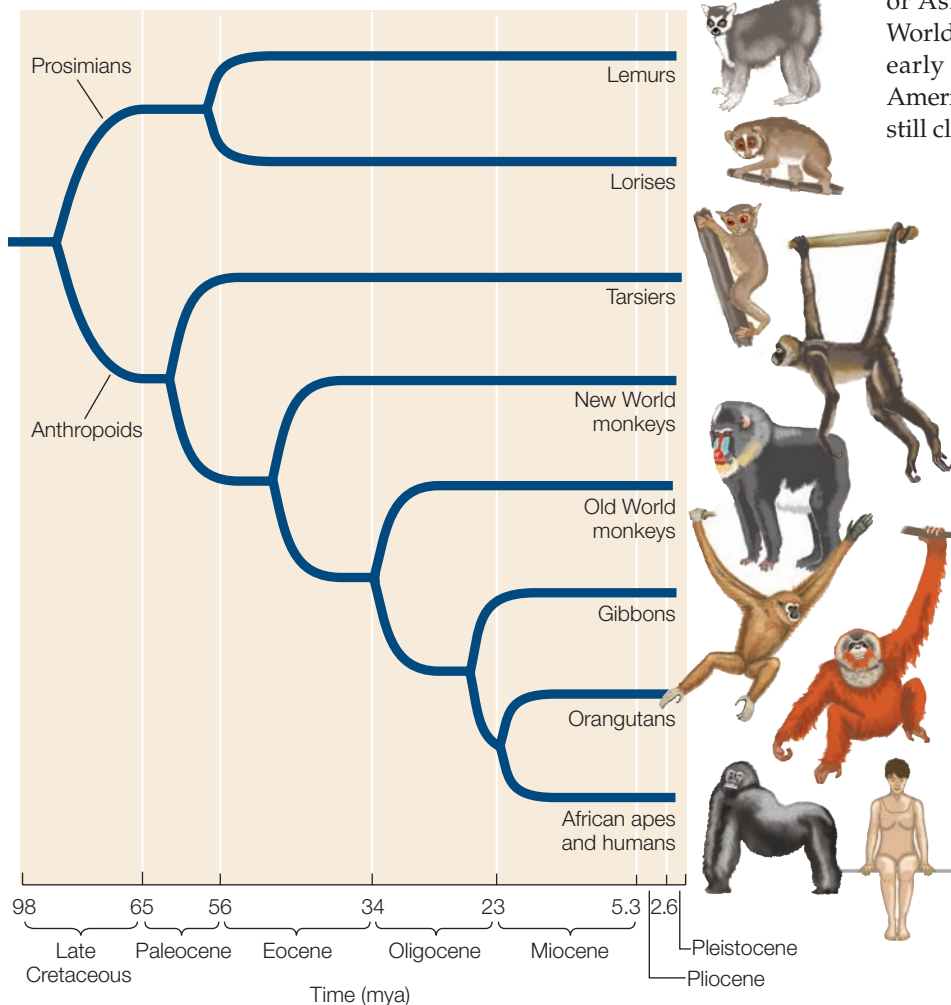

TABLE 33.1		
Major Groups of Living Eutherian Mammals		
GROUP	APPROXIMATE NUMBER OF LIVING SPECIES	EXAMPLES
Gnawing mammals (Rodentia)	2,300	Rats, mice, squirrels, woodchucks, ground squirrels, beaver, capybara
Flying mammals (Chiroptera)	1,100	Bats
Soricomorph insectivores (Soricomorpha)	430	Shrews, moles
Even-toed hoofed mammals and cetaceans (Cetartiodactyla)	320	Deer, sheep, goats, cattle, antelopes, giraffes, camels, swine, hippopotamus, whales, dolphins
Carnivores (Carnivora)	290	Wolves, dogs, bears, cats, weasels, pinnipeds (seals, sea lions, walruses)
Primates (Primates)	235	Lemurs, monkeys, apes, humans
Lagomorphs (Lagomorpha)	80	Rabbits, hares, pikas
African insectivores (Afrosoricida)	50	Tenrecs, golden moles
Spiny insectivores (Erinaceomorpha)	24	Hedgehogs
Armored mammals (Cingulata)	21	Armadillos
Tree shrews (Scandentia)	20	Tree shrews
Odd-toed hoofed mammals (Perissodactyla)	20	Horses, zebras, tapirs, rhinoceroses
Long-nosed insectivores (Macroscelidea)	16	Elephant shrews
Pilosans (Pilosa)	10	Anteaters, sloths
Pholidotans (Pholidota)	8	Pangolins
Sirenians (Sirenia)	5	Manatees, dugongs
Hyracoids (Hyracoidea)	4	Hyraxes, dassies
Elephants (Proboscidea)	3	African and Indian elephants
Dermopterans (Dermoptera)	2	Flying lemurs
Aardvark (Tubulidentata)	1	Aardvark

33.4 RECAP

The vertebrate colonization of dry land was facilitated by the evolution of an impermeable body covering, efficient kidneys, and the amniote egg—a structure that resists desiccation and provides an aqueous internal environment in which the embryo grows. Major amniote groups include turtles, lepidosaurs, archosaurs (crocodilians and birds), and mammals.

- In the not-too-distant past, the idea that birds were reptiles met with skepticism. Explain how fossils, morphology, and molecular evidence now support the position of birds among the reptiles. **See pp. 708–709**
- In reviewing the discussion of the various vertebrate groups, identify several reasons why tooth structure is such an important area of study.

The evolutionary history of one eutherian group—the primates—is of special interest to us because it includes the human lineage. The primates have been the subject of extensive research in most aspects of their biology, including behavior, ecol-

ogy, physiology, and molecular biology. Let's take a closer look at the characteristics and evolutionary history of the primates.

33.5 What Traits Characterize the Primates?

The eutherian **primates** underwent extensive evolutionary radiation from an ancestral small, arboreal, insectivorous mammal. A nearly complete fossil of an early primate, *Carpolestes*, was found in Wyoming and dated at 56 million years ago; it had grasping feet with an opposable big toe that had a nail rather than a claw. Grasping limbs with opposable digits are one of the major adaptations to arboreal life that distinguish primates from other mammals.

Early in their evolutionary history, the primates split into two main clades, the prosimians and the anthropoids (**Figure 33.27**). *Prosimians*—lemurs, lorises, and their close relatives—once lived on all continents, but today they are restricted to Africa, Madagascar, and tropical Asia. All mainland prosimian species are arboreal and nocturnal (**Figure 33.28**). On the island of Mad-

agascar, however, the site of a remarkable radiation of lemurs, there are also diurnal and terrestrial species.

A second primate lineage, the *anthropoids*—tarsiers, New World monkeys, Old World monkeys, and apes—evolved about 65 million years ago in Africa or Asia. New World monkeys diverged from Old World monkeys and apes at a slightly later date, but early enough that they might have reached South America from Africa when those two continents were still close to each other. All New World monkeys are arboreal (**Figure 33.29A**). Many of them have a long, prehensile tail with which they can grasp branches. Many Old World monkeys are arboreal as well, but a number of species are terrestrial (**Figure 33.29B**). No Old World primate has a prehensile tail.

About 35 million years ago, a lineage that led to the modern apes separated from the Old World monkeys. Between 22 and 5.5 million years ago, dozens of species of apes lived in Europe, Asia, and Africa. The Asian apes—gibbons and orangutans (**Figure 33.30A and B**)—descended from two of these ape lineages. Another extinct genus, *Dryopithecus*, is the sister group of the modern African apes—gorillas and chimpanzees (**Figure 33.30C and D**)—and of humans.

About 35 million years ago, a lineage that led to the modern apes separated from the Old World monkeys. Between 22 and 5.5 million years ago, dozens of species of apes lived in Europe, Asia, and Africa. The Asian apes—gibbons and orangutans (**Figure 33.30A and B**)—descended from two of these ape lineages. Another extinct genus, *Dryopithecus*, is the sister group of the modern African apes—gorillas and chimpanzees (**Figure 33.30C and D**)—and of humans.

33.27 Phylogeny of the Primates The phylogeny of primates is among the best studied of any major group of mammals. This tree is based on evidence from many genes, morphology, and fossils.

Eulemur coronatus

33.28 A Prosimian The crowned lemur is one of many lemur species found in Madagascar, where it is part of a unique assemblage of endemic plants and animals.

(A) *Ateles geoffroyi*(B) *Mandrillus sphinx*

33.29 Monkeys (A) The spider monkeys of Central America are typical of the New World monkeys, all of which are arboreal. (B) Although many Old World monkey species are arboreal, the mandrills are among the many terrestrial groups.

(A) *Hylobates lar*(B) *Pongo pygmaeus*(C) *Gorilla gorilla*

33.30 Apes (A) The several genera of gibbons are all smaller in size than the other apes. Gibbons are found throughout southeastern Asia. (B) Orangutans are also native to Asia, living in the forests of Sumatra and Borneo. (C) Gorillas—the largest apes—are restricted to humid African forests. This male is a lowland gorilla. (D) Chimpanzees, our closest relatives, are found in forested regions of Africa.

(D) *Pan troglodytes*

Human ancestors evolved bipedal locomotion

About 6 million years ago in Africa, a lineage split occurred that would lead to the chimpanzees on the one hand and to the *hominid* clade that includes modern humans and their extinct close relatives on the other.

The earliest protohominids, known as *ardipithecines*, had distinct morphological adaptations for *bipedal locomotion* (walking on two legs). Bipedal locomotion frees the forelimbs to manipulate objects and to carry them while walking. It also elevates the eyes, enabling the animal to see over tall vegetation to spot predators and prey. Bipedal locomotion is also energetically more economical than quadrupedal locomotion. All three advantages were probably important for the *ardipithecines* and their descendants, the *australopithecines*.

The first *australopithecine* skull was found in South Africa in 1924. Since then *australopithecine* fossils have been found at many sites in Africa. The most complete fossil skeleton of an *australopithecine* yet found was discovered in Ethiopia in 1974. The skeleton was approximately 3.5 million years old and was that of a young female who has since become known to the world as “Lucy.” Lucy was assigned to the species *Australopithecus afarensis*, and her discovery captured worldwide interest. Fossil remains of more than 100 *A. afarensis* individuals have since been discovered, and there have been recent discoveries of fossils of other *australopithecines* who lived in Africa 4 to 5 million years ago.

Experts disagree over how many species are represented by *australopithecine* fossils, but it is clear that multiple species of hominids lived together over much of eastern Africa several million years ago (**Figure 33.31**). A lineage of larger species (weighing about 40 kilograms) is represented by *Paranthropus robustus* and *P. boisei*, both of which died out between 1 and 1.5 million years ago. Members of a smaller lineage of *australopithecines* gave rise to the genus *Homo*.

Early members of the genus *Homo* lived contemporaneously with *Paranthropus* in Africa for about a million years. Some 2-million-year-old fossils of an extinct species called *H. habilis* were discovered in the Olduvai Gorge, Tanzania. Other fossils of *H. habilis* have been found in Kenya and Ethiopia. Associated with the fossils are tools that these early hominids used to obtain food.

Another extinct hominid species, *Homo erectus*, evolved in Africa about 1.6 million years ago. Soon thereafter it had spread as far as eastern Asia, becoming the first hominid to leave Africa. Members of *H. erectus* were nearly as large as modern people, but their brains were smaller and they had comparatively thick skulls. The cranium, which had thick, bony walls, may have

33.31 A Phylogenetic Tree of Hominids At times in the past, more than one species of hominid lived on Earth at the same time. Originating in Africa, hominids spread to Europe and Asia multiple times. All these closely related species are now extinct, while modern *Homo sapiens* have colonized nearly every corner of the planet.

been an adaptation to protect the brain, ears, and eyes from impacts caused by a fall or a blow from a blunt object. What would have been the source of such blows? Fighting with other *H. erectus* individuals is a possible answer.

Homo erectus used fire for cooking and for hunting large animals, and made characteristic stone tools that have been found in many parts of the Old World. Populations of *H. erectus* survived until at least 250,000 years ago, although more recent fossils may also be attributable to this species. In 2004 some 18,000-year-old fossil remains of a small *Homo* were found on the island of Flores in Indonesia. Since then, numerous additional fossils of this diminutive hominid have been found on Flores, dating from 95,000 to 17,000 years ago. Many anthropologists think that this small species, named *H. floresiensis*, was most closely related to *H. erectus*.

Human brains became larger as jaws became smaller

In the hominid lineage leading to *Homo sapiens* and *H. neanderthalensis*, the brain increased rapidly in size. At the same time, the powerful jaw muscles of our ancestors dramatically decreased in size. These two changes were simultaneous, suggesting they might have been functionally correlated. A mutation in a regulatory gene that is expressed only in the head may have removed a barrier that had previously prevented this remodeling of the human cranium.

The striking enlargement of the brain relative to body size in the hominid lineage was probably favored by an increasingly complex social life. Any features that allowed group members to communicate more effectively with one another would have been valuable in cooperative hunting and gathering and for improving one's status in the complex social interactions that must have characterized early human societies, just as they do in ours today.

Several *Homo* species coexisted during the mid-Pleistocene epoch, from about 1.5 million to about 250,000 years ago. All were skilled hunters of large mammals, but plants were important components of their diets. During this period another distinctly human trait emerged: rituals and a concept of life after death. Deceased individuals were buried with tools and clothing, supplies for their presumed existence in the next world.

One species, *Homo neanderthalensis*, was widespread in Europe and Asia between about 500,000 and 28,000 years ago. Neanderthals were short, stocky, and powerfully built. Their massive skull housed a brain somewhat larger than our own. They manufactured a variety of tools and hunted large mammals, which they probably ambushed and subdued in close combat. Early modern humans (*H. sapiens*) expanded out of Africa between 70,000 and 60,000 years ago. Then about 35,000 years ago, *H. sapiens* moved into the range of *H. neanderthalensis* in Europe and western Asia, so the two species must have interacted with one another. Neanderthals abruptly disappeared about 28,000 years ago. Many anthropologists believe it is likely that the Neanderthals were exterminated by these early modern humans. Scientists have been able to isolate large parts of the genome of *H. neanderthalensis* from recent fossils and to compare it with our own. These studies suggest little or no interbreeding be-

tween the two species while they occupied the same range in Europe and western Asia.

Early modern humans made and used a variety of sophisticated tools. They created the remarkable paintings of large mammals, many of them showing scenes of hunting, found in European caves. The animals depicted were characteristic of the cold steppes and grasslands that occupied much of Europe during periods of glacial expansion. Early modern humans also spread across Asia, reaching North America perhaps as early as 20,000 years ago, although the date of their arrival in the New World is still uncertain. Within a few thousand years, they had spread southward through North America to the southern tip of South America.

Humans developed complex language and culture

As our ancestors evolved larger brains, their behavioral capabilities increased, especially the capacity for language. Most animal communication consists of a limited number of signals, which refer mostly to immediate circumstances and are associated with charged emotional states induced by those circumstances. Human language is far richer in its symbolic character than other animal vocalizations. Our words can refer to past and future times and to distant places. We are capable of learning thousands of words, many of them referring to abstract concepts. We can rearrange words to form sentences with complex meanings.

The expanded mental abilities of humans enabled the development of a complex **culture**, in which knowledge and traditions are passed along from one generation to the next by teaching and observation. Cultures can change rapidly because genetic changes are not necessary for a cultural trait to spread through a population. Cultural norms, however, are not transferred automatically and must be deliberately taught to each generation.

Cultural transmission greatly facilitated the development and use of domestic plants and animals and the resultant conversion of most human societies from ones in which food was obtained by hunting and gathering to ones in which *pastoralism* (herding large animals) and *agriculture* provided most of the food. The development of agriculture led to an increasingly sedentary life, the growth of cities, greatly expanded food supplies, rapid increases in the human population, and the appearance of occupational specializations, such as artisans, shamans, and teachers.

33.5 RECAP

Grasping limbs with opposable digits distinguish primates from other mammals. Human ancestors developed bipedal locomotion and large brains.

- What are some major trends in primate evolution?
- Describe the differences between Old World and New World monkeys. **See p. 713**
- Do you understand how cultural evolution differs from genetic evolution? **See p. 716**

CHAPTER SUMMARY

33.1 What Is a Deuterostome?

- Deuterostomes vary greatly in adult form, but based on the distinctive patterns of early development they share and on phylogenetic analyses of gene sequences, they are judged to be monophyletic. There are far fewer species of deuterostomes than of protostomes, but many deuterostomes are large and ecologically important. **Review Figure 33.1, WEB ACTIVITY 33.1**

33.2 What Are the Major Groups of Echinoderms and Hemichordates?

- Echinoderms and hemichordates both have bilaterally symmetrical, ciliated larvae.
- Adult echinoderms have **pentaradial symmetry**. Echinoderms have an internal skeleton of calcified plates and a unique **water vascular system** connected to extensions called **tube feet**. **Review Figure 33.3**
- Hemichordate adults are bilaterally symmetrical and have a three-part body that is divided into a proboscis, collar, and trunk. They include the acorn worms and the pterobranchs. **Review Figure 33.5**

33.3 What New Features Evolved In the Chordates?

- Chordates fall into three principal subgroups: **cephalochordates**, **urochordates**, and **vertebrates**.
- At some stage in their development, all chordates have a dorsal hollow nerve cord, a post-anal tail, and a **notochord**. **Review Figure 33.6**
- Urochordates include the ascidians (sea squirts), the larvaceans, and the thaliaceans (salps). Cephalochordates are the lancelets, which live buried in the sand of shallow marine and brackish waters.
- The vertebrate body is characterized by a rigid internal skeleton, which is supported by a **vertebral column** that replaces the notochord, internal organs suspended in a coelom, a ventral heart, and an anterior skull with a large brain. **Review Figure 33.10**

- The evolution of jaws from gill arches enabled individuals to grasp large prey and, together with teeth, cut them into small pieces. **Review Figure 33.11**
- **Chondrichthyans** have skeletons of cartilage; almost all species are marine. The skeletons of **ray-finned fishes** are made of bone; these fishes have colonized all aquatic environments.

33.4 How Did Vertebrates Colonize the Land?

- Lungs and jointed appendages enabled vertebrates to colonize the land. The earliest split in the **tetrapod** tree is between the **amphibians** and the **amniotes** (reptiles and mammals).
- Most modern amphibians are confined to moist environments because they and their eggs lose water rapidly. **Review Figure 33.16, ANIMATED TUTORIAL 33.1**
- An impermeable skin, efficient kidneys, and an egg that could resist desiccation evolved in the amniotes. **Review Figure 33.17, WEB ACTIVITY 33.2**
- The major living **reptile** groups are the turtles, the lepidosaurs (tuataras, lizards, snakes, and amphisbaenians), and the archosaurs (crocodilians and birds). **Review Figure 33.18**
- **Mammals** are unique among animals in supplying their young with a nutritive fluid (milk) secreted by mammary glands. There are two primary mammalian clades: the prototherians (of which there are only five species) and the species-rich therians. The therian clade is further subdivided into the marsupials and the eutherians. **Review Table 33.1**

33.5 What Traits Characterize the Primates?

- Grasping limbs with opposable digits distinguish **primates** from other mammals. The prosimian clade includes the lemurs and lorises; the anthropoid clade includes monkeys, apes, and humans. **Review Figure 33.27**
- Hominid ancestors were terrestrial primates that developed efficient bipedal locomotion. In the lineage leading to *Homo*, brains became larger as jaws became smaller; the two events may have been developmentally linked. **Review Figure 33.31**

SEE WEB ACTIVITY 33.3 for a concept review of this chapter.

SELF-QUIZ

- Which of the following are *not* deuterostomes?
 - Acorn worms
 - Sea stars
 - Urochordates
 - Brachiopods
 - Lancelets
- The structure used by adult urochordates to capture food is a
 - pharyngeal basket.
 - proboscis.
 - lophophore.
 - mucus net.
 - radula.
- The pharyngeal gill slits of chordate ancestors functioned as sites for
 - uptake of oxygen only.
 - release of carbon dioxide only.
 - both uptake of oxygen and release of carbon dioxide.
 - removal of small prey from the water.
 - forcible expulsion of water to move the animal.
- A bony skeleton evolved in the most recent common ancestor of
 - gnathostomes.
 - vertebrates and hagfishes.
 - craniates and urochordates.
 - ray-finned fishes and sarcopterygians.
 - amniotes and amphibians.
- In most ray-finned fishes, lunglike sacs evolved into
 - pharyngeal gill slits.
 - true lungs.
 - coelomic cavities.
 - swim bladders.
 - none of the above

6. Many amphibians return to water to lay their eggs because
 - a. water is isotonic to egg fluids.
 - b. adults must be in water while they guard their eggs.
 - c. there are fewer predators in water than on land.
 - d. amphibians get their nutrition from water.
 - e. amphibian eggs quickly lose water and desiccate if their surroundings are dry.
7. The horny scales that cover the skin of reptiles prevent them from
 - a. using their skin as an organ of gas exchange.
 - b. sustaining high levels of metabolic activity.
 - c. laying their eggs in water.
 - d. flying.
 - e. crawling into small spaces.
8. Which statement about bird feathers is *not* true?
 - a. They are highly modified reptilian scales.
 - b. They provide insulation for the body.
 - c. They exist in two layers.
 - d. They help birds fly.
 - e. They are important sites of gas exchange.
9. Prototherians differ from other mammals in that they
 - a. do not produce milk.
 - b. lack body hair.
 - c. lay eggs.
 - d. live in Australia.
 - e. have a pouch in which the young are raised.
10. Bipedalism is believed to have evolved in the hominid lineage because bipedal locomotion is
 - a. more efficient than quadrupedal locomotion.
 - b. more efficient than quadrupedal locomotion and frees the forelimbs to manipulate objects.
 - c. less efficient than quadrupedal locomotion but frees the forelimbs to manipulate objects.
 - d. less efficient than quadrupedal locomotion, but bipedal animals can run faster.
 - e. less efficient than quadrupedal locomotion, but natural selection does not act to improve efficiency.

FOR DISCUSSION

1. In what animal groups has the ability to fly evolved? How do the structures used for flying differ among these animals?
2. Extracting suspended food from the water is a common mode of feeding among animals. Which groups contain species that extract prey from the air? Why is this mode of obtaining food so much less common than extracting prey from the water?
3. What risks and benefits are posed by large size?
4. Amphibians have survived and prospered for many millions of years, but today many species are disappearing, and populations of others are declining seriously. What features of their life histories might make amphibians especially vulnerable to the kinds of environmental changes now happening on Earth?
5. The body plan of most vertebrates is based on four appendages. What are the varied forms that these appendages take, and how are they used?
6. Compare the ways in which different animal lineages colonized the land. How were those ways influenced by the body plans of animals in the different groups?

ADDITIONAL INVESTIGATION

A mutation in the gene that encodes the myosin heavy chain (see Chapter 48) decreased the size of the jaw muscles in human ancestors. This mutation may have enabled a restructuring of

the cranium and larger brain size. How could we determine when this mutation arose in the phylogenetic history of the primates?

34

The Plant Body

The doomsday vault

Carved into a sandstone mountain, surrounded by permafrost on the Arctic island of Spitsbergen, Norway, the Svalbard vault is almost the size of a soccer field. It is stable enough to withstand a major earthquake, even though earthquakes are very unlikely at that location. It is high enough in elevation to remain above sea level even if all the polar ice caps were melted by global warming. A cooling system run on energy from local coal holds its interior at -18°C , and even if this system fails, insulation and the cold weather outside ensure that it will be weeks before the interior temperature rises. It is surrounded by a technologically advanced security system.

The 120 nations that participated in establishing this facility agree that the vault at Svalbard needs to be very secure. Does it contain gold bars? No, it contains seeds, the carriers of plant embryos. As photosynthesizers, plants are the keys to the biosphere. They have also been the mainstay of human survival. Of the approximately 300,000 species of plants, humans depend directly on only a few dozen. You can name some of them—wheat, rice, and corn for food; cotton for fiber; forest trees for paper. Mil-

lennia ago, humans selected certain plants growing in the wild for their own uses and began to cultivate them. After many generations of artificial selection, the plants looked very distinct from their wild relatives. In addition, because these plants were grown in different environments and for different purposes, different genetic strains of plants came into being.

By the twentieth century, there were thousands of genetically distinct varieties of crop plants—an amazing 100,000 varieties of rice alone. A crop plant variety, also called a *cultivar*, is a member of a species that has been artificially selected for one or more of its useful traits. Although only a small number of these varieties are in use at a given time, plant biologists realized that the genetic diversity of the remaining species should not be allowed to disappear. Because plant seeds are generally quite hardy

The Svalbard Global Seed Vault The vault is located 390 feet inside a sandstone mountain on the Norwegian island of Spitsbergen, about 700 miles from the North Pole. The location was chosen for secure, long-term storage of seeds because earthquakes are unlikely there and the ground is permeated with permafrost.

Seed vaults Airlock doors Office and handling area Sleeve to protect tunnel from erosion and climactic changes Tunnel entrance Bridge

Plant in Storage Every seed contains an embryo with the means to create all parts of the plant body.

and relatively easy to store for long periods, seed banks were established. One of the largest is the National Seed Bank in Colorado, USA, where over half a million plant varieties are stored as seeds. When a plant breeder wants to develop a new genetic strain of corn—for example, one that is naturally resistant to a fungal disease—samples of seed can be withdrawn from the seed bank and used for cross-breeding.

The newly established seed vault in Norway is not so much a bank as a safe deposit box. Seed banks from all over the world are depositing samples of seeds for safe-keeping in the vault in the event of a disaster that might destroy the seed banks. Such destruction does happen; for example, two valuable seed banks in Iraq and Afghanistan were destroyed during recent wars. As the existence of the Svalbard vault clearly demonstrates, seeds, and the plants that they form, are vital to humanity.

IN THIS CHAPTER we will examine plant structure at the levels of cells, tissues, organs, and tissue systems. We will see how that structure arises from clusters of undifferentiated cells, called meristems, that permit continuous growth throughout a plant's lifetime. The chapter concludes with a look at how humans have altered plant form through crop domestication.

CHAPTER OUTLINE

- 34.1** What Is the Basic Body Plan of Plants?
- 34.2** How Does the Cell Wall Support Plant Growth and Form?
- 34.3** How Do Plant Tissues and Organs Originate?
- 34.4** How Do Meristems Build a Continuously Growing Plant Body?
- 34.5** How Has Domestication Altered Plant Form?

34.1 What Is the Basic Body Plan of Plants?

Plants live by harvesting energy from sunlight and by collecting water and mineral nutrients from the soil. These resources, however, are incredibly sparse in the environment, so plants face the challenge of collecting them from huge areas, both above and below ground. Another challenge plants face is their inability to move. Plants cannot relocate themselves from, say, a dry, shady location to one that is wet and sunny.

The plant body plan allows plants to respond to these challenges. Stems, leaves, and roots enable plants anchored to one spot to capture scarce resources effectively, both above and below the ground. More important, to compensate for their inability to move, plants can grow throughout their lifetimes. Thus, while plants cannot move to a new water source or a new sunny clearing, they can respond to environmental cues by redirecting their growth to exploit opportunities that arise in their immediate environment.

In Chapters 28 and 29 we saw how modern plants arose from aquatic ancestors, giving rise to simple land plants and then vascular plants. Despite their obvious differences in size and form, all vascular plants have essentially the same simple structural organization. This chapter describes the basic architecture of the largest group of vascular plants, the angiosperms (flowering plants), and shows how so much diversity can literally grow out of such a simple basic form.

As we saw in Figure 29.1, angiosperms first appeared about 140 million years ago, radiated explosively over a period of about 60 million years, and became the dominant plant life on this planet. There are over 250,000 angiosperm species today. Flowers, the angiosperms' devices for sexual reproduction and their main distinguishing feature, consist of modified leaves and stems and will be considered in detail in Section 38.1. In this chapter we'll focus on the three kinds of vegetative (nonsexual) organs angiosperms possess: roots, stems, and leaves. Each of these vegetative organs can be understood in terms of its structure. By *structure* we mean both its overall form, called its *morphology*, and its internal component cells and tissues and their arrangement, known as its *anatomy*.

Plant organs are organized into two systems (**Figure 34.1**):

- The **root system** anchors the plant in place, absorbs water and dissolved minerals, and stores the products of photosynthesis from the shoot system. The extreme branching of plant roots and their high surface area-to-volume ratios allow them to absorb water and mineral nutrients from the soil efficiently.

34.1 Vegetative Organs and Systems The basic plant body plan, with root and shoot systems, and the principal vegetative organs are similar in eudicots and monocots, although there are also some differences between the two clades.

- The **shoot system** of a plant consists of the stems, leaves, and flowers. Broadly speaking, the **leaves** are the chief organs of photosynthesis. The **stems** hold and display the leaves to the sun and provide connections for the transport of materials between roots and leaves.

As we saw in Section 29.3, most angiosperms belong to one of two major clades. *Monocots* are generally narrow-leaved flowering plants such as grasses, lilies, orchids, and palms. *Eudicots* are broad-leaved flowering plants such as soybeans, roses, sunflowers, and maples. These two clades, which account for 97 percent of flowering plant species, differ in several important basic characteristics (see Figure 34.1). Let's take a closer look at how the root and shoot systems are elaborated in eudicots and monocots.

The root system anchors the plant and takes up water and dissolved minerals

Water and minerals enter most plants through the root system, which is located in the soil. Because light does not penetrate the soil, roots typically lack the capacity for photosynthesis. Although hidden from view, the root system is often larger than the visible shoot system. For example, the root system of a 4-month-old winter rye plant (*Secale cereale*) was found to be 130 times larger than the shoot system, with almost 13 million branches that had a cumulative length of over 500 km!

The **shoot system** consists of stems and leaves, in which photosynthesis takes place.

The **root system** anchors the plant and provides water and nutrients for the shoot system.

The root system of angiosperms originates in an embryonic root called the *radicle*. From this common starting point, the root systems of monocots and eudicots develop differently. Following seed germination, the radicle of most eudicots develops as a primary root (called the **taproot**), which extends downward by tip growth and outward by initiating **lateral roots**. The taproot and the lateral roots form a **taproot system**, which can take a variety of forms. For example, the taproot itself often functions as a nutrient storage organ, as in carrots (*Daucus carota*), sugar beets (*Beta vulgaris*), and sweet potato (*Ipomoea batatas*) (**Figure 34.2A**).

In contrast, the primary root of monocots (and some eudicots) is short-lived. Because they originate from the stem at

(B) Fibrous root system

(C) Prop roots

34.2 Root Systems of Eudicots and Monocots

(A) The taproot systems of eudicots, such as carrots, sugar beets, and sweet potato, contrast with (B) the fibrous root system of a leek and (C) the adventitious prop roots of corn.

ground level or below, the roots of a typical monocot are called **adventitious** (“arriving from outside”) **roots**, and they form a **fibrous root system** composed of numerous thin roots that are all roughly equal in diameter (**Figure 34.2B**). Many fibrous root systems have a large surface area for the absorption of water and minerals. A fibrous root system clings to soil very well. The fibrous root systems of grasses, for example, may protect steep hillsides where runoff from rain would otherwise cause erosion.

In some monocots—corn, banyan trees, and some palms, for example—adventitious roots function as props to help support the shoot. **Prop roots** are critical to these plants, which, unlike most eudicot tree species, are unable to support aboveground growth through the thickening of their stems (**Figure 34.2C**).

The stem supports leaves and flowers

The central function of stems is to elevate and support the photosynthetic organs (leaves) as well as the reproductive organs (flowers).

Unlike roots, stems bear buds of various types. A **bud** is an undeveloped shoot that may or may not develop further to produce additional branches or leaves. Shoots are composed of repeating modules called **phytomers** (see Figure 34.1). A phytomer includes one or more leaves, which are attached to the stem at a **node**; an **internode** (the interval of stem between two nodes); and one or more **axillary buds**, which form in the angle (*axil*) where each leaf meets the stem. The axillary buds are distinguished from the bud at the end of a stem or branch, which

is called a **terminal bud**. If it becomes active, an axillary bud can develop into a new *branch*, or extension of the shoot system. The arrangement of leaves along the stem (called the *phyllotaxy*) is often characteristic of the plant species.

Various modifications of stems are seen in nature. The *tuber* of a potato, for example—the part of the plant eaten by humans—is not a root, but rather an underground stem. The “eyes” of a potato are depressions containing axillary buds—in other words, a sprouting potato is just a branching stem (**Figure 34.3A**). Many desert plants have enlarged, water-retaining stems (**Figure 34.3B**). The *runners* of strawberry plants are horizontal stems from which roots grow at frequent intervals (**Figure 34.3C**). If the links between the rooted portions are broken, independent plants can develop on each side of the break—a form of vegetative (asexual) reproduction (see Section 38.3).

Although most young stems are green and capable of photosynthesis, leaves are the principal sites of photosynthesis in most plants. There are, however, exceptions: for example, photosynthesis occurs primarily in the stem of the barrel cactus featured in Figure 34.3B.

Leaves are the primary sites of photosynthesis

In gymnosperms and in most flowering plants, the leaves are responsible for most of the plant’s photosynthesis. Leaves are marvelously adapted for gathering light. Typically, the **blade** of a leaf is a thin, flat structure attached to the stem by a stalk called a **petiole** (see Figure 34.1). In many plants, the leaf blade is held by its petiole at an angle almost perpendicular to the rays of the sun. This orientation, with the leaf surface facing the sun, maximizes the amount of light available for photosynthesis. Some leaves track the sun over the course of the day, moving so that they constantly face it.

In some plant species, leaves are highly modified for special functions. For example, some modified leaves serve as storage depots for energy-rich molecules, as in the bulbs of onions. In other species, such as succulents, the leaves store water. The protective spines of cacti are modified leaves (see Figure 34.3B). Other plants, such as peas, have modified portions of leaves called *tendrils* that support the plant by wrapping around other structures or plants.

34.3 Modified Stems (A) A potato is a modified stem called a tuber; the sprouts that grow from its eyes are shoots, not roots. (B) The stem of this barrel cactus is enlarged to store water. Its highly modified leaves serve as thorny spines. Most of this plant’s photosynthesis occurs in the stem. (C) The runners of beach strawberry are horizontal stems that produce roots and shoots at intervals. Rooted portions of the plant can live independently if the runner is cut.

34.1 RECAP

The basic vegetative plant body plan consists of a **root system** and a **shoot system**. Stems and leaves, which are part of the shoot system, may be highly modified.

- How do plants explore their environment for resources even though they cannot move? **See p. 720**
- How would you distinguish between a piece of a root and a piece of a shoot? **See pp. 721–722**
- What are the differences between the root systems of eudicots and monocots? **See p. 721 and Figure 34.2**

Our closer examination of the plant body begins with its fundamental building blocks: its cells. Although plant cells share many features with animal cells, including nucleus, mitochondria, plasma membrane, and Golgi apparatuses (see Section 5.3), it is their distinguishing features that we will consider in this chapter.

34.2 How Does the Cell Wall Support Plant Growth and Form?

Plant cells have the essential organelles that are shared by all eukaryotes (see Figure 5.7), but certain additional structures and organelles distinguish them from many other eukaryotic cells:

- *Chloroplasts* or other plastids
- A central *vacuole*
- Rigid, cellulose-containing *cell walls*

As mentioned earlier, plant form is dictated in part by the need to collect energy for photosynthesis, which takes place in the chloroplasts (see Section 10.2). Less obvious is the importance of vacuoles and cell walls in determining plant form.

Cell walls and vacuoles help determine plant form

Mature plant cells usually contain a single **central vacuole**, which may account for a staggering 90 percent of its volume (see Figure 5.16). The vacuole is a watery sac containing a high concentration of solutes, including enzymes, amino acids, and sugars produced by photosynthesis. Many of these solutes are pumped into the vacuole by transporter proteins located in the **tonoplast**, the vacuolar membrane. This active accumulation of solutes provides the osmotic force for water uptake into the vacuole (as we will see in Section 35.1). As the vacuole expands, it exerts turgor pressure on the cell wall (see Figure 6.10). Turgor pressure not only keeps plants upright, but also is essential for plant growth.

The structure of cell walls allows plants to grow

Cell walls are a feature of bacteria, fungi, algae, and plants. They serve to regulate cell volume, determine cell shape, and protect the cell contents. Plant cell walls have unique features that derive from their chemical composition. Furthermore, most of the

34.4 Plant Cell Wall Formation Plant cell walls form as the final step in cell division.

carbon in terrestrial ecosystems is sequestered in the molecules that make up plant cell walls. As such, it is worth taking a closer look at their formation and structure.

The cytokinesis of a plant cell is completed when the two daughter cells are separated by a cell plate (**Figure 34.4**; see also Figure 11.13). A glue-like substance that forms within the cell plate constitutes the **middle lamella**, which persists as a thin layer between the walls of the two daughter cells. Each daughter cell then secretes three types of polysaccharides to form a **primary cell wall** (**Figure 34.5**):

- *Cellulose* is made up of linear polymers of thousands of glucose molecules (see Figure 3.16) that are organized into bundles of **microfibrils**, which form a lattice within the cell wall.
- *Hemicelluloses* are highly branched polysaccharide chains that extensively cross-link the cellulose microfibrils.

- *Pectins* are heterogeneous polysaccharides that are more soluble than the other components. (Pectin is responsible for the gel properties of fruit jams and jellies.)

This secretion and deposition of polysaccharides continues as the cell expands to its final size.

One of the major ways that plants grow is by cell expansion. Some cells can increase in volume by 100,000 to 1,000,000 times! How can a plant cell expand when it is surrounded by a rigid cell wall? Recall that osmotic pressure leads to expansion of the central vacuole, which exerts turgor pressure on the cell wall. The living contents of the plant cell—that is, the plasma membrane and everything contained within it—constitute the **protoplast**. The cell wall responds to the increasing size of the protoplast by loosening the linkages between cellulose microfibrils. A class of proteins that reside in the cell wall, called *expansins*, are

thought to assist in cell wall loosening by disrupting the non-covalent bonds that link the hemicelluloses and pectins to the cellulose microfibrils. To prevent the cell wall from becoming too thin (so that it does not blow out like an overinflated balloon), new cell wall components are synthesized and integrated.

When cell expansion stops, some types of plant cells deposit one or more additional cellulosic layers to form a thick **secondary cell wall** internal to the primary cell wall (see Figure 34.4). Secondary cell walls provide the mechanical support that allows some plants to produce large stems. Like the primary wall, the secondary wall contains layers of ordered cellulose microfibrils. However, rather than being embedded in pectins, the microfibrils are embedded in a remarkable substance called **lignin**. When secondary walls become lignified, the primary wall and even the middle lamella are also lignified. Lignin is a complex, carbon-containing polymer that forms a hydrophobic matrix that is strong, waterproof, and resistant to digestion by animals. After cellulose, lignin is the most abundant biological polymer on Earth, accounting for 20–35 percent of the dry weight of wood.

Scientists have just begun to dissect the complexity and dynamics of plant cell walls. Their basic components—celluloses, hemicelluloses, pectins, and lignins—are classes of molecules that can be built from several components and modified in a variety of ways. Thus the composition of plant cell walls varies among different types of plant cells. In addition, the composition of the wall of a single plant cell may not be uniform. For example, it is possible that directional growth reflects the deposition of cell wall components that are more easily loosened at one end of the cell. One measure of how much remains unknown is the finding that the genome of the tiny plant *Arabidopsis thaliana* contains more than a thousand genes related to cell wall biosynthesis, the functions of only a small fraction of which are currently known.

Building a plant body requires cooperation between groups of cells. Although they may appear to be isolated by their cell walls, plant cells interact in two ways to build and maintain a complex organism. First, in most areas, the cell wall is permeable to water and mineral ions and allows small molecules to

34.6 Plasmodesmata (A) An electron micrograph shows that plant cell walls are traversed by plasmodesmata (dark stain). The green objects are cytoskeletal microtubules (see Section 5.3). (B) Plasmodesmata connect the endoplasmic reticula of adjacent plant cells.

reach the plasma membrane. Second, the endoplasmic reticula (ER) of adjacent cells are connected by cytoplasm-filled canals called **plasmodesmata** that pass through the primary wall, allowing direct communication between plant cells (**Figure 34.6**). A single plant cell may be connected to its neighbors by up to a thousand plasmodesmata, which permit the movement of proteins and even RNAs from cell to cell. Some of these plasmodesmata are formed during cytokinesis when the cell plate is deposited.

Evolution has given some plant viruses a clever way to use this intercellular highway to their advantage. Tobacco mosaic virus (TMV), for example, encodes a protein called movement protein, or MP, that helps the virus spread throughout the plant. Without MP, the RNA genome of TMV cannot move from cell to cell. However, in some unknown way, the MP-RNA complex is able to move easily from cell to cell via plasmodesmata.

34.2 RECAP

Plants synthesize a primary cell wall during cell division and cell expansion. In some types of plant cells, a secondary cell wall, reinforced with lignin, forms within the primary cell wall when cell expansion stops, providing additional structural support.

- What are the components of plant cell walls in which most of the carbon in terrestrial ecosystems is sequestered? See **pp. 723–724**
- How do plant cell walls accommodate an expanding protoplast? See **p. 724 and Figure 34.5**
- Describe two features that allow plant cells to interact with one another. See **pp. 724–725 and Figure 34.6**

That there are dramatic differences between plant and animal body plans should not be surprising, since the multicellular forms of plants and animals evolved independently from entirely distinct protist ancestors (see Figure 1.10). In the next two sections we will look more closely at the unique characteristics of the plant body by following its development from a zygote into an adult.

34.3 How Do Plant Tissues and Organs Originate?

How does a single plant cell (a zygote) divide and grow into an organism like a redwood tree, which may grow continuously for over a thousand years to a height of over 100 meters? While still in the seed, a plant establishes the basic body plan for its mature form.

Two patterns that contribute to the plant body plan are established in the embryo:

- The **basal–apical axis**: the arrangement of cells and tissues along the main axis from root to shoot
- The **radial axis**: the concentric arrangement of the tissue systems

In addition, two clusters of undifferentiated cells form at the tips of the embryonic root and shoot. These clusters, called **meristems** (from the Greek *merizein*, “to divide”), will orchestrate all postembryonic development and allow the plant to form organs throughout its lifetime.

Both axes and meristems are best understood in developmental terms. We focus here on embryogenesis (embryo formation) in the model eudicot *Arabidopsis thaliana*, in which the process has been most intensively studied.

The first step in the formation of a plant embryo is a mitotic division of the zygote that gives rise to two daughter cells (**Figure 34.7, step 1**). These two cells face different fates (see Section 19.4). An asymmetrical (uneven) distribution of cytoplasm within the zygote causes one daughter cell to produce the embryo proper and the other daughter cell to produce a supporting structure, the **suspensor** (**Figure 34.7, step 2**). This asymmetrical division of the zygote establishes polarity as well as the basal–apical axis of the new plant. A long, thin suspensor and a more spherical or globular embryo are distinguishable after just four mitotic divisions. The suspensor soon ceases to elongate.

In eudicots, the initially globular embryo develops into the characteristic **heart stage** as the **cotyledons** (“seed leaves”) start to grow (**Figure 34.7, step 3**). Further elongation of the cotyledons and of the main axis of the embryo gives rise to the **torpedo stage**, during which some of the internal tissues begin to differentiate (**Figure 34.7, step 4**). Between the cotyledons is the **shoot apical meristem**; at the other end of the axis is the **root apical meristem**. Each of these regions contains undifferentiated cells that will continue to divide to give rise to the organs developing over the life of the plant.

34.7 Plant Embryogenesis The basic body plan of the model eudicot (*Arabidopsis thaliana*) is established in several steps. By the heart stage, the three tissue systems are established: the dermal (gold), ground (light green), and vascular (blue) tissue systems.

By the end of embryogenesis, the radial axis of the plant has also been established. The embryonic plant contains three tissue systems, arranged concentrically, that will give rise to the tissues of the adult plant body.

The plant body is constructed from three tissue systems

A **tissue** is an organized group of cells that have features in common and that work together as a structural and functional unit. In plants, tissues, in turn, are grouped into **tissue systems**. Despite their structural diversity, all vascular plants are constructed from three tissue systems: *dermal*, *vascular*, and *ground*. These three tissue systems are established during embryogenesis and ultimately extend throughout the plant body in a concentric arrangement (**Figure 34.8**). Each tissue system has distinct functions and is composed of different mixtures of cell types.

DERMAL TISSUE SYSTEM The **dermal tissue system** forms the *epidermis*, or outer covering, of a plant, which usually consists of a single cell layer. The stems and roots of woody plants develop a dermal tissue called *periderm*.

During plant development, the epidermis must grow to cover the expanding plant body. The cells of the epidermis are small and round and usually have a small central vacuole or none at all. Once cell division ceases in the epidermis of an organ, the epidermal cells expand. Some epidermal cells differentiate to form one of three specialized structures:

- *Stomatal guard cells*, which form stomata (pores) for gas exchange in leaves
- *Trichomes*, or leaf hairs, which provide protection against insects and damaging solar radiation
- *Root hairs*, which greatly increase root surface area, thus providing more surface for the uptake of water and mineral nutrients.

Aboveground epidermal cells secrete a protective extracellular **cuticle** made of *cutin* (a polymer composed of long chains of fatty acids), a complex mixture of waxes, and cell wall polysaccharides. The cuticle limits water loss, reflects potentially damaging solar radiation, and serves as a barrier against pathogens.

GROUND TISSUE SYSTEM Virtually all the tissue lying between dermal tissue and vascular tissue in both shoots and roots is part of the **ground tissue system**, which therefore makes up most of the plant body. Ground tissue functions primarily in storage, support, and photosynthesis. To fulfill these diverse functions, ground tissues incorporate three cell types that are classified according to their cell wall structure: *parenchyma*, *collenchyma*, and *sclerenchyma*.

The most common cell type in plants is the **parenchyma** cell (**Figure 34.9A**). Parenchyma cells have large vacuoles and thin walls consisting only of a primary wall and the shared middle

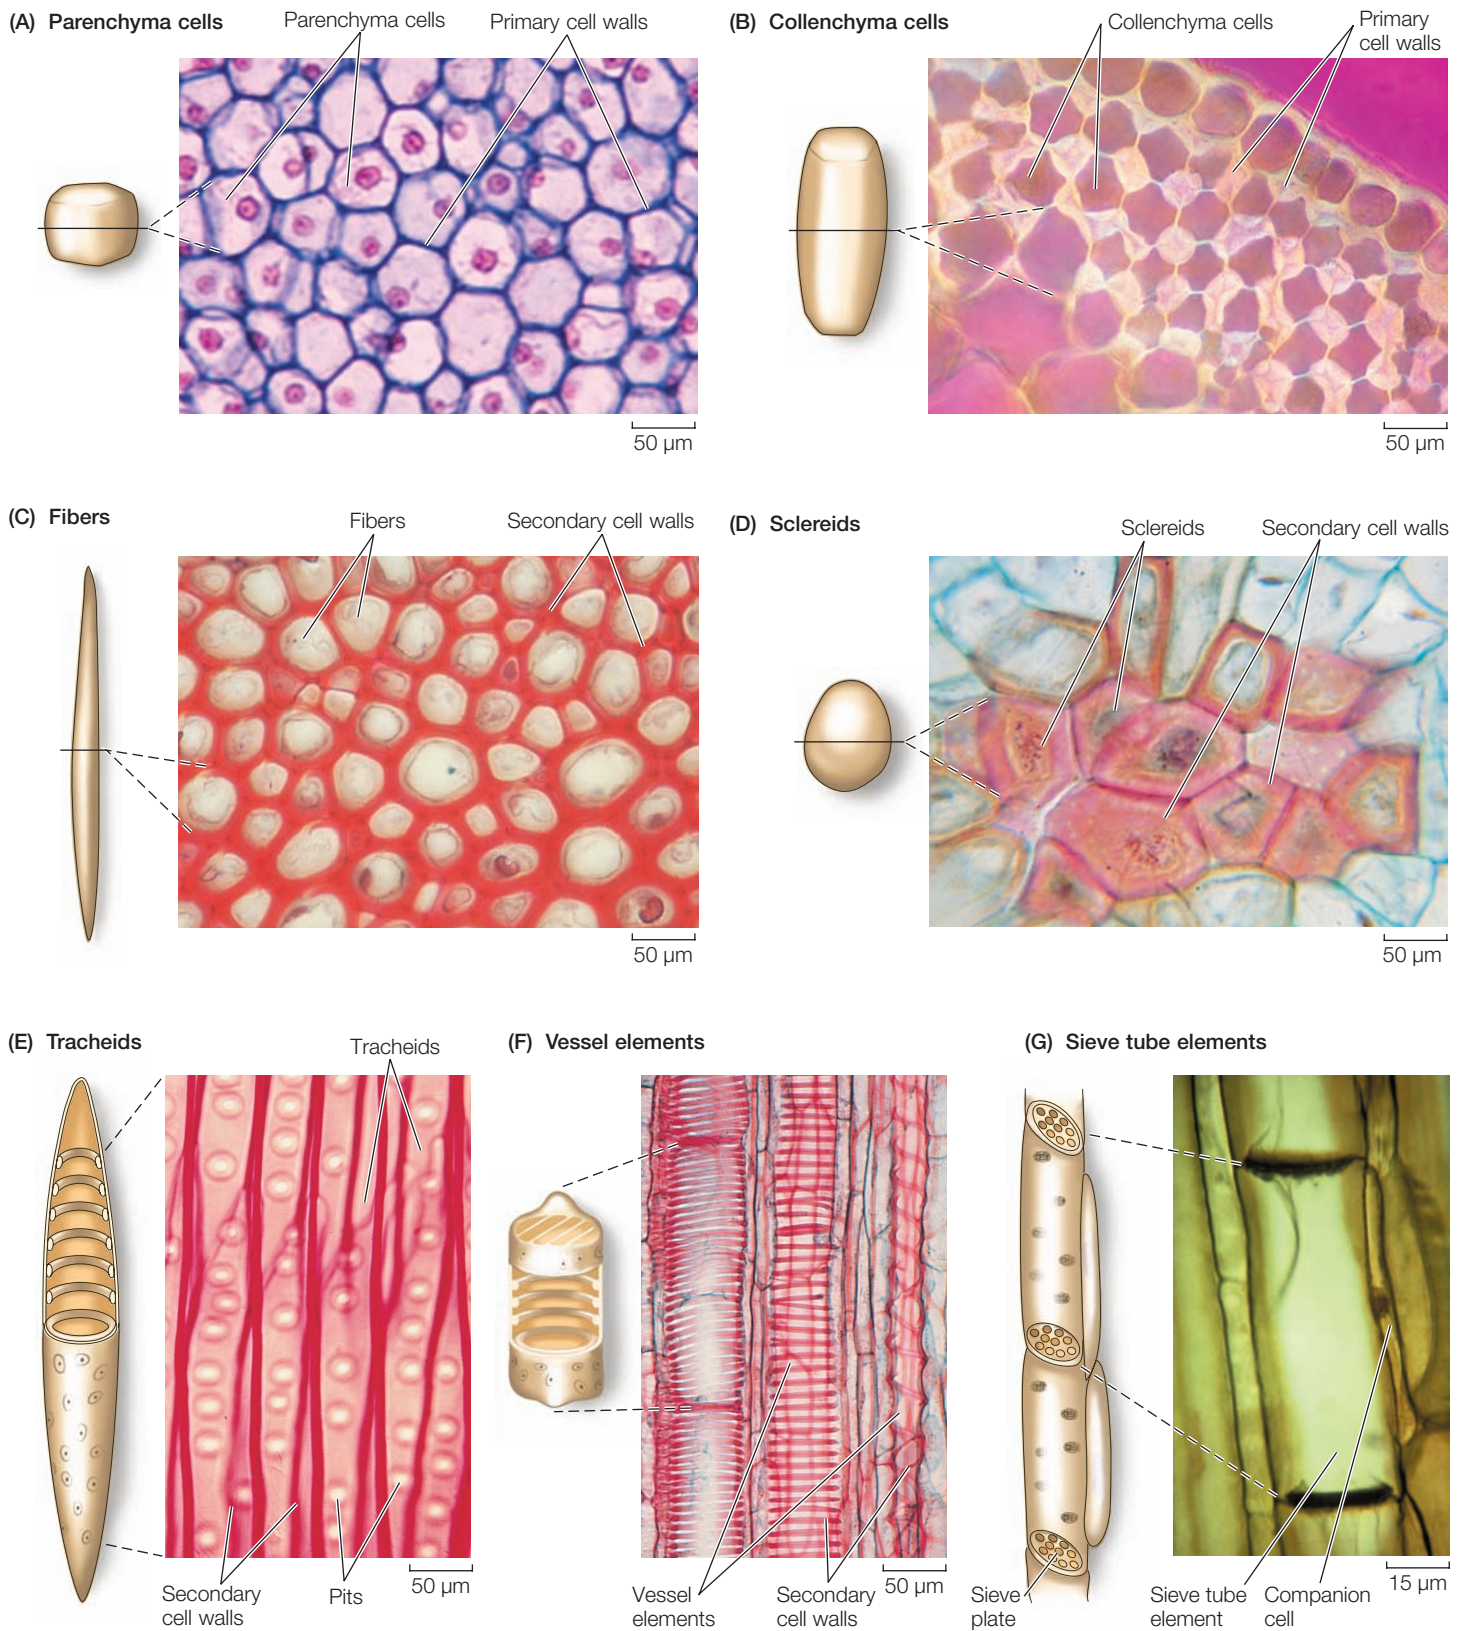

34.8 Three Tissue Systems Extend Throughout the Plant Body

The arrangement shown here is typical of eudicots, but the three tissue systems are continuous in the bodies of all vascular plants.

lamella. They play important roles in photosynthesis (in leaves) and in the storage of, for example, protein (in fruits) and starch (in roots). Many retain the capacity to divide and hence may give rise to new cells, as when a wound results in cell proliferation.

Collenchyma cells resemble parenchyma cells that have been modified to provide flexible support. Their primary walls are characteristically thick at the corners of the cells (**Figure 34.9B**). Collenchyma cells are generally elongated. In these cells, the primary wall thickens in part due to the deposition of pectins, but no secondary wall forms. Collenchyma provides support to leaf petioles, nonwoody stems, and growing organs. Tissue made of collenchyma cells is flexible, permitting stems and petioles to sway in the wind without snapping. The familiar “strings” in celery consist primarily of collenchyma cells.

Sclerenchyma cells have thickened secondary walls that perform their major function: support. Many sclerenchyma cells undergo programmed cell death (apoptosis; see Section 11.6) after lignifying their cell walls, and thus perform their supporting function when dead. There are two types of sclerenchyma cells: elongated **fibers** and variously shaped **sclereids**. Fibers provide relatively rigid support to wood and other parts of the plant, in which they are often organized into bundles (**Figure 34.9C**). The bark of trees owes much of its mechanical strength to long fibers. Sclereids may pack together densely, as in a nut’s shell or in some seed coats (**Figure 34.9D**). Isolated clumps of sclereids, called *stone cells*, in pears and some other fruits give them their characteristic gritty texture.

34.9 Plant Cell Types (A) Parenchyma cells in the petiole of *Coleus*. Note the thin, uniform cell walls. (B) Collenchyma cells make up the five outer cell layers of this spinach leaf vein. Their walls are thick at the corners of the cells and thin elsewhere. (C) Sclerenchyma: fibers in a sunflower stem (*Helianthus*). The thick secondary walls are stained red. (D) Sclerenchyma: sclereids. The extremely thick secondary walls of sclereids

are laid down in layers. They provide support and a hard texture to structures such as nuts and seeds. (E, F) Tracheary elements: (E) Tracheids in pinewood. The thick secondary walls are stained dark red. (F) Vessel elements in the stem of a squash. The secondary walls are stained red; note the different patterns of thickening, including rings and spirals. (G) Sieve tube elements and companion cells in the stem of a cucumber.

VASCULAR TISSUE SYSTEM The **vascular tissue system** is the plant's plumbing or transport system—the distinguishing feature of vascular plants. Its two constituent tissues, the xylem and phloem, distribute materials throughout the plant. The **xylem** distributes water and mineral ions taken up by the roots to all the cells of the stems and leaves. **Phloem**, as a result of its cellular complexity, can perform a variety of functions, including transport, support, and storage. All the living cells of the plant body require a source of energy and chemical building blocks. The phloem meets these needs by transporting carbohydrates from sites of production (called *sources*, primarily leaves) to sites of utilization or storage (called *sinks*, such as growing tissue, storage tubers, and developing flowers).

Let's take a closer look at the structure of the diverse cell types that make up these vascular tissues. In Chapter 35 we will see how they transport water and materials throughout the plant body.

Cells of the xylem transport water and dissolved minerals

Xylem contains conducting cells called **tracheary elements**, which undergo apoptosis before assuming their function of transporting water and dissolved minerals. There are two types of tracheary elements: *tracheids* and *vessel elements*. **Tracheids** are spindle-shaped cells, found in gymnosperms and other vascular plants, that are evolutionarily more ancient than vessel elements (**Figure 34.9E**). When the protoplast disintegrates upon cell death, water and minerals can move with little resistance from one tracheid to its neighbors by way of *pits*, interruptions in the secondary wall that leave the primary wall unobstructed.

Flowering plants evolved a water-conducting system made up of *vessels*, formed from individual cells, called **vessel elements**, that are laid down end-to-end. Vessel elements have pits in their cell walls, as do tracheids, but are generally larger in diameter than tracheids. Vessel elements secrete lignin into their secondary walls, then partially break down their end walls before undergoing apoptosis. The result is a continuous hollow tube consisting of many vessel elements, providing an open pipeline for water conduction (**Figure 34.9F**). In the course of angiosperm evolution, vessel elements have become shorter, and their end walls have become less and less obliquely oriented and less obstructed, presumably increasing the efficiency of water transport through them. The xylem of many angiosperms includes tracheids as well as vessel elements.

Cells of the phloem transport the products of photosynthesis

The transport cells of the phloem, unlike those of the mature xylem, are living cells. In flowering plants, the characteristic cells of the phloem are **sieve tube elements** (**Figure 34.9G**). Like vessel elements, these cells meet end-to-end. They form long *sieve tubes*, which transport carbohydrates and many other materials from their sources to tissues that consume or store them. In plants with mature leaves, for example, products of photosynthesis move from leaves to root tissues.

Unlike vessel elements, which break down their end walls, sieve tube elements contain plasmodesmata in their end walls that enlarge to form pores. The result is end walls that look like sieves, called *sieve plates*. Although the sieve tube elements remain alive, some components of the protoplast break down. They are closely connected to *companion cells* that retain all their organelles and function as a “life support system” for the sieve tube elements.

34.3 RECAP

Plant embryos have an embryonic root and shoot containing three concentric tissue systems: dermal, ground, and vascular. These tissue systems carry out different functions through their unique combinations of specialized cell types.

- What distinguishes the three tissue systems in terms of their location and functions? **See pp. 726–728 and Figure 34.8**
- What structural differences make tissues made of collenchyma cells more flexible than those consisting primarily of sclerenchyma cells? **See p. 726**
- Outline the differences between tracheids and vessel elements. **See p. 728 and Figure 34.9**

By the end of embryogenesis, the plant embryo is encased in a seed and is ready to germinate. We will return to seeds and their germination in the chapters that follow. For now, let's consider the beginning of life as faced by plants and see how the cells and tissues we have just described allow the embryo to build an adult plant body.

34.4 How Do Meristems Build a Continuously Growing Plant?

As noted at the beginning of this chapter, plants and animals develop and function differently. While animals use their mobility to forage for food, plants are sessile and must collect scarce resources from above and below ground by growing. Plants thus grow in two directions—toward sunlight, and toward water and dissolved minerals in the soil—through the growth of shoots and roots, respectively.

All parts of the animal body grow as an individual develops from embryo to adult, but in most animals this growth is **determinate**—that is, the growth of the individual and all its parts ceases when the adult state is reached. Determinate growth is also characteristic of some plant organs, such as leaves, flowers, and fruits. The growth of shoots and roots, however, is a lifelong process. Such open-ended growth is called **indeterminate**.

Plants increase in size through primary and secondary growth

Plants increase their surface area above and below ground by growing. All plants experience **primary growth**, which is characterized by the lengthening of roots and shoots and by the pro-

liferation of new roots and shoots through branching. In addition, many gymnosperms and eudicots, especially trees, experience **secondary growth**, by which they increase in girth.

Primary and secondary growth lead to distinctive traits in the plant body. Primary growth develops what is called the **primary plant body**, while secondary growth develops the **secondary plant body**. All seed plants have a primary plant body, which consists of all the *nonwoody* parts of the plant. Many herbaceous plants—monocots in particular—consist entirely of a primary plant body. *Woody* plants, such as trees and shrubs, have, in addition to the primary plant body, a secondary plant body consisting of wood and bark. As the tissues of the secondary plant body are laid down, the stems and roots thicken. The secondary plant body continues to grow and thicken throughout the life of the plant. The primary plant body also continues to grow, lengthening and branching the shoot and root systems and forming new leaves.

A hierarchy of meristems generates the plant body

Meristems, as we have seen, are localized regions of undifferentiated cells that are the source of all new organs in the adult plant. Even before seed germination, the plant embryo has two meristems: a shoot apical meristem at the end of the embryonic shoot, and a root apical meristem near the end of the embryonic root (see Figure 34.7).

Meristematic cells are small and closely packed, with very small central vacuoles and a very thin primary cell wall. Meristematic cells are undifferentiated and forever young, retaining the ability to produce new cells indefinitely. The cells that perpetuate the meristems, called **initials**, are comparable to animal stem cells (discussed in Section 19.2). When an initial divides, one daughter cell develops into another meristem cell the size of its parent, while the other daughter cell differentiates into a more specialized cell.

While the plant embryo experiences primary growth through the activities of the root and shoot apical meristems, growth of the adult plant reflects the activity of additional meristem types. Our discussion of postembryonic plant growth begins with a closer look at how the adult plant grows throughout its lifetime and the critical role of meristems in that growth.

Two types of meristems contribute to the growth and development of the adult plant (**Figure 34.10**):

- **Apical meristems** orchestrate primary growth, giving rise to the primary plant body. This growth is characterized by cell division followed by cell enlargement (vertical elongation).
- **Lateral meristems** orchestrate secondary growth. Two lateral meristems, *vascular cambium* and *cork cambium*, contribute to the secondary plant body.

34.10 Apical and Lateral Meristems Apical meristems produce the primary plant body, lengthening it; lateral meristems produce the secondary plant body, thickening it.

Indeterminate primary growth originates in apical meristems

Because apical meristems can perpetuate themselves indefinitely, a shoot or root can continue to lengthen and grow indefinitely; in other words, growth of the shoot or root is indeterminate. Primary growth leads to elongation of shoots and roots and formation of organs (see Figure 34.10). All plant organs arise ultimately from cell divisions in apical meristems, followed by cell expansion and differentiation. Several types of apical meristems play roles in organ formation:

- *Shoot apical meristems* supply the cells that extend stems and branches, allowing more leaves to form and photosynthesize. Apical meristems that form leaves are called *vegetative meristems*. Flowers are formed by apical meristems that become *inflorescence meristems* (see Section 38.2 for more on floral development).
- *Root apical meristems* supply the cells that extend roots, enabling the plant to penetrate and explore the soil for water and minerals.

Apical meristems in both the shoot and the root give rise to a set of cylindrical **primary meristems**, which produce the tissues of the primary plant body. From the outside to the inside of the root or shoot, which are both cylindrical organs, the primary meristems are the **protoderm**, the **ground meristem**, and the **procambium**. These meristems, in turn, give rise to the three tissue systems:

Because meristems can continue to produce new organs throughout the lifetime of the plant, the plant body is much more variable in form than the animal body, which produces each organ only once. To see how meristems function, let's look more closely at how the root apical meristem produces the root system.

The root apical meristem gives rise to the root cap and the root primary meristems

The root apical meristem produces all the cells that contribute to growth in the length of a root (**Figure 34.11A**). Some of the daughter cells from the apical (tip) end of the root apical meristem contribute to a **root cap**, which protects the delicate growing region of the root as it pushes through the soil. The root cap secretes a mucopolysaccharide (slime) that acts as a lubricant. Even so, the cells of the root cap are often damaged or scraped away and must therefore be replaced constantly. The root cap

is also the structure that detects the pull of gravity and thus controls the downward growth of roots.

In the middle of the root apical meristem is a *quiescent center*, in which cell divisions are rare. The quiescent center can become more active when needed—following injury, for example. The daughter cells produced above the quiescent center (that is, away from the root cap) become the three cylindrical primary meristems: the protoderm, the ground meristem, and the procambium.

The apical and primary meristems constitute the **zone of cell division**, the source of all the cells of the root's primary tissues. Just above this zone is the **zone of cell elongation**, where the newly formed cells are elongating and thus pushing the root farther into the soil. Above that zone is the **zone of maturation**, where the cells are differentiating, taking on specialized forms and functions. These three zones grade imperceptibly into one another; there is no abrupt line of demarcation.

The products of the root's primary meristems become root tissues

The products of the three primary meristems (the protoderm, ground meristem, and the procambium) are the tissue systems of the mature root (**Figure 34.12**).

The protoderm gives rise to the **epidermis**, an outer layer of cells that is adapted for protection of the root and absorption of mineral ions and water. Many of the epidermal cells become

34.11 Tissues and Regions of the Root Tip

(A) Extensive cell division creates the complex structure of the root. (B) Root hairs, seen with a scanning electron microscope.

Some daughter cells become part of the **root cap**, which is constantly being eroded away.

New daughter cells are produced in the **root apical meristem**. Most daughter cells differentiate into the primary tissues of the root.

34.12 Products of the Root's Primary Meristems The protoderm gives rise to the outermost layer (epidermis). The ground meristem produces the cortex, the innermost layer of which is the endodermis. The primary vascular tissues of the root are found in the stele, which is the product of the procambium. The arrangement of tissues in the stele differs in the roots of eudicots and monocots.

AND Web Activity 34.2 • Monocot Root

long, delicate **root hairs**, which vastly increase the surface area of the root (**Figure 34.11B**). Root hairs grow out among the soil particles, probing nooks and crannies and taking up water and minerals.

Internal to the epidermis, the ground meristem gives rise to a region of ground tissue that is many cells thick, called the **cortex**. The cells of the cortex are relatively unspecialized and often serve as storage depots. The innermost layer of the cortex is the **endodermis**. Unlike those of other cortical cells, the cell walls of the endodermal cells contain *suberin*, a waterproof substance. Strategic placement of suberin in only certain parts of the cell wall enables the cylindrical ring of endodermal cells to control the movement of water and dissolved mineral ions into the vascular tissue system.

Moving inward past the endodermis, we enter the vascular cylinder, or **stele**, produced by the procambium. The stele consists of three tissues: pericycle, xylem, and phloem. The **pericycle** consists of one or more layers of relatively undifferentiated cells. It has three important functions:

- It is the tissue within which lateral roots arise (**Figure 34.13A**).
- It can contribute to secondary growth by giving rise to lateral meristems that thicken the root.
- Its cells contain membrane transport proteins that export nutrient ions into the cells of the xylem.

At the very center of the root of a eudicot lies the xylem. Seen in cross section, it typically has the shape of a star with a variable number of points (**Figure 34.13B**). Between the points are bundles of phloem. In monocots, a region of parenchyma cells, called the **pith**, typically lies in the center of the root, surrounded by xylem and phloem (**Figure 34.13C**). Pith, which often stores carbohydrate reserves, is also found in the stems of both eudicots and monocots.

The products of the stem's primary meristems become stem tissues

Recall that shoots are composed of repeating modules called **phytomers**, each consisting of a node with its attached leaf or leaves, the internode between nodes, and axillary buds in the angle between each leaf and the stem (see **Figure 34.1**). Shoots grow by adding new phytomers. Those new phytomers originate from cells in shoot apical meristems, which are formed at the tips of stems and in axillary buds.

The shoot apical meristem, like the root apical meristem, forms three primary meristems: protoderm, ground meristem, and procambium. These primary meristems, in turn, give rise to the three shoot tissue systems. The shoot apical meristem

34.13 Root Anatomy (A) Cross section through the tip of a lateral root in a willow tree. Cells in the pericycle divide and the products differentiate, forming the tissues of a lateral root. (B, C) Cross sections of the stele of (B) a representative eudicot (the buttercup, *Ranunculus*) and (C) a representative monocot (corn, *Zea mays*), showing the arrangement of the primary root tissues.

repetitively lays down the beginnings of leaves and axillary buds. Leaves arise from bulges called *leaf primordia*, which form as cells divide on the sides of the shoot apical meristem (see Figure 34.10). *Bud primordia* form at the bases of the leaf primordia and where they may become new apical meristems and initiate new shoots. The growing stem has no protective structure analogous to the root cap, but the leaf primordia can act as a protective covering for the shoot apical meristem.

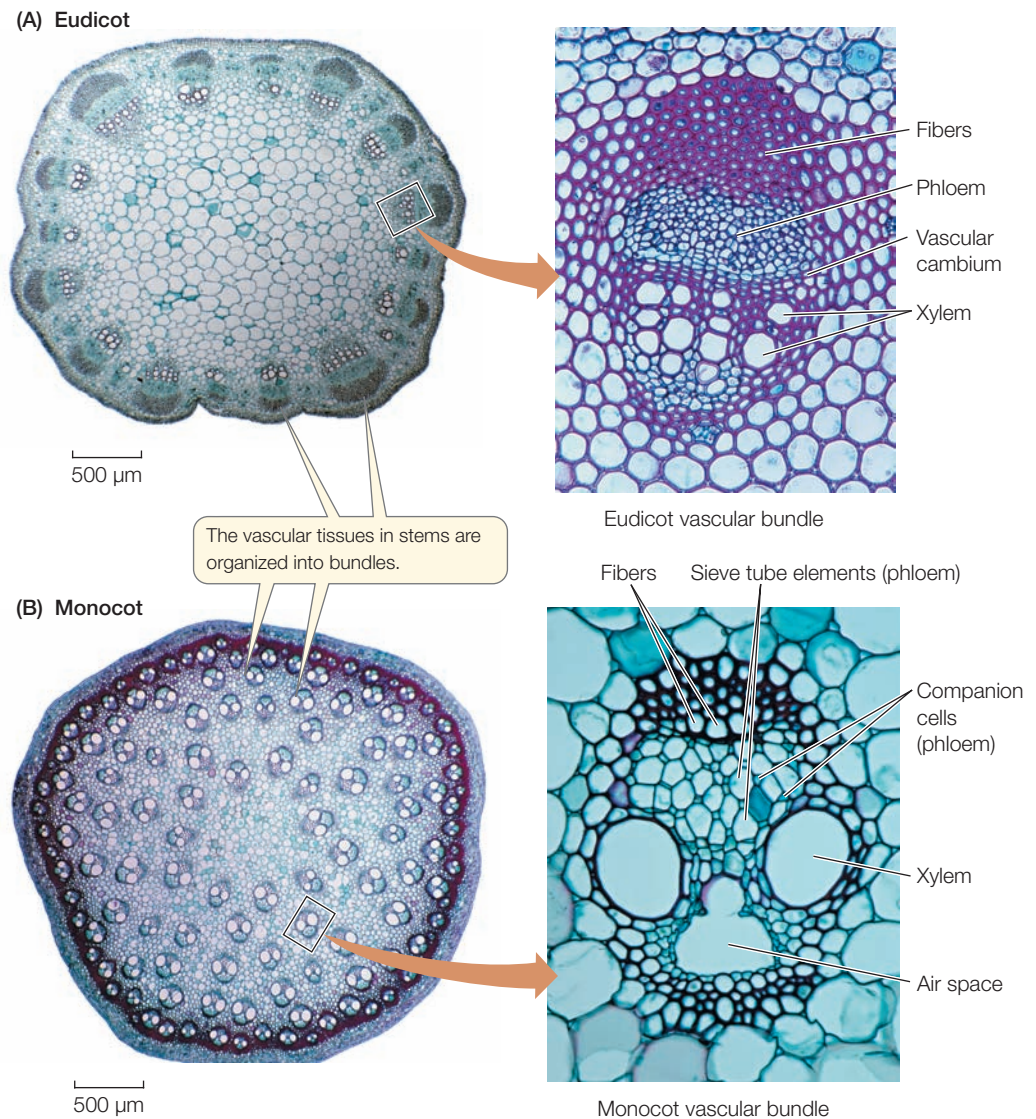

The plumbing of stems differs from that of roots. In a root, the vascular tissue lies deep in the interior, with the xylem at or near the center (see Figure 34.13B and C). The vascular tissue of a young stem, however, is divided into discrete **vascular bundles** (Figure 34.14). Each vascular bundle contains both xylem and phloem. In eudicots, the vascular bundles generally form a cylinder, but in monocots, they are seemingly scattered throughout the stem.

In addition to the vascular tissues, the stem contains other important storage and supportive tissues. In eudicots, the pith lies to the inside of the ring of vascular bundles and also extends between them, forming regions called *pith rays*. To the outside lies the cortex, which may contain supportive collenchyma cells with thickened walls. The pith and cortex constitute the ground tissue system of the stem. The outermost cell layer of the young stem is the epidermis.

Leaves are determinate organs produced by shoot apical meristems

For most of its life a plant produces leaves from apical meristems. Apical meristems that produce leaves are called **vegetative meristems**. As shown in Figure 34.10, leaves originate from the edges of the apical meristem as initial cells that differentiate into leaf primordia. A highly simplified way to think of the development of the leaf from the leaf primordia is to imagine leaves as flattened stems. However, there are two important differences. First, unlike the indeterminate growth of the stem, the growth of a leaf is determinate. Second, while the tissues of the stem are arranged in a radial pattern, the leaf, as a flat organ, has a distinct top side and bottom side.

Leaf anatomy is beautifully adapted to carry out photosynthesis and to support that process by exchanging the gases O_2 and CO_2 with the environment, limiting evaporative water loss, and exporting the products of photosynthesis to the rest of the

34.14 Vascular Bundles in Stems (A) In herbaceous eudicot stems, the vascular bundles are arranged in a cylinder, with pith in the center and the cortex outside the cylinder. (B) A scattered arrangement of vascular bundles is typical of monocot stems.

AND Web Activity 34.4 • Monocot Stem

plant. **Figure 34.15A** shows a section of a typical eudicot leaf in three dimensions.

Most eudicot leaves have two zones of photosynthetic parenchyma tissue called **mesophyll** (which means “middle of the leaf”). The upper layer or layers of mesophyll, which consist of elongated cells, constitute a zone called *palisade mesophyll*. The lower layer or layers, which consist of irregularly shaped cells, constitute a zone called *spongy mesophyll*. Within the mesophyll is a great deal of air space through which CO_2 can diffuse to photosynthesizing cells.

34.15 The Eudicot Leaf (A) This three-dimensional diagram shows a section of a eudicot leaf. (B) The network of fine veins in this maple leaf carries water to the mesophyll cells and carries photosynthetic products away from them. (C) Carbon dioxide enters the leaf through stomata like this one on the epidermis of a eudicot leaf.

yourBioPortal.com

GO TO Web Activity 34.5 • Eudicot Leaf

Vascular tissue branches extensively throughout the leaf, forming a network of *veins* (Figure 34.15B). Veins extend to within a few cell diameters of all the cells of the leaf, ensuring that the mesophyll cells are well supplied with water and minerals. The products of photosynthesis are loaded into the veins for export to the rest of the plant.

Covering virtually the entire leaf on both its upper and lower surfaces is a layer of nonphotosynthetic cells, the epidermis. The epidermal cells have an overlying waxy cuticle that is impermeable to water. Although this impermeability prevents excessive water loss, it also poses a problem: while the epidermis keeps water in the leaf, it also keeps out CO₂—the other raw material of photosynthesis.

The problem of balancing water retention and carbon dioxide availability is solved by an elegant regulatory system that will be discussed in more detail in Section 35.3. Stomatal *guard cells* are modified epidermal cells that can change their shape, thereby opening or closing pores called *stomata* (singular *stoma*), which serve as passageways between the environment and the leaf's interior (Figure 34.15C). When the stomata are open, carbon dioxide can enter and oxygen can leave, but water can also be lost.

Many eudicot stems and roots undergo secondary growth

As we have seen, the roots and stems of some eudicots develop a secondary plant body, the tissues of which we commonly refer to as *wood* and *bark*. These tissues are derived by secondary growth from the two lateral meristems, the vascular cambium and the cork cambium.

The **vascular cambium** is a cylindrical tissue consisting predominantly of elongated cells that divide frequently. It supplies the cells of the secondary xylem and secondary phloem, which eventually become wood and bark. The **cork cambium** produces mainly waxy-walled protective cells. It supplies some of the cells that become bark.

Each year, deciduous trees lose their leaves, leaving bare branches and twigs in winter. These twigs illustrate both primary and secondary growth (Figure 34.16). The apical meristems of the twigs are enclosed in buds protected by *bud scales*. When the buds begin to grow in spring, the scales fall away, leaving scars, which show us where the bud was and allow us to identify each year's growth. The dormant twig shown in Figure 34.16 is the product of primary and secondary growth. Only the buds consist entirely of primary tissues.

The vascular cambium is initially a single layer of cells lying between the primary xylem and the primary phloem within the vascular bundles (see Figure 34.16). The root or stem increases in diameter when the cells of the vascular cambium divide, producing secondary xylem cells toward the inside of the root or stem and producing secondary phloem cells toward the outside (Figure 34.17). In the stem, cells in the pith rays between the vascular bundles also divide, forming a continuous cylinder of vascular cambium running the length of the stem. This cylinder, in turn, gives rise to complete cylinders of secondary xylem (**wood**) and secondary phloem, which contributes to the bark. It also produces vascular rays for lateral transport, a structure not found in primary xylem and phloem. The principal cell products of the vascular cambium are vessel elements, tracheids, and supportive fibers in the secondary xylem, and sieve tube elements, companion cells, fibers, and parenchyma cells in the secondary phloem.

34.16 A Woody Twig Has Both Primary and Secondary Growth

The apical meristems in this dormant twig will produce primary growth in spring. Lateral meristems are responsible for secondary growth.

As secondary growth of stems or roots continues, the expanding vascular tissue stretches and breaks the epidermis and the outer layers of the cortex, which ultimately flake away. Tissue derived from the secondary phloem then becomes the outermost part of the stem. Before the dermal tissues are broken away, cells lying near the surface of the secondary phloem begin to divide, forming a cork cambium. This meristematic tissue produces layers of *cork*, a protective tissue composed of cells with thick walls waterproofed with suberin. The cork soon becomes the outermost tissue of the stem or root (see Figure 34.16). Without the activity of the cork cambium, the sloughing off of the outer primary tissues would expose the plant to potential damage, such as excessive water loss or invasion by microorganisms. Sometimes the cork cambium produces cells to the inside as well as to the outside; these cells constitute a tissue known as the *phelloderm*.

The cork cambium, cork, and phelloderm constitute a secondary dermal tissue called **periderm**. As the vascular cambium continues to produce secondary vascular tissue, these corky layers are lost, but the continuous formation of new cork cambia in the underlying secondary phloem gives rise to new corky layers. The periderm and the secondary phloem—that is, all the tissues external to the vascular cambium—constitute the **bark**.

34.17 Vascular Cambium Thickens Stems and Roots Stems and roots grow thicker because a thin layer of cells, the vascular cambium, remains meristematic. These highly diagrammatic images emphasize the pattern of deposition of secondary xylem and phloem by the vascular cambium.

GO TO Animated Tutorial 34.1 • Secondary Growth:
The Vascular Cambium

34.18 Lenticels Allow Gas Exchange through the Periderm The region of periderm that appears broken open is a lenticel in a year-old elderberry (*Sambucus*) twig; note the spongy tissue that constitutes the lenticel.

When periderm forms on stems or roots, the underlying tissues still need to release carbon dioxide and take up oxygen for cellular respiration. *Lenticels* are spongy regions in the periderm that allow such gas exchange (**Figure 34.18**).

Cross sections of most trunks (mature stems) of trees in temperate-zone forests show annual rings of wood (**Figure 34.19**), which result from seasonal environmental conditions. In spring, when water is relatively plentiful, the tracheids or vessel elements produced by the vascular cambium tend to be large in diameter and thin-walled. Such wood is well adapted for transporting water and minerals. As water becomes less available during the summer, narrower cells with thicker walls are pro-

34.19 Annual Rings Rings of secondary xylem are the most noticeable feature of this cross section from a tree trunk.

duced, making this summer wood darker and perhaps more dense than the wood formed in spring. Thus each growing season is usually recorded in a tree trunk by a clearly visible annual ring. Trees in the moist tropics do not undergo seasonal growth, so they do not lay down such obvious regular rings. Variations in temperature or water supply can lead to the formation of more than one “annual” ring in a single year, but commonly each year brings a new annual ring and a new batch of leaves.

Only eudicots and other non-monocot angiosperms, along with many gymnosperms, have a vascular cambium and a cork cambium and thus undergo secondary growth. The few monocots that form thickened stems—palms, for example—do so without secondary growth. Palms have a very wide apical meristem that produces a wide stem, and dead leaf bases add to the diameter of the stem. All monocots grow in essentially this way, as do other angiosperms that lack secondary growth.

34.4 RECAP

Meristems are localized regions of cell division that are the source of all new organs in the adult plant. Apical meristems are responsible for primary growth, which is associated with the lengthening and branching of shoots and roots. Lateral meristems increase plant girth and form wood and bark in many eudicots.

- Explain how an apical meristem can be maintained for years while continuing to form leaves. **See p. 729 and Figure 34.10**
- What cells are derived from the root apical meristem and what is the general process of root growth? **See pp. 730-731 and Figure 34.11**
- How does the vascular cambium give rise to thicker stems and roots? **See p. 733 and Figure 34.16**

The building of the plant body by meristems allows a plant to respond to its environment by redirecting its growth. Thus individual plants of the same species can vary greatly in form. What underlies this variation, and how have humans used it to our advantage?

34.5 How Has Domestication Altered Plant Form?

We have seen in this chapter that a very simple plant body plan—with roots, stems, leaves, meristems, and relatively few tissue and cell types—underlies the remarkable diversity of the flowering plants that cover our planet. However, while a difference in plant form between members of different species is expected, members of the same species can be remarkably diverse in form as well. From a genetic perspective, this observation suggests that minor differences in gene content or gene regulation can underlie dramatic differences in plant form. (Nevertheless, different plant species do differ greatly sometimes in gene content and genome organization.)

Let's return to the Doomsday Vault. We saw at the opening of this chapter that the vault will be used as a backup for seed banks around the world. Many of these seed banks concentrate on seed from a particular crop species, such as the Maize Stock Center at the University of Illinois (corn) or the Genetic Resources Center of the International Rice Research Institute in the Philippines (rice). In addition to containing large collections of cultivated varieties, these seed banks also contain seeds from populations of their wild relatives.

Why maintain collections of seed from both cultivated crops and their wild relatives? Despite sometimes vast morphological differences, crops and their wild relatives are still members of the same species. As such, when they are crossbred, they can produce viable progeny. These progeny will carry new combinations of their parents' traits.

It is hard to believe that modern corn was domesticated from the wild grass teosinte, which still grows in the hills of Mexico (**Figure 34.20**). One of the most conspicuous differences is that teosinte, like other wild grasses, is highly branched, with many shoots, while domesticated corn has a single shoot. This morphological difference is due in large part to the activity of a single gene called *teosinte branched 1* (*tb1*). The protein product of *tb1* regulates the growth of axillary buds (see Figure 34.1). The allele of *tb1* in domesticated corn represses branching, while the allele in teosinte permits branching.

Even harder to believe is that a single species, *Brassica oleracea* (wild mustard), is the ancestor of so many familiar and morphologically diverse crops such as kale, broccoli, Brussels sprouts, and cabbage (see Figure 21.4). An understanding of how the basic body plan of plants arises makes it possible to appreciate how each of these crops was domesticated. Starting with morphologically diverse populations of the wild ancestor, humans selected and planted the seed from variants with the trait they found desirable. Many generations of such artificial selection produced the crops that fill the produce section of the supermarket or the stands of the farmers' market.

Just as they were for ancient farmers, the genomes of plants are priceless resources today. The genetic variation in crop plants and their wild relatives can be used to improve our crop plants or adapt them to changing conditions. The improvement of crop plants is a work in progress that is being carried out in plant breeding programs worldwide. In fact, these programs are more important than ever. Increased human activity is dramatically changing our planet and leading to the extinction of more and more plant species. When seen in this light, the

34.20 Modern Corn Was Domesticated from the Wild Grass Teosinte

Beginning more than 8,000 years ago in Mexico, farmers favored plants with minimal branching. Reducing the number of branches results in fewer ears per plant, but allows each ear to grow larger and produce more seeds.

Doomsday Vault is an insurance policy for our crop plants against the loss of our most valuable resource, the genetic diversity underlying plant form and growth.

34.5 RECAP

Crop domestication involves artificial selection of certain desirable traits found in wild plant populations. By understanding the basic body plan of plants, one can more easily understand the morphological relationship between a crop plant and its wild relatives.

- Why is seed from wild relatives of crop plants valuable? **See p. 736 and Figure 34.20**

CHAPTER SUMMARY

34.1 What Is the Basic Body Plan of Plants?

- The vegetative organs of flowering plants are roots, which form a **root system**, and stems and leaves, which form a **shoot system**. **Review Figure 34.1**
- The two major clades of flowering plants, eudicots and monocots, differ from each other in a number of structural respects.

Most eudicots have a **taproot system**, and most monocots have a **fibrous root system**. **Review Figure 34.2**

- **Stems** bear undeveloped shoots called buds. **Axillary buds** can develop into new branches. A **terminal bud** is found at the end of a shoot.
- **Leaves** are the primary sites of photosynthesis. The leaf **blade** is attached to the stem by a **petiole**.

34.2 How Does the Cell Wall Support Plant Growth and Form?

- Plant cells differ from other eukaryotic cells in having chloroplasts or other plastids, large **central vacuoles**, and cellulose-containing cell walls.
- Once cytokinesis of a plant cell is complete, each daughter plant cell produces a **primary cell wall**. The walls of the two cells are separated by a **middle lamella**. **Review Figure 34.4**
- The primary cell wall is made up of bundles of cellulose **microfibrils** cross-linked by hemicellulose and pectin. **Review Figure 34.5**
- The primary cell wall is rigid but dynamic. By loosening the linkages between microfibrils, the cell wall can expand in volume by up to a million times.
- Some cells produce a thick **secondary cell wall**. **Lignin** in the secondary cell wall offers exceptional structural support.
- **Plasmodesmata** connect adjacent plant cells and allow direct communication between them. **Review Figure 34.6**

34.3 How Do Plant Tissues and Organs Originate?

- During embryogenesis, the basal–apical axis and the radial axis of the plant body are established. **Review Figure 34.7**
- The **shoot apical meristem** and the **root apical meristem** are also established during embryogenesis. These clusters of undifferentiated cells will orchestrate all postembryonic development.
- Three **tissue systems**, arranged concentrically, extend throughout the plant body: the vascular tissue, dermal tissue, and ground tissue systems. **Review Figure 34.8**
- The **dermal tissue system** protects the plant body surface. Dermal cells form the epidermis and, in woody plants, the periderm.
- The **ground tissue system** contains cells of three types. Some **parenchyma** cells carry out photosynthesis; others store starch. **Collenchyma** cells provide flexible support. **Sclerenchyma** cells include **fibers** and **sclereids** that provide strength and mechanical support. **Review Figure 34.9**
- The **vascular tissue system** includes **xylem**, which conducts water and minerals absorbed by the roots, and **phloem**, which conducts the products of photosynthesis throughout the plant body.

- **Tracheary elements** include **tracheids** and **vessel elements**, which are the conducting cells of the xylem. **Sieve tube elements** are the conducting cells of the phloem.

34.4 How Do Meristems Build a Continuously Growing Plant?

- All seed plants possess a **primary plant body** consisting of non-woody tissues. Woody plants also possess a **secondary plant body** consisting of wood and bark. **Apical meristems** generate the primary plant body, and **lateral meristems** generate the secondary plant body. **Review Figure 34.10**
- Apical meristems are responsible for **primary growth** (lengthening of roots and shoots). Apical meristems at the tips of stems and roots give rise to three **primary meristems** (**protoderm**, **ground meristem**, and **procambium**), which in turn produce the three tissue systems of the primary plant body
- The root apical meristem gives rise to the **root cap** and to three primary meristems. Root tips have overlapping **zones of cell division, elongation, and maturation**. **Review Figure 34.11**
- The vascular tissue of roots is contained within the **stele**. It is arranged differently in eudicot and monocot roots. **Review Figures 34.12 and 34.13, WEB ACTIVITIES 34.1 and 34.2**
- In nonwoody stems, the vascular tissue is divided into **vascular bundles**, each containing both xylem and phloem. **Review Figure 34.14, WEB ACTIVITIES 34.3 and 34.4**
- Eudicot leaves have two zones of photosynthetic **mesophyll** that are supplied by **veins** with water and minerals. Veins also carry the products of photosynthesis to other parts of the plant body. A waxy **cuticle** limits water loss from the leaf. **Guard cells** control openings (stomata) in the leaf that allow CO₂ to enter, but also allow some water to escape. **Review Figure 34.15, WEB ACTIVITY 34.5**
- Two lateral meristems, the **vascular cambium** and **cork cambium**, are responsible for secondary growth. The vascular cambium produces secondary xylem (wood) and secondary phloem. The cork cambium produces a protective tissue called **cork**. **Review Figures 34.16 and 34.17, ANIMATED TUTORIAL 34.1**

34.5 How Has Domestication Altered Plant Form?

- The plant body plan is simple, yet it can be changed dramatically by minor differences in genes, as evidenced by the natural diversity of wild plants.
- Crop domestication involves artificial selection of certain desirable traits found in wild populations. **Review Figure 34.20**

SELF-QUIZ

- Which of the following is a difference between monocots and eudicots?
 - Only eudicots have phytomers.
 - Only monocots have shoot and root apical meristems.
 - Monocot stems do not undergo secondary growth.
 - The vascular bundles of monocot stems are commonly arranged as a cylinder.
 - Eudicot embryos commonly have one cotyledon.
- Roots
 - always form a fibrous root system that holds the soil.
 - possess a root cap at their tip.
 - form branches from axillary buds.
 - are commonly photosynthetic.
 - do not show secondary growth.
- The primary plant cell wall
 - lies immediately inside the plasma membrane.
 - is an impermeable barrier between cells.
 - is always waterproofed with either lignin or suberin.
 - always consists of a primary wall and a secondary wall, separated by a middle lamella.
 - contains cellulose and other polysaccharides.
- Which statement about parenchyma cells is *not* true?
 - They are alive when they perform their functions.
 - They typically lack a secondary wall.
 - They often function as storage depots.
 - They are the most common cell type in the plant body.
 - They are found only in stems and roots.

5. Tracheids and vessel elements
 - a. must die to become functional.
 - b. are important constituents of all seed plants.
 - c. have no secondary cell wall.
 - d. are always accompanied by companion cells.
 - e. are found only in the secondary plant body.
6. Which statement about meristems is *not* true?
 - a. They are formed during embryogenesis.
 - b. They have secondary cell walls.
 - c. Their cells have small central vacuoles.
 - d. They are clusters of undifferentiated cells.
 - e. They retain the ability to produce new cells indefinitely.
7. The pericycle
 - a. is the innermost layer of the cortex.
 - b. is the tissue within which lateral roots arise.
 - c. consists of highly differentiated cells.
 - d. forms a star-shaped structure at the very center of the root.
 - e. is waterproofed by suberin.
8. Which of these statements is true of secondary growth, but *not* primary growth?
 - a. It occurs in eudicots and monocots.
 - b. It involves the proliferation of roots and shoots through branching.
 - c. It derives from the vascular cambium and the cork cambium.
 - d. It occurs in palms.
 - e. It derives from the shoot apical meristem
9. Periderm
 - a. contains lenticels that allow for gas exchange.
 - b. is produced during primary growth.
 - c. is permanent; it lasts as long as the plant does.
 - d. is the innermost part of the plant.
 - e. contains vascular bundles.
10. Which statement about leaf anatomy is *not* true?
 - a. Opening of stomata is controlled by guard cells.
 - b. The cuticle is secreted by the epidermis.
 - c. The veins contain xylem and phloem.
 - d. The cells of the mesophyll are packed together, minimizing air space.
 - e. The spines of cacti are actually modified leaves.

FOR DISCUSSION

1. When a young oak was 5 m tall, a thoughtless person carved his initials in its trunk at a height of 1.5 m above the ground. Today that tree is 10 m tall. How high above the ground are those initials? Explain your answer in terms of plant growth.
2. Distinguish between the primary cell wall and the secondary cell wall. When do secondary walls form? What cell types lack secondary walls?
3. Distinguish between sclerenchyma cells and collenchyma cells in terms of structure and function.
4. Distinguish between primary and secondary growth. Do all angiosperms undergo secondary growth? Explain.
5. What anatomical features make it possible for a plant to retain water? Describe the plant tissues involved and how and when they form.
6. The Doomsday Vault contains the seeds of both domesticated and wild plants. Why is it important to preserve collections of seeds of both domesticated and wild plants? What kinds of situations would necessitate the withdrawal of seeds from the Doomsday vault?
7. Take a walk through a farmer's market or the produce section of a supermarket. Use your knowledge of plant growth and form to figure out what desirable trait was selected to produce some of your favorite vegetables.

ADDITIONAL INVESTIGATION

Of the approximately 20,000 genes in the sequenced genome of *Arabidopsis thaliana*, over 1,000 are involved in cell wall biosynthesis. Based on the composition, growth, and functions of cell

walls, what types of proteins would you predict some of these genes encode?

Engineering water-conserving crops

Everyone knows that plants need water to grow. However, it may come as a surprise that the cultivation of crop plants consumes far more water than all other human activities combined. Worldwide demand for water is increasing at the same time that supplies are declining. This situation makes it imperative that we understand how plants use water so that we can breed plants that use it more efficiently.

The question of just how much water plants use while they grow was addressed in 1690 by John Woodward, a professor at Cambridge University. He reported that a plant that gained just 1 g in weight used 76,000 g of water over 77 days. He proposed that most of the water taken up by plants was “drawn off and conveyed through the pores of the leaves and exhaled into the atmosphere.”

We know now, of course, that much of the mass plants acquire as they grow is due to net fixation of atmospheric CO_2 into carbohydrates through photosynthesis. But Woodward nevertheless articulated a crucial insight: plants need to take up a lot of water to grow. Plant biologists have a name for the ratio of net photosynthetic carbon fixation to water uptake: *water-use efficiency*.

Droughts and a dwindling water supply are challenging farmers all over the world. One of the least water-efficient of all crop plants is, unfortunately, one of our most important: rice. Rice plants use up to 3 times more water per unit of growth than other crops such as wheat and maize (corn). The precariousness of heavily water-dependent rice farming was dramatically demonstrated in eastern India between 1997 and 2003, when drought re-

duced rice production by over 5 million tons—some farmers lost up to 50 percent of their crop.

Clearly, a strain of rice that needs less water would not only make the world supply of rice less vulnerable to drought but also help conserve water for other uses. A team of molecular biologists, plant physiologists, and crop scientists led by Andrew Pereira at Virginia Polytechnic began their quest for such a strain of rice by studying an entirely different plant—the model organism *Arabidopsis thaliana* (thale cress). They searched for genetic variants of *Arabidopsis* that had improved

Thirsty Rice Cultivation of rice, the most important food crop in Asia, requires large quantities of water.

A Need for Improved Water-Use Efficiency in Plants

Rice that could use water more efficiently would be less vulnerable to drought and might help maintain or even increase crop yields.

water-use efficiency. One variant they chose to study was particularly hard to pull out of the ground because of its extensive root system (indicating more capacity for water uptake) and had thick leaves with abundant photosynthetic tissue (indicating prolific photosynthesis). Molecular and physiological characterization of this *Arabidopsis* strain showed that its improved water usage was linked to a mutation in a single gene that codes for a transcription factor. When this gene (called *HARDY*) was isolated and put into rice plants using recombinant DNA technology, the rice plants also were more efficient, and indeed tolerated dry soil much better than their normal counterparts. While the *HARDY* gene may or may not lead to crops with higher water-use efficiency, many laboratories around the world are using *Arabidopsis* to isolate genes that can be used to improve water usage and other important characteristics of crop plants.

IN THIS CHAPTER we will consider the uptake of water and minerals from the soil and the transport of these materials up the plant in the xylem. We will also look at the control of evaporative water loss from leaves, and the translocation (movement from one location to another) of dissolved substances in the phloem.

CHAPTER OUTLINE

- 35.1** How Do Plants Take Up Water and Solutes?
- 35.2** How Are Water and Minerals Transported in the Xylem?
- 35.3** How Do Stomata Control the Loss of Water and the Uptake of CO₂?
- 35.4** How Are Substances Translocated in the Phloem?

35.1 How Do Plants Take Up Water and Solutes?

Terrestrial plants must obtain both water and mineral nutrients from the soil, usually through their roots. The roots, in turn, obtain carbohydrates and other important materials from the leaves (**Figure 35.1**). Water is required for carbohydrate production by photosynthesis in leaves (see Section 10.1), for transporting solutes between plant organs, for cooling the plant, and for developing the internal pressure that supports the plant body.

As our opening story conveys, plants lose large quantities of water to evaporation. To balance this loss, an equally large amount of water must be absorbed through the roots, continue up the stem, and be transported into the leaves. The minerals that a plant needs are transported along with the water. Several steps in water and mineral transport will be considered in this chapter. In this section we will focus on the first part of the journey—the uptake of water and minerals into the roots and their transport into the xylem.

Water potential differences govern the direction of water movement

The process of water uptake by plants requires water to move through at least one, and usually many cell membranes. Accordingly, we will begin our discussion of water transport by examining the rules that govern the movement of water across membranes. As described in Section 6.3, the movement of water through a membrane in accordance with the laws of diffusion is called *osmosis*.

The overall tendency of a solution to take up water from pure water, across a membrane, is called its **water potential** and is represented as ψ , the Greek letter *psi* (pronounced “sigh”). The water potential of a solution is measured as the sum of its (negative) solute potential (ψ_s) and its (usually positive) pressure potential (ψ_p):

$$\psi = \psi_s + \psi_p$$

Whenever water moves by osmosis, the following important rule applies: *water always moves across a selectively permeable membrane toward the region of lower (more negative) water potential.*

We can measure solute potential, pressure potential, and water potential in *megapascals* (MPa), a unit of pressure. Atmospheric pressure, “one atmosphere,” is about 0.1 MPa, or 14.7 pounds per square inch; a typical pressure in an automobile tire is about 0.2 MPa.

35.1 The Pathways of Water and Solute in a Plant

Water travels from the soil to the atmosphere, with only a small fraction used within the plant.

We explore the meaning of the water potential equation in **Figure 35.2**, which assigns values to ψ_s and ψ_p and illustrates how changes in the values of these parameters alter the water potential (ψ) and determine the direction of water movement between two compartments (for example, the inside and outside of a plant cell) separated by a semipermeable membrane.

The **solute potential** (ψ_s , also called the *osmotic potential*) of a solution is a measure of the effect of dissolved solutes on the osmotic behavior of the solution. The addition of solutes removes free water from the solution because the solute molecules bind water molecules to their surfaces. This is reflected in a more negative value for ψ_s (-0.4 MPa in our example; see Figure 35.2A), which lowers the water potential ($\psi = -0.4$ MPa) and leads to the movement of water through the membrane to the region of lower ψ . Equilibrium is reached when there is no difference in ψ on either side of the membrane (see Figure 35.2B). Now let's see how these same forces determine the direction of water flow through plant cells.

Mature plant cells usually contain a large central vacuole filled with solutes, which are often pumped into the vacuole by transporter proteins. The active accumulation of solutes provides the osmotic force for water uptake into the vacuole. Plant cells are surrounded by a relatively rigid cell wall that resists the expansion of the underlying protoplast. The pressure exerted by the cell wall is equivalent to the positive pressure exerted by the piston on the water column in the idealized example shown in Figure 35.2C. When the pressure potential equals the solute potential, there is no net movement of water through the membrane.

35.2 Water Potential, Solute Potential, and Pressure Potential

As can be seen in these idealized examples, water flows towards regions of lower water potential (ψ), which is the sum of the solute potential (ψ_s) and the pressure potential (ψ_p). For pure water under no applied pressure, all three of these parameters are equal to zero.

35.3 Turgor Turgor pressure builds up inside the cell as the cell wall resists further expansion of the cell.

When the wall of a plant cell is exerting no pressure on the underlying protoplast, the cell is said to be *flaccid* (Figure 35.3, left). In this situation,

$$\psi_s = -0.7 \text{ MPa and } \psi_p = 0 \text{ MPa}$$

$$\text{So, } \psi = \psi_s + \psi_p = -0.7 \text{ MPa}$$

When a flaccid cell is placed in pure water, water initially moves into the cell due to its negative solute potential (Figure 35.3, right). However, the cell can't expand because it is contained by the cell wall; thus, as water enters, the cell's internal pressure increases and resists the further entry of water.

$$\psi_s = -0.7 \text{ MPa and } \psi_p = 0.7 \text{ MPa}$$

$$\text{So, } \psi = 0$$

This opposing pressure is called **turgor pressure** in plants and is equivalent to the pressure potential (ψ_p) exerted by the piston in Figure 35.2C. Water will enter plant cells by osmosis until the pressure potential exactly balances the solute potential. At this point, the cell is **turgid**; that is, it has a significant positive pressure potential. The physical structure of many plants is maintained by the (positive) pressure potential of their cells; if the pressure potential drops (for example, if the plant does not have enough water), the plant *wilts* (Figure 35.4).

35.4 A Wilted Plant A plant wilts when the pressure potential of its cells is zero.

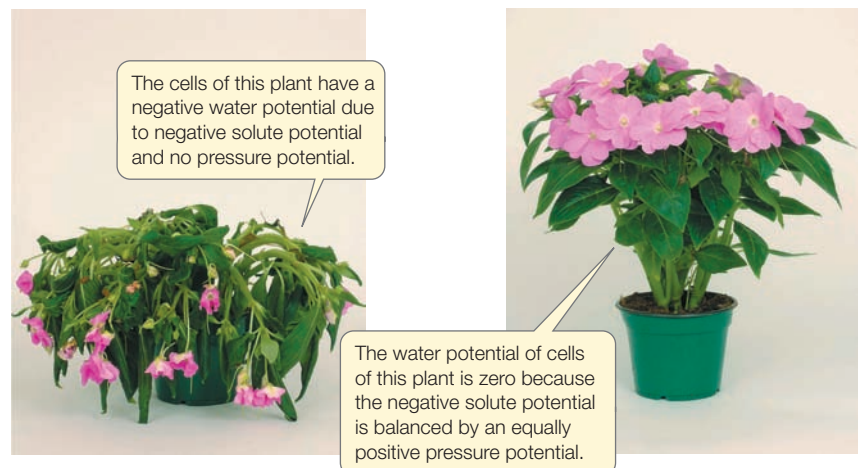

Within living plant tissues, the movement of water from cell to cell follows a gradient of water potential. Over long distances, in unobstructed tubes such as xylem vessels and phloem sieve tubes, the flow of water and dissolved solutes is driven by a *gradient of pressure potential*, not a gradient of water potential. The movement of a solution from a region of higher pressure potential to a region of lower pressure potential is called **bulk flow**. We'll see that bulk flow in the xylem is between regions of differing *negative* pressure potential (tension), while bulk flow in the phloem is between regions of differing *positive* (turgor) pressure potential.

Aquaporins facilitate the movement of water across membranes

The large quantities of water lost to evaporation from the leaves must be balanced by water taken up by the roots. Yet only a trickle of water can pass through the hydrophobic environment created by the phospholipid bilayers of cell membranes. How do plants turn this trickle into a gusher? The answer is that water diffuses through cell membranes mainly through channels called **aquaporins** (see Figure 6.13), which are located in both the plasma membrane and the tonoplast (vacuolar membrane) of plant cells. Aquaporins allow water to move rapidly from environment to cell and from cell to cell. The abundance of aquaporins in a plant cell varies with environmental conditions, depending on a cell's need to obtain and retain water. The permeability of some aquaporins also can be regulated. Alterations in aquaporin abundance and permeability change the *rate* of osmosis across the membrane. Note, however, that water movement through aquaporins is always passive, so the *direction* of water movement is unchanged.

Uptake of mineral ions requires membrane transport proteins

Although water molecules can cross membranes through aquaporins, mineral ions generally cannot. The ions, which carry electric charges, are blocked by the hydrophobic interior of the

membrane, and they are too large to pass through aquaporins. Instead, mineral ions generally cross membranes through transport proteins, including ion channels and carrier proteins (see Sections 6.3 and 6.4).

We have just seen that water moves through a water-permeable membrane in response to a water potential gradient. Other molecules and ions also follow their own concentration gradients, as permitted by the characteristics of the membrane. When the concentration of charged ions in the soil is greater than that in the plant, transport proteins can move them into the plant by facilitated diffusion, which is a passive process. The concentrations of most ions in the soil solution, however, are lower than those required inside the plant. In these cases, the plant must actively take up ions *against* their concentration gradients—a process that requires energy.

Electric charge differences also play a role in the uptake of mineral ions. For example, a negatively charged ion that moves into a negatively charged compartment is moving against an *electrical gradient*, and this requires energy. Concentration and electrical gradients combine to form an *electrochemical gradient*. Uptake against an electrochemical gradient involves *active transport*, which requires specific transport proteins and is fueled by ATP generated by cellular respiration.

Unlike animals, plants do not have a sodium–potassium pump (see Section 6.4) for active transport. Rather, plants have a **proton pump**, which uses energy obtained from ATP to move protons out of the cell against a proton concentration gradient (Figure 35.5, step 1). Because protons (H^+) are positively charged, their accumulation outside the cell has two results:

- An electrical gradient is created such that the region outside the cell becomes more positively charged relative to the region inside.

- A proton concentration gradient develops, with more protons outside the cell than inside.

Each of these results has consequences for the movement of other ions. Because the inside of the cell is now more negative than the outside, cations (positively charged ions) such as potassium (K^+) move into the cell by facilitated diffusion through their specific membrane channels (Figure 35.5, step 2). In addition, the proton concentration gradient can be harnessed to drive secondary active transport, in which anions (negatively charged ions) such as chloride (Cl^-) are moved into the cell against an electrochemical gradient by a symport protein that couples their movement with that of H^+ (Figure 35.5, step 3).

In sum, there is vigorous traffic of water molecules and mineral ions across plant cell membranes. This traffic involves specific membrane channels and transport proteins, and both active and passive processes. Now we will step back and see how these membrane transport processes participate in the journey of water and nutrients from the soil to the xylem.

Water and ions pass to the xylem by way of the apoplast and symplast

The journey from the soil through the roots to the xylem occurs primarily by one of two pathways, the fast lane (called the *apoplast*) and the slow(er) lane (called the *symplast*) (Figure 35.6):

- The **apoplast** (Greek *apo*, “away from”; *plast*, “living material”) consists of the cell walls, which lie outside the plasma membranes, and the intercellular spaces (spaces between cells) that are common in many plant tissues. The apoplast is a continuous meshwork through which water and dissolved substances can flow without ever having to cross a membrane. Movement of materials through the apoplast is thus unregulated and rapid—until it reaches the *Casparian strips* of the endodermis.
- The **symplast** (Greek *sym*, “together with”) passes through the continuous cytoplasm of the living cells connected by plasmodesmata. The selectively permeable plasma membranes of the root cells control access to the symplast, so movement of water and dissolved substances into the symplast is tightly regulated.

35.5 The Proton Pump in Transport of K^+ and Cl^-

The active transport of hydrogen ions (H^+) out of the cell by the proton pump (1) drives the movement of both cations (2) and anions (3) into the cell.

35.6 Apoplast and Symplast Plant cell walls and intercellular spaces constitute the apoplast. The symplast comprises the living cells, which are connected by plasmodesmata. To enter the symplast, water and solutes must pass through a plasma membrane. No such selective barrier limits movement through the apoplast. The Casparian strip in the endodermis of the cortex is impregnated with the water-repelling substance suberin and separates apoplast in the cortex from apoplast in the stele.

Water and minerals that pass from the soil solution through the apoplast can travel as far as the endodermis, the innermost layer of the root cortex. The endodermis is distinguished from the rest of the ground tissue by the presence of the **Casparian strip**. This waxy, suberin-impregnated region of the endodermal cell wall forms a water-repelling (hydrophobic) belt around each endodermal cell where it is in contact with other endodermal cells. The Casparian strip acts as a seal that prevents water and ions from moving between the cells (see Figure 35.6).

The Casparian strip of the endodermis completely separates the apoplast of the cortex from the apoplast of the stele. Accordingly, the only way water and ions can enter the stele is by way of the symplast—that is, by entering and passing through the cytoplasm of the endodermal cells. Water and ions already in the symplast can enter the endodermal cells through plasmodesmata, but those in the apoplast must cross the plasma membranes of the endodermal cells (this is possible because the Casparian strip does not obstruct the inner or outer faces of endodermal cells). Thus transport proteins in the plasma mem-

yourBioPortal.com
GO TO Web Activity 35.1 • Apoplast and Symplast of the Root

branes of the epidermal and cortical cells (for mineral ions traveling through the symplast) and endodermal cells (for those traveling through the apoplast) determine which mineral ions pass into the stele, and at what rates.

Once they have passed the endodermal barrier, water and minerals remain in the symplast until they reach parenchyma cells in the pericycle or xylem. These cells then actively export mineral ions into the apoplast of the stele. As mineral ions are transported into the solution in the cell walls of the stele, the water potential in the apoplast becomes more negative; consequently, water moves out of the cells and into the apoplast by osmosis. In other words, ions are transported actively, and water follows passively. The end result is that water and minerals end up in the xylem, where they constitute the *xylem sap*.

35.1 RECAP

Differences in water potential govern the osmotic flow of water from the soil into the plant stele; this is a passive process. Uptake of minerals from the soil occurs along an electrochemical gradient and is therefore an active process requiring energy and membrane transport proteins. Water and minerals can move into the root through either the apoplast or the symplast, but must enter and leave the symplast to reach the xylem.

- What distinguishes water potential, solute potential, and pressure potential? **See pp. 740–741 and Figure 35.2**
- Explain why the cell wall is so important in determining the direction of water movement. **See pp. 741–742**
- What are aquaporins? Why are they needed? **See p. 742**
- Describe the differences between the apoplast and the symplast. **See p. 743 and Figure 35.6**

So far we've described the movement of water and minerals into plant roots and their entry into the root xylem. How does the xylem sap move once it is in the xylem?

35.2 How Are Water and Minerals Transported in the Xylem?

Water has arrived in the xylem—it is all uphill from there! Before we consider the ascent to the leaves, let's revisit the cells that make up the xylem, the xylem vessels (see Figure 34.9E and F). In this section you will learn that the properties of xylem vessels make it possible for water and solutes to be transported efficiently over long distances. Recall that xylem vessels are dead and lack all cell contents. When fused end to end, the xylem vessels form a long tubular “straw” of lignified cell walls that provide both structural support and the rigidity needed to maintain a gradient of pressure.

Consider the magnitude of what xylem accomplishes in transporting a *large amount of water over a great distance* within the plant. A single maple tree 15 meters tall has been estimated to have some 177,000 leaves, with a total leaf surface area of 675 square meters—half again the area of a basketball court. During a summer day, that tree loses 220 liters of water *per hour* to the atmosphere by evaporation from the leaves. So to prevent wilting, the xylem needs to transport 220 liters of water from the roots to the leaves every hour. (By comparison, a 50-gallon drum holds 189 liters.) The tallest leaves can be quite far from the root. The tallest gymnosperm, the coast redwood *Sequoia sempervirens*, and the tallest angiosperm, the Australian *Eucalyptus regnans*, are more than 110 meters tall. Any successful explanation of water transport in the xylem must account for the transport of water to these great heights.

Scientists have proposed various models to explain the ascent of xylem sap. We begin by reviewing some illuminating experiments that ruled out early models, and then turn to evidence in support of the current model.

Xylem sap is not pumped by living cells

Some of the earliest attempts to explain the rise of sap in the xylem were based on the hypothesis that a pumping action by living cells in the stem might push the sap upward. However, in 1893 the German botanist Eduard Strasburger conducted and published experiments that definitively ruled out such models.

Strasburger worked with trees about 20 meters tall. He sawed through the trunk of each tree at its base and plunged the cut end into a solution of a poison, such as copper sulfate. The solution rose through the trunk, as was evident from the progressive death of the bark higher and higher up. When the solution reached the leaves, the leaves died too, at which point the movement of the solution stopped (as shown by the liquid level in the bucket, which stopped dropping).

This simple experiment established three important points:

- Living, “pumping” cells were not responsible for the upward movement of the solution, because the solution itself killed all living cells with which it came in contact.
- The leaves played a crucial role in transport. As long as they were alive, the solution continued to move upward; when the leaves died, movement ceased.
- The roots did not cause the movement, because the trunk had been completely separated from the roots.

Root pressure alone does not account for xylem transport

A second hypothesis about xylem transport involved **root pressure**—pressure exerted by the root tissues that would force liquid up the xylem. The basis for root pressure is a higher solute concentration, and accordingly a more negative water potential, in the xylem sap than in the soil solution. This water potential draws water into the stele; once there, the water has nowhere to go but up, so it rises in the xylem vessels.

Root pressure certainly exists—for example, it is responsible for the phenomenon of *guttation*, in which liquid water is forced out through special openings at the margins of leaves. Guttation occurs only when atmospheric humidity is high and soil water is plentiful, conditions that occur most commonly at night. Root pressure is also the source of the sap that oozes from the cut stumps of some plants when their tops are cut off.

Root pressure, however, cannot account for the ascent of sap in trees. Root pressure seldom exceeds 0.1–0.2 MPa (1–2 atmospheres). If root pressure were driving sap up the xylem, we would observe a positive pressure potential in the xylem at all times. In fact, as we are about to see, the xylem sap in most trees is under *tension*—has a *negative* pressure potential—when it is ascending. Furthermore, as Strasburger had already shown, materials can be transported upward in the xylem even when the

roots have been removed. If the roots are not pushing the xylem sap upward, what causes it to rise?

The transpiration–cohesion–tension mechanism accounts for xylem transport

The current model of xylem transport relies on an alternative to pushing: pulling. The evaporative loss of water from the leaves indirectly generates a pulling force—**tension**—on the water in the apoplast of the leaves, which pulls the xylem sap upward. Hydrogen bonding between water molecules makes the sap in the xylem cohesive enough to withstand the tension and rise by bulk flow. Let's see how this process works (Figure 35.7).

The concentration of water vapor in the atmosphere is lower than that in the leaf. Because of this difference, water vapor diffuses from the intercellular spaces of the leaf, through the *stomata* (which we will consider in more detail later) to the outside air,

in a process called **transpiration**. Within the leaf blade, water evaporates from the moist walls of the mesophyll cells and enters the intercellular spaces. As water evaporates from the aqueous film coating each cell, the film shrinks back into tiny spaces in the cell walls, increasing the curvature of the water surface and thus increasing its surface tension. This increased tension (negative pressure potential) in the surface film draws more water into the cell walls, replacing that which was lost. The resulting tension in the mesophyll draws water from the xylem of the nearest vein into the apoplast surrounding the mesophyll cells. The removal of water from the veins, in turn, establishes tension on the entire column of water contained within the xylem, so that the column is drawn upward all the way from the roots.

Water can be pulled upward through tiny tubes because of the remarkable **cohesion** of water—the tendency of water molecules to stick to one another by hydrogen bonding (see Section 2.4 and Figure 35.7, step 6). The narrower the tube, the greater the tension the water column can withstand without breaking. The integrity of the column is also maintained by the *adhesion* of water to the xylem walls.

In summary, the key elements of water transport in the xylem are:

- *Transpiration* of water molecules from the leaves by evaporation
- *Tension* in the xylem sap resulting from transpiration from the leaves
- *Cohesion* of water molecules in the xylem sap, from the leaves to the roots

35.7 The Transpiration–Cohesion–Tension Mechanism Transpiration causes evaporation from mesophyll cell walls, generating tension on the xylem. Cohesion among water molecules in the xylem transmits the tension from the leaf to the root, causing water to flow in the xylem from the roots to the atmosphere.

GO TO Animated Tutorial 35.1 • Xylem Transport

The water transport process we have described, called the **transpiration-cohesion-tension mechanism**, requires no work (that is, no expenditure of energy) on the part of the plant. At each step between soil and atmosphere, water moves passively; first toward a region with lower water potential, and then to a region of lower pressure potential. Dry air has the most negative water potential (-95 MPa at 50% relative humidity), and the soil solution has the least negative water potential (between -0.01 and -3 MPa). Xylem sap has a water potential more negative than that of cells in the cortex of the root, but less negative than that of mesophyll cells in the leaf.

In the tallest trees, such as a 110-meter *Sequoia*, the difference in pressure potential between the top and the bottom of the column may be as great as 3 MPa. Compare this to root pressure and the pressure in a typical automobile tire, which seldom exceed 0.2 MPa. The cohesion of water in the xylem is great enough to withstand the huge tensions that develop in the tallest trees.

Mineral ions contained in the xylem sap rise passively with water as it ascends from root to leaf. In this way the nutritional needs of the shoot are met. Some of the mineral elements brought to the leaves are subsequently redistributed to other parts of the plant by way of the phloem, but the initial delivery from the roots is through the xylem.

In addition to promoting the transport of minerals, transpiration has an added benefit of cooling a plant's leaves. The evaporation of water from mesophyll cells consumes heat, thereby decreasing the leaf temperature. A farmer can hold a leaf between thumb and forefinger to estimate its temperature; if the leaf doesn't feel cool, that means that transpiration is not occurring and it must be time to water.

The cooling effect of evaporation (also evident in the cooling of our skin when we sweat) may also be important in enabling plants to live in hot environments. However, while transpiration may lead to the cooling of the leaf, this effect is a consequence of the need to transpire, not a reason for it.

A pressure chamber measures tension in the xylem sap

The transpiration-cohesion-tension model holds true only if the column of sap in the xylem is under tension (has a negative pressure potential). The most elegant demonstrations of this tension, and of its adequacy to account for the ascent of xylem sap in tall trees, were performed by the biologist Per Scholander, who measured tension in stems with an instrument called a **pressure chamber** (Figure 35.8).

Scholander used the pressure chamber to study dozens of plant species from diverse habitats, growing under a variety of conditions. The rate at which xylem sap ascends is not the same at all times. No flow of xylem sap takes place at night, when there is little or no transpiration. By day, when the sap is ascending, the rate of ascent depends on several factors. These include

TOOLS FOR INVESTIGATING LIFE

35.8 Measuring the Pressure of Xylem Sap with a Pressure Chamber

Xylem sap pulls away from a cut stem because the pressure in the intact xylem is lower than that of the atmosphere. The negative pressure potential originally present in the plant can be measured in a pressure chamber in which the pressure can be raised. The cut surface remains outside the chamber. As gas pressure increases, the xylem sap is pushed back to the cut surface. When the sap first becomes visible again at the cut surface, the pressure in the chamber is recorded. This pressure is equal in magnitude but opposite in sign to the tension (negative pressure potential) originally present in the xylem.

temperature, light intensity, and wind velocity, all of which affect the transpiration rate, and hence the rate of sap flow. In addition, Scholander found that the xylem sap in developing vines was not under tension until leaves formed. Once leaves developed, the tension increased and transport in the xylem began.

35.2 RECAP

The transpiration-cohesion-tension mechanism explains the ascent of xylem sap. Transpiration draws water out of leaves, resulting in tension that pulls water from the xylem. Because of cohesion between water molecules, water is pulled passively through the xylem vessels in continuous columns, always toward a region with lower pressure potential.

- What are the roles of transpiration, cohesion, and tension in xylem transport? **See p. 746 and Figure 35.7**
- What properties of the water molecule contribute to cohesion and tension? **See p. 746**
- Describe how mineral ions get from the roots to the leaves. **See p. 747**

Although transpiration provides the driving force for the transport of water and minerals in the xylem, it also results in the loss of tremendous quantities of water from the plant. How plants control this loss is the subject of the next section.

35.3 How Do Stomata Control the Loss of Water and the Uptake of CO₂?

The epidermis of leaves and stems minimizes transpirational water loss by secreting a waxy cuticle, which is impermeable to water. However, the cuticle is also impermeable to carbon dioxide. This poses a problem: how can the plant balance its need to retain water with its need to obtain CO₂ for photosynthesis?

An elegant compromise has evolved in plants in the form of pores called **stomata** (singular *stoma*) in the epidermis of their leaves. A pair of specialized epidermal cells, called **guard cells**, controls the opening and closing of each stoma (**Figure 35.9A**). When the stomata are open, CO₂ can enter the leaf by diffusion—but water vapor diffuses out of the leaf at the same time. Closed stomata prevent water loss, but also exclude CO₂ from the leaf.

Most plants open their stomata only when the light intensity is sufficient to maintain a moderate rate of photosynthesis. At night, when darkness precludes photosynthesis, their stomata are closed; no CO₂ is needed at this time, and water is conserved. Even during the day, the stomata close if water is being lost at too great a rate.

Stomata are ancient structures that are found in plant fossils that are over 400 million years old. For this reason, they are thought to predate the evolution of leaves. Stomata are found in all vascular plants and in many nonvascular plants, including mosses (but not liverworts; see Chapter 28).

The stoma and guard cells seen in Figure 35.9A are typical of eudicots. Monocots typically have specialized epidermal cells associated with their guard cells. However, the principle of operation, which we will now describe in more detail, is the same for both monocot and eudicot stomata.

The guard cells control the size of the stomatal opening

Light causes the stomata of most plants to open, admitting CO₂ for photosynthesis. Another cue for stomatal opening is the level of CO₂ in the intercellular spaces inside the leaf. A low level favors opening of the stomata, thus allowing the uptake of more CO₂.

Stomata can respond to changes in light and CO₂ in a matter of minutes. How can such an important biological process happen so rapidly? The answer is that the opening and closing of stomata is controlled by turgor pressure changes in the guard cells. Changes in turgor pressure are in turn driven by changes in K⁺ concentration in the guard cells. Blue light, absorbed by a pigment in the guard cell plasma membrane, activates a proton pump, which actively transports H⁺ out of the guard cells and into the apoplast of the surrounding epidermis. The resulting electrochemical gradient drives K⁺ into the guard cells, where it accumulates (**Figure 35.9B**). The increased internal concentration of K⁺ makes the water potential of the

35.9 Stomata (A) Scanning electron micrograph of an open stoma formed by two sausage-shaped guard cells. (B) Potassium ion concentrations affect the water potential of the guard cells, controlling the opening and closing of stomata. Negatively charged ions (e.g., Cl⁻) that accompany K⁺ maintain electrical balance and contribute to the changes in water potential that open and close the stomata.

guard cells more negative. Negatively charged chloride ions and organic ions also move into and out of the guard cells along with the potassium ions, maintaining electrical balance and contributing to the change in the solute potential of the guard cells. Water enters by osmosis (guard cell membranes are particularly

rich in aquaporin protein channels), increasing the pressure potential of the guard cells. The arrangement of the cellulose microfibrils in their cell walls (see Figure 34.5) is such that the guard cells change shape in response to the increase in pressure potential, so that a gap—the stoma—appears between them.

The stoma closes in the absence of blue light. The proton pump becomes less active, potassium ions diffuse passively out of the guard cells, water follows by osmosis, the pressure potential decreases, and the guard cells sag together and seal off the stoma.

INVESTIGATING LIFE

35.10 Measuring Potassium Ion Concentration in Guard Cells

G. D. Humble and Klaus Raschke used the electron probe microanalyzer to examine individual stomata of the broad bean. In electron probe microanalysis, electron bombardment of the sample causes it to emit X rays. The wavelength and intensity of the lines in the X-ray spectrum can be analyzed to identify the elements present in the specimen and estimate their concentrations.

HYPOTHESIS Guard cells of open stomata contain more potassium ions than do those of closed stomata.

METHOD

1. Peel strips of epidermis from leaves of broad beans in the dark (closed stomata) and in the light (open stomata).
2. Examine the strips to locate stomata.
3. Scan across guard cells with the electron probe microanalyzer set to measure K⁺ concentration.

RESULTS

CONCLUSION K⁺ concentration within the guard cells surrounding an open stoma was much greater than that in the guard cells surrounding a closed stoma.

FURTHER INVESTIGATION: What other ion or ions would you study in order to further explore the mechanism of stomatal opening?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

Showing how much potassium moves into the guard cells to open a stoma was a difficult feat. A typical guard cell is very small, with a total volume of less than 0.03 nanoliters when the stoma is closed and almost 0.05 nanoliters when it is open. The scientists who solved the problem used an *electron probe microanalyzer*, an instrument normally used by metallurgists to study the fine structure of alloys (Figure 35.10).

Individual stomata are tiny and plants lose large amounts of water (a single corn plant can lose 2 quarts per day); even so, you may find it surprising that there can be up to 250,000 stomata per square inch of leaf surface! To survive, plants limit water loss by controlling stomata in two very different ways:

- By regulating stomatal opening and closing
- By controlling the total number of stomata

The opening and closing of stomata is regulated by several environmental and endogenous factors. For example, water stress is a common problem for plants, especially on hot, windy days. In response to these conditions, plants will close their stomata, even when the sun is shining. The water potential of the mesophyll cells is the cue for this protective response. If the mesophyll is too dehydrated—that is, if its water potential is too negative—its cells release a plant hormone called *abscisic acid*. Absciscic acid causes the guard cells to close the stomata and prevent further drying of the leaf. This response reduces the rate of photosynthesis, but it protects the plant. Stomata also close in most plants when CO₂ levels in the mesophyll spaces are high. Can you think of a reason why this makes good biological sense?

A plant can also reduce its total number of stomata when water is in short supply. Trees can do this by losing some of their leaves. Other plants reduce the number of stomata on the new leaves they produce. For example, if the model plant *Arabidopsis* is exposed to high CO₂ levels, the new leaves that form on the plant have fewer stomata than they would have had under normal conditions. Why do you think this might be advantageous?

35.3 RECAP

Leaf pores called stomata admit the CO₂ needed for photosynthesis and also permit the exit of water by transpiration. Stomata can be opened or closed by guard cells to regulate water loss.

- What is the role of K⁺ ions in the functioning of guard cells? See p. 748 and Figure 35.9
- Describe how the external environment (including CO₂ level and light intensity) can affect stomatal function and number during the life of a plant. See p. 749

Stomata are normally open during daylight hours, allowing CO₂ to be fixed and converted to the products of photosynthesis. In the next section we'll see how these products are delivered to other parts of the plant, supporting plant growth.

35.4 How Are Substances Translocated in the Phloem?

Photosynthesis occurs primarily in the leaf (see Figure 10.1). The carbohydrate products of photosynthesis (mainly sucrose) diffuse to the nearest small vein (composed of xylem and phloem), where they are actively transported into sieve tube elements. The movement of carbohydrates and other solutes through the plant in the phloem is called **translocation**. Phloem content has several names, including *phloem sap*, *photosynthate*, and *assimilates*.

Substances in the phloem are translocated from *sources* to *sinks*.

- A **source** is an organ (such as a mature leaf or a storage root) that *produces* (by photosynthesis or by digestion of stored reserves) more sugars than it requires.
- A **sink** is an organ (such as a root, flower, developing fruit or tuber, or immature leaf) that *consumes* sugars for its own growth and storage needs.

Sugars (primarily sucrose), amino acids, some minerals, and a variety of other solutes are translocated between sources and sinks in the phloem. However, an organ that is a sink can turn into a source. For example, storage roots (such as sweet potatoes) are sinks when they accumulate carbohydrates but are sources when the stored reserves are needed to nourish other organs in the plant.

How do we know that such organic solutes are translocated in the phloem, rather than in the xylem? Over 300 years ago, the Italian scientist Marcello Malpighi performed a classic experiment in which he removed a ring of bark (containing the phloem) from the trunk of a tree—that is, he *girdled* the tree (**Figure 35.11**). Over time, the bark in the region above the girdle swelled. We now know that the swelling resulted from the accumulation of organic solutes that came from higher up the tree and could no longer continue downward because of the disruption of the phloem. Later, the bark below the girdle died because it no longer received sugars from the leaves. Eventually the roots, and then the entire tree, died.

Any explanation of the translocation of organic solutes must account for a few important observations:

35.11 Girdling Blocks Translocation in the Phloem By girdling—removing a ring of bark containing the phloem—Malpighi blocked the translocation of organic solutes in a tree. Bark below the girdle died because it no longer received nutrients; eventually the entire tree died.

- Translocation stops if the phloem tissue is killed by heating or other methods; thus the mechanism must be different from that of transport in the xylem. Recall that xylem is composed of dead cells.
- Translocation often proceeds in both directions—with some phloem transporting up the stem and parallel phloem transporting down the stem. The direction depends on the location of sources and sinks.
- Translocation is inhibited by compounds that inhibit respiration and thus limit the ATP supply in the source. Thus transport in the phloem, unlike the xylem, depends on the input of energy.

Let's first revisit the structure of the phloem to find clues to how it functions. Recall from Chapter 34 that the characteristic cells of the phloem are **sieve tube elements** (see Figure 34.9G). Like vessel elements, these cells meet end-to-end. However, unlike vessel elements, which break down their end walls as they mature, sieve tube elements contain plasmodesmata in the end walls. During sieve tube development, the diameter of these plasmodesmata increases 10- to 100-fold to form pores, enhancing the connection between neighboring cells. The result is end walls that look like sieves, called **sieve plates** (**Figure 35.12**).

35.12 Sieve Tubes Individual sieve tube elements join together to form long tubes that transport carbohydrates and other nutrient molecules throughout the plant body in the phloem. Sieve plates form at the ends of each sieve tube element, and phloem sap passes through the pores in the sieve plate.

What happens next is truly remarkable and makes sieve tube elements among the most unusual cell types in nature. As the holes in the sieve plates expand, most of the cell contents are lost, including the nucleus, Golgi apparatus, and most of the ribosomes and cytoskeleton. Despite this, sieve tube elements live for an entire growing season in trees and for decades in some cases. How can they live for so long with no nucleus? The answer is that each sieve tube element has one or more **companion cells** (see Figure 35.12), produced as daughter cells along with the sieve tube element when a parent cell divides. Numerous plasmodesmata link a companion cell with its sieve tube element. Companion cells retain all their organelles and, through the activities of their nuclei, provide all the functions needed to maintain the sieve tube elements—they may be thought of as the “life support systems” of the sieve tube elements.

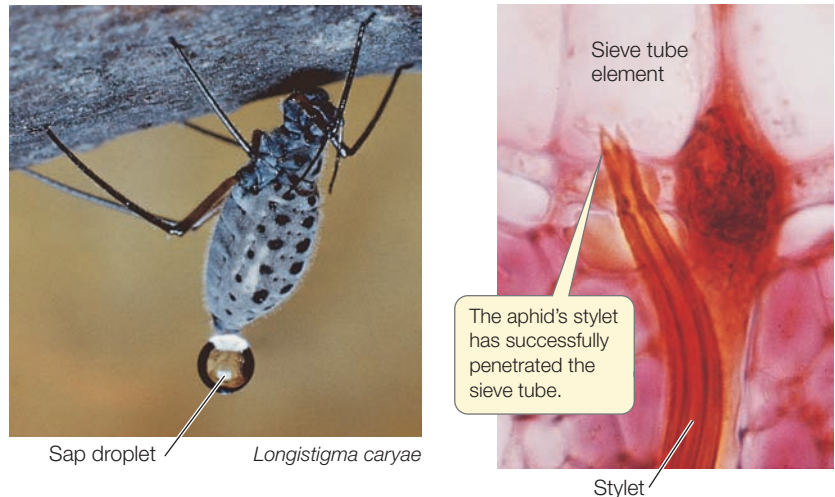

A mature sieve tube element is filled with phloem sap consisting of water, dissolved sugars, and other solutes. This solution moves through the sieve tube within the symplast, moving from cell to cell through enlarged plasmodesmata. However, because of the unique structural features of the living sieve tubes, phloem sap is able to move rapidly by bulk flow (like xylem sap).

Now that we have a better picture of the structure of the phloem, let's consider the experiments that led to our current understanding of phloem function.

To investigate translocation, plant physiologists needed to obtain samples of pure sieve tube sap from individual sieve tube elements. This difficult task was simplified when it was discovered that a common garden pest, the aphid, feeds on plants by drilling into a sieve tube with its specialized feeding organ, the *stylet*. The pressure within the sieve tube is higher than outside the plant, so the nutritious sieve tube sap is forced through the stylet and into the aphid's digestive tract. So great is the pressure that sugary liquid is forced through the insect's body and out the anus (Figure 35.13). This works because the phloem sap is under strongly positive pressure, unlike the negative pressure potential in the xylem. (We will discuss the forces underlying phloem movement a bit later in this section.)

Plant physiologists use aphids to collect phloem sap. When liquid appears on the aphid's abdomen, indicating that the insect has connected with a sieve tube, the physiologist quickly freezes the aphid and cuts its body away from the stylet, which remains in the sieve tube element and can exude phloem sap for hours. Chemical analysis of phloem sap collected from such a stylet reveals the contents of a single sieve tube element over time. Physiologists can also infer the rates at which different substances are translocated by measuring how long it takes for radioactive tracers administered to a leaf to appear at stylets at different distances from the leaf.

Recall that different substances can move in opposite directions in the phloem of a stem. Experiments with aphid stylets have shown that all the contents of any given sieve tube element move in the same direction. Thus, to account for bidirectional

35.13 Aphids Collect Sap Aphids feed on sap drawn from a sieve tube, which they penetrate with a modified feeding organ, the stylet. Pressure inside the sieve tube forces sap through the aphid's digestive tract.

translocation in the phloem, different sieve tubes must be conducting sap in opposite directions. These and other experiments led to the general adoption of the *pressure flow model* as an explanation for translocation in the phloem.

The pressure flow model appears to account for translocation in the phloem

As briefly noted above, phloem sap flows under positive pressure through the sieve tubes, moving from one sieve tube element to the next by bulk flow through the sieve plates, without crossing a membrane. We need to understand how this pressure is generated in order to understand translocation in the phloem.

Two steps in translocation require metabolic energy:

- Transport of sucrose and other solutes from sources into the sieve tubes; called *loading*
- Removal of the solutes from the sieve tubes into sinks; called *unloading*

According to the **pressure flow model** of translocation in the phloem, sucrose is actively transported into sieve tube elements at a source, giving those cells a greater sucrose concentration than the surrounding cells (think lower solute potential—more negative ψ_s). Water therefore enters the sieve tube elements from xylem vessels by osmosis. The entry of this water causes a greater pressure potential (turgor pressure) at the source end of the sieve tube, so that the entire fluid content of the sieve tube is pushed toward the sink end of the tube—in other words, the sap moves by bulk flow in response to a pressure gradient (Figure 35.14). In the sink, the sucrose is unloaded both passively and by active transport and water moves back to xylem vessels. In this way the gradient of solute potential and pressure potential needed for movement of phloem sap is maintained.

The pressure flow model of translocation in the phloem is contrasted with the transpiration–cohesion–tension model of xylem transport in Table 35.1.

TABLE 35.1

Mechanisms of Sap Flow in Plant Vascular Tissues

	XYLEM	PHLOEM
Driving force for bulk flow	Transpiration from leaves	Active transport of sucrose at source
Site of bulk flow	Nonliving vessel elements and tracheids	Living sieve tube elements
Pressure potential in sap	Negative (pull from top; tension)	Positive (push from source; pressure)

The pressure flow model has been experimentally tested

Even though the pressure flow model was first proposed more than half a century ago, some of its features are still being debated. Other mechanisms have been proposed to account for translocation in sieve tubes, but some have been disproved, and others do not have as much support as the pressure flow model.

Two requirements must be met in order for the pressure flow model to be valid:

- The sieve plates must be unobstructed, so that bulk flow from one sieve tube element to the next is possible.
- There must be an effective method for loading sucrose and other solutes into the phloem in source tissues and unloading them in sink tissues.

Let's see whether these requirements are met.

ARE THE SIEVE PLATES OPEN? Early electron microscopic studies of phloem samples cut from plants seemed to contradict the pressure flow model. The pores in the sieve plates always appeared to be plugged with masses of a fibrous protein, suggesting that sieve tube sap could not flow freely.

However, the fibrous protein seen in early electron micrographs turned out to be a normal plant response to wounding. When phloem is cut, the contents of the sieve elements are forced out through the sieve plate pores. To prevent massive losses of phloem sap, a fibrous protein, called P-protein, is synthesized in companion cells, enters the sieve elements through plasmodesmata, moves to the sieve plate pores, and seals them off. This short-term solution gives the plant time to repair the wound

site by synthesizing a polysaccharide called *callose*, which is thought to strengthen the cell wall.

More recent studies using rapid freezing, which prevents the wounding response, show open pores (see Figure 35.13) in the sieve plates.

HOW ARE SIEVE TUBE ELEMENTS LOADED AND UNLOADED? If the pressure flow model is correct, there must be mechanisms for loading sugars and other solutes into the phloem in source regions and for unloading them in sink regions.

Two general routes can be taken by sugars and other solutes as they move from the mesophyll cells to the phloem: apoplastic and symplastic.

The exact details vary widely among plant species. In many plants, sugars and other solutes follow the *apoplastic pathway*; they leave the mesophyll cells and enter the apoplast before they reach the sieve elements. Specific sugars and amino acids are then actively transported into cells of the phloem, and in this way reenter the symplast. Because the solutes cross at least one selectively permeable membrane in the apoplastic pathway, selective transport can be used to regulate which specific substances enter the phloem. In other plants, solutes follow a *symplastic pathway*; the solutes remain within the symplast all the way from the mesophyll cells to the sieve tube cells. Because no membranes are crossed in the symplastic pathway, a mechanism that does not involve membrane transport is used to load sucrose into the phloem.

In the apoplastic pathway, sucrose is actively loaded into the companion cells and sieve tubes by sucrose–proton symport, a secondary active transport mechanism. A proton pump actively pumps protons out of the phloem cells, increasing the concentration of protons in the apoplast. The protons then diffuse back

35.14 The Pressure Flow Model Water potential differences produce a pressure gradient and bulk flow of phloem sap from sources to sinks.

yourBioPortal.com

GO TO Animated Tutorial 35.2 • The Pressure Flow Model

into the phloem cells through sucrose–proton symport proteins, bringing sucrose with them.

In sink regions, the solutes are actively transported *out* of the sieve tube elements and into the surrounding tissues. This unloading serves two purposes: it helps maintain the gradient of solute potential and hence of pressure potential in the sieve tubes; and it helps build up high concentrations of sugars and starch in storage organs, such as developing fruits and seeds. Thus the second requirement of the pressure flow model is met, and the model is supported.

35.4 RECAP

Carbohydrates produced by photosynthesis are translocated from source to sink through the phloem by a pressure flow mechanism.

- Explain the difference between a source and a sink. **See p. 750**
- How does loading of sucrose at the source result in bulk flow toward the sink? **See p. 751 and Figure 35.14**

CHAPTER SUMMARY

35.1 How Do Plant Cells Take Up Water and Solutes?

- Water moves through biological membranes by osmosis, always moving toward regions with a more negative water potential. The **water potential** (ψ) of a cell or solution is the sum of the **solute potential** and the **pressure potential**. **Review Figure 35.2**
- **Turgid** plant cells have significant positive pressure potential because the rigid cell wall pushes back on the protoplast. This positive pressure (**turgor pressure**) maintains the physical structure of many plant cells; if the pressure potential drops, the plant *wilts*. **Review Figures 35.3 and 35.4**
- The movement of a solution due to a difference in pressure potential between two parts of a plant is called **bulk flow**.
- **Aquaporins** are channel proteins that facilitate movement of water molecules through biological membranes.
- Mineral uptake requires transport proteins. Some minerals enter the plant passively by facilitated diffusion; others enter by active transport. A **proton pump** provides energy for the active transport of many mineral ions across membranes in plants. **Review Figure 35.5**
- Water and minerals pass from the soil into the root by way of the **apoplast** and **symplast**, but must pass through the symplast to cross the endodermis and enter the xylem. The **Casparian strip** in the endodermis blocks movement of water and minerals through the apoplast. **Review Figure 35.6, WEB ACTIVITY 35.1**

35.2 How Are Water and Minerals Transported in the Xylem?

- **Root pressure** is responsible for guttation and for the oozing of sap from cut stumps, but it cannot account for the ascent of xylem sap in trees.
- Water transport in the xylem results from the combined effects of **transpiration**, **cohesion**, and **tension**—the **transpiration–**

cohesion–tension mechanism. Evaporation from the leaf produces tension in the mesophyll cells, which pulls a column of water—held together by cohesion—up through the xylem from the root. **Review Figure 35.7, ANIMATED TUTORIAL 35.1**

- Transport in the xylem is by bulk flow. It does not require the expenditure of energy. Dissolved minerals are carried passively in the water.

35.3 How Do Stomata Control the Loss of Water and the Uptake of CO₂?

- **Stomata** allow a compromise between water retention and carbon dioxide uptake.
- A pair of **guard cells** controls the size of the stomatal opening. A light-activated proton pump, moves protons out of the guard cells to the walls of surrounding epidermal cells, setting up an electrochemical gradient that drives the transport of potassium ions into the guard cells. Water follows osmotically, swelling the guard cells and opening the stomata. **Review Figures 35.9 and 35.10**
- When threatened by dehydration, mesophyll cells release abscisic acid, which causes guard cells to close the stomata, even in the light.

35.4 How Are Substances Translocated in the Phloem?

- Products of photosynthesis, as well as some minerals, are translocated through sieve tubes in the phloem by way of living **sieve tube elements**. **Review Figure 35.12**
- **Translocation** in the phloem can proceed in both directions in the stem, although it only goes one way in any given sieve tube. Translocation requires a supply of ATP.
- Translocation in the phloem is explained by the **pressure flow model**: the difference in solute concentration between **sources** and **sinks** creates a difference in (positive) pressure potential along the sieve tubes, resulting in bulk flow. **Review Figure 35.14 and Table 35.1, ANIMATED TUTORIAL 35.2**

SELF-QUIZ

1. Osmosis
 - a. requires ATP.
 - b. results in the bursting of plant cells placed in pure water.
 - c. can cause a cell to become turgid.
 - d. is independent of solute concentrations.
 - e. continues until the pressure potential equals the water potential.
2. Water potential
 - a. is the difference between the solute potential and the pressure potential.
 - b. is analogous to the air pressure in an automobile tire.
 - c. is the movement of water through a membrane.
 - d. determines the direction of water movement between cells.
 - e. is defined as 1.0 MPa for pure water under no applied pressure.

3. Which statement about aquaporins is *not* true?
 - a. They are membrane transport proteins.
 - b. Water movement through aquaporins is always active.
 - c. The permeability of some aquaporins is subject to regulation.
 - d. They vary in abundance depending on environmental conditions.
 - e. They enable water to pass through the phospholipid bilayer without encountering a hydrophobic environment.
4. Which statement about proton pumping across the plasma membrane of plants is *not* true?
 - a. It requires ATP.
 - b. The region inside the membrane becomes positively charged with respect to the region outside.
 - c. It enhances the movement of K^+ ions into the cell.
 - d. It pushes protons out of the cell against a proton concentration gradient.
 - e. It can drive the secondary active transport of negatively charged ions.
5. Which statement is *not* true?
 - a. The symplast consists of the interconnected cytoplasm of living cells.
 - b. Water can enter the stele without entering the symplast.
 - c. The Casparian strips prevent water from moving between endodermal cells.
 - d. The endodermis is a cell layer in the cortex.
 - e. Water can move freely in the apoplast without entering cells.
6. In the xylem,
 - a. the products of photosynthesis travel down the stem.
 - b. living, pumping cells push the sap upward.
 - c. the driving force is in the roots.
 - d. the sap is often under tension.
 - e. the sap must pass through sieve plates.
7. Which of the following is *not* part of the transpiration–cohesion–tension mechanism?
 - a. Water evaporates from the walls of mesophyll cells.
 - b. Removal of water from the xylem exerts a pull on the water column.
 - c. Water is remarkably cohesive.
 - d. The wider the tube, the greater the tension its water column can withstand.
 - e. At each step, water moves to a region with a more strongly negative water potential.
8. Stomata
 - a. control the opening of guard cells.
 - b. release less water to the environment than do other parts of the epidermis.
 - c. open when CO_2 levels inside the leaf are high.
 - d. do not respond to light.
 - e. close when water is being lost at too great a rate.
9. Which statement about phloem transport is *not* true?
 - a. It takes place in sieve tubes.
 - b. It depends on mechanisms for loading solutes into the phloem at sources.
 - c. It stops if the phloem is killed by heat.
 - d. A high pressure potential is maintained in the sieve tubes.
 - e. At sinks, solutes are actively transported into sieve tube elements.
10. The fibrous protein in sieve tube elements
 - a. may plug leaks when a plant is damaged.
 - b. clogs the sieve plates at all times.
 - c. never clogs the sieve plates.
 - d. serves no known function.
 - e. provides the driving force for transport in the phloem.

FOR DISCUSSION

1. Epidermal cells protect against excess water loss. How do they perform this function? What differences might you expect to find in the structure of the epidermis in stems, roots, and leaves?
2. Phloem transports material from sources to sinks. Give examples of each. How might the distribution of sources and sinks change in the course of a year?
3. What is the minimum number of plasma membranes a water molecule would have to cross in order to get from the soil solution to the atmosphere by way of the stele? To get from the soil solution to a mesophyll cell in a leaf?
4. Transpiration exerts a powerful pulling force on the water column in the xylem. When would you expect transpiration to proceed most rapidly? Why? Describe the source of the pulling force.

ADDITIONAL INVESTIGATION

In the story that opened this chapter we saw that a mutation in the *HARDY* gene resulted in *Arabidopsis* plants with a more extensive root system and thicker leaves than wild-type plants. When the *HARDY* gene was isolated, it was found to encode a transcription factor that stimulates expression of genes for

increased water use efficiency. What type of mutation in the *HARDY* gene would cause *Arabidopsis* plants to use water more efficiently? How would you investigate the effect of the *HARDY* mutation on stomata? What results would you expect?

When the land blew away

Two of the greatest disasters of recent times occurred because of the mismanagement of soil resources. One was in North America in the 1930s and the other is ongoing in Haiti.

Beginning in the early 1930s, a prolonged drought, combined with a culturally modified landscape, turned the central plains of North America into the Dust Bowl. The native vegetation in the Plains States in the nineteenth century was long grass in the east and short grass in the west. Cattlemen moved in to where their herds could eat a seemingly endless supply of food. But in fact the supply wasn't endless. As one area was overgrazed, the cattle were moved on to new areas, leaving damaged soil in their wake. Settlers followed, "busted the sod" with plows, planted crops, and disrupted vegetation cycles that had persisted for centuries.

In the early twentieth century, farmers in the Plains States began growing wheat, plowing both good and marginal soils. But wheat requires more water than did the native grasses, and rainfall was irregular throughout the 1920s. In 1932 rainfall was almost nonexistent and did not return at adequate levels until 1939.

Without water, crops failed—if they even started to grow. The U.S. plains are windy regions, and without plant roots there was nothing to hold the soil in place when the winds blew. The farms literally blew away. Farmers spent the last of their money on seeds, but dry year followed dry year. Destitute farmers migrated westward, along with others whose livelihoods had depended on the farmers. But they only encountered more difficulties, as these events took place during the Great Depression.

Unfortunately Dust Bowl conditions are not just a thing of the past. Today many countries around the world are struggling with land use issues. The consequences of poor land management, principally deforestation, are dramatically visible on the Caribbean island of Hispaniola. The island is shared by the countries of Haiti, which has mismanaged its soil resources, and the Dominican Republic, which hasn't. From an airplane window it is easy to see the 120-mile-long bor-

Dreams Disappeared in a Cloud of Dust

This photograph of a family displaced by the Dust Bowl was taken by Dorothea Lange in the winter of 1936. The family had traveled to northern California looking for work as migrant farm labor. In Lange's words, "I saw and approached the hungry and desperate mother...I did not ask her name or her history. ...She said that they had been living on frozen vegetables from the surrounding fields, and birds that the children killed. She had just sold the tires from her car to buy food."

A Border Marks Life and Death An aerial view of the border between Haiti (left) and the Dominican Republic (right) provides a dramatic illustration of the extent of deforestation in Haiti.

der between these two countries. The Dominican side is verdant and forested, while the Haitian side is devoid of plant life and most of its soil is gone.

Haiti's population, in addition to living in the poorest nation in the Western Hemisphere, has paid a huge price for the loss of its trees and soil. Because there are few plant roots to stabilize the soil in mountainous areas, rain washes the soil into the sea. Not only is this soil loss detrimental to agriculture, but the runoff hurts offshore reefs and the fisheries they support. To make matters worse, tropical storms all too often result in devastating landslides like the one that killed 2,600 Haitians in 2004.

As human activity increases, ecological disasters become all too common. Today, parts of sub-Saharan Africa's farmland are losing their topsoil as a result of poor land management, swelling populations, and a challenging climate. Crop failures, starvation, and large-scale human displacements are inevitable consequences.

IN THIS CHAPTER we consider the nutritional conditions that foster healthy and sustained plant growth. We identify nutrients that are essential to plants and how plants acquire them. Because most plant nutrients come from the soil, we discuss the formation of soils and the effects of plants on soils. We devote a section to the role played by fungi and bacteria in the uptake of phosphorus and nitrogen by plants, and we conclude with a look at carnivorous and parasitic plants.

CHAPTER OUTLINE

- 36.1** How Do Plants Acquire Nutrients?
- 36.2** What Mineral Nutrients Do Plants Require?
- 36.3** How Does Soil Structure Affect Plants?
- 36.4** How Do Fungi and Bacteria Increase Nutrient Uptake by Plant Roots?
- 36.5** How Do Carnivorous and Parasitic Plants Obtain a Balanced Diet?

36.1 How Do Plants Acquire Nutrients?

Every living thing—and plants are no exception—must obtain raw materials from its environment. These **nutrients** include the major ingredients of macromolecules: carbon, hydrogen, oxygen, and nitrogen. Plants are *autotrophs*, and obtain carbon from atmospheric carbon dioxide through the carbon-fixing reactions of photosynthesis (see Chapter 10). Hydrogen and oxygen come mainly from water, so these elements are plentiful with an adequate water supply. Nitrogen, as you will see later in this chapter, enters plants primarily through the activities of bacteria.

Living organisms need other **mineral nutrients** as well, which most plants obtain from the soil. For example, proteins contain sulfur (S), nucleic acids contain phosphorus (P), chlorophyll contains magnesium (Mg), cytochromes contain iron (Fe), and cellular signaling can involve calcium (Ca). Within the soil, these and other minerals dissolve in water as ions, forming a solution—called the **soil solution**—that contacts the roots of plants.

How does a stationary organism find nutrients?

Many organisms can move from place to place to find the nutrients they need. An organism that cannot move, termed a *sessile* organism, must obtain nutrients from sources that are somehow brought to it. With the exception of the carbon and oxygen in CO₂, a plant's supply of nutrients is strictly local, and a plant may use up the water and mineral nutrients in its local environment as it grows. How does a plant cope with the problem of scarce nutrient supplies?

As discussed in Chapter 34, plants differ fundamentally from animals in that they grow throughout their lifetimes. In fact, growth is a plant's version of movement. For example, roots obtain most of the mineral nutrients plants need. By growing through the soil, roots mine it for new sources of mineral nutrients and water. The growth of stems and leaves helps a plant secure light and carbon dioxide, which in turn allows the roots to continue their growth through the soil.

As it grows, a plant—or even a single root—must deal with a variable environment. Animal droppings create high local concentrations of nitrogen. A particle of calcium carbonate may make a tiny area of the soil alkaline, while dead organic matter may make a nearby area acidic. Such microenvironments encourage or discourage the proliferation of a root system and help direct its growth.

36.1 RECAP

Plants are autotrophs that obtain carbon by photosynthesis, and mineral nutrients and water from the soil.

- Why do plants need phosphorus? Why do they need nitrogen? [See p. 756](#)
- How does the ability to grow throughout their lifetime allow plants to seek out nutrients? [See p. 756](#)

We know that plants need nutrients to support their growth. Let's look in more detail at the specific mineral nutrients they need.

36.2 What Mineral Nutrients Do Plants Require?

Plants require many mineral nutrients ([Table 36.1](#)). Except for nitrogen, all mineral nutrients derive from rock and are usually taken up from the soil solution. A nutrient is called an **essential element** if its absence causes severe disruption of normal plant growth and reproduction. An essential element cannot be replaced by another element.

Essential elements fall roughly into two categories—*macronutrients* and *micronutrients* (see [Table 36.1](#))—based on the amounts required by plants.

- A plant needs **macronutrients** in concentrations of at least 1 gram per kilogram of the plant's dry matter.
- A plant needs **micronutrients** in concentrations of less than 100 milligrams per kilogram of the plant's dry matter.

How do we know if a plant is getting enough of a particular nutrient?

Deficiency symptoms reveal inadequate nutrition

Before a plant that is deficient in an essential element dies, it usually displays characteristic **deficiency symptoms**. [Table 36.1](#) lists the symptoms of some common mineral deficiencies, one of which is also shown in [Figure 36.1](#). Such symptoms help horticulturists diagnose mineral nutrient deficiencies in plants. With proper diagnosis, the missing nutrient(s) can be provided in the form of a **fertilizer** (an added source of mineral nutrients).

We know that the elements listed in [Table 36.1](#) are essential to the life of all plants. How did biologists discover which elements are essential?

TABLE 36.1

Mineral Elements Required by Plants

ELEMENT	ABSORBED FORM	MAJOR FUNCTIONS	DEFICIENCY SYMPTOMS
MACRONUTRIENTS			
Nitrogen (N)	NO_3^- and NH_4^+	In proteins, nucleic acids	Oldest leaves turn yellow and die prematurely; plant is stunted
Phosphorus (P)	H_2PO_4^- and HPO_4^{2-}	In nucleic acids, ATP, phospholipids	Plant is dark green with purple veins and is stunted
Potassium (K)	K^+	Enzyme activation; water balance; ion balance; stomatal opening	Older leaves have dead edges
Sulfur (S)	SO_4^{4-}	In proteins and coenzymes	Young leaves are yellow to white with yellow veins
Calcium (Ca)	Ca^{2+}	Affects the cytoskeleton, membranes, and many enzymes; second messenger	Growing points die back; young leaves are yellow and crinkly
Magnesium (Mg)	Mg^{2+}	In chlorophyll; required by many enzymes; stabilizes ribosomes	Older leaves have yellow stripes between veins
MICRONUTRIENTS			
Iron (Fe)	Fe^{2+} and Fe^{3+}	In active site of many redox enzymes and electron carriers; chlorophyll synthesis	Young leaves are white or yellow
Chlorine (Cl)	Cl^-	Photosynthesis; ion balance	Leaf tips wilt; leaves turn yellow and die
Manganese (Mn)	Mn^{2+}	Activation of many enzymes	Younger leaves are pale with green veins
Boron (B)	B(OH)_3	Required for proper cell wall formation and expansion	Poor growth of leaves and roots
Zinc (Zn)	Zn^{2+}	Enzyme activation; auxin synthesis	Young leaves are abnormally small; older leaves have many dead spots
Copper (Cu)	Cu^{2+}	In active site of many redox enzymes and electron carriers	New leaves are dark green, may have dead spots
Nickel (Ni)	Ni^{2+}	Activation of the enzyme urease	Leaf tips die; deficiency is rare
Molybdenum (Mo)	MoO_4^{2-}	Nitrate reduction	Leaves turn yellow between veins; older leaves die

36.1 Iron Deficiency Symptoms In crop plants, mineral deficiencies can often be detected in leaves, as in these blueberry leaves. As is typical of iron deficiency, the younger leaves are yellow, whereas the older leaves look normal.

used in nineteenth-century experiments on plant nutrition were sometimes so impure that they provided micronutrients that investigators thought they had excluded. Furthermore, some micronutrients are required in such tiny amounts that a seed may contain enough to supply the embryo and the resultant second-generation plant throughout its lifetime. There might even be enough left over to pass on to third-generation plants. Because of such difficulties, nutrition experiments must be performed in tightly controlled laboratories with special air filters that exclude microscopic salt particles in the air, and must use only the purest available chemicals.

Iron was the first micronutrient to be clearly established as essential, in the 1840s. The last micronutrient to be listed as essential was nickel, in 1983 (the experiment is described in **Figure 36.3**).

GO TO Animated Tutorial 36.1 • Nitrogen and Iron Deficiencies

Hydroponic experiments identified essential elements

An element is considered essential to plants if a plant fails to complete its life cycle or grows abnormally when that element is absent or insufficient. The essential elements for plants were identified by growing plants **hydroponically**—that is, with their roots suspended in nutrient solutions instead of soil (**Figure 36.2**). Growing plants in this manner allows for greater control of nutrient availability than is possible in a complex medium like soil. In the first successful experiments of this type, performed a century and a half ago, plants grew seemingly normally in solutions containing only calcium nitrate [$\text{Ca}(\text{NO}_3)_2$], magnesium sulfate (MgSO_4), and potassium phosphate (KH_2PO_4). A solution missing any of these compounds could not support normal growth. Tests with other compounds that included various combinations of these elements soon established six macronutrients—calcium, nitrogen, magnesium, sulfur, potassium, and phosphorus—as essential elements.

Identifying essential *micronutrients* by this experimental approach proved to be more difficult. The chemicals

TOOLS FOR INVESTIGATING LIFE

36.2 Growing Plants Hydroponically

Hydroponics is used to grow plants without soil. It is a classic procedure for identifying nutrients essential to plants. Nitrogen is used here as an example.

INVESTIGATING LIFE

36.3 Is Nickel an Essential Element for Plant Growth?

Using highly purified salts in growth media, Patrick Brown and his colleagues tested whether barley can complete its life cycle in the absence of nickel. Other investigators showed that no other element could substitute for nickel.

HYPOTHESIS Nickel is an essential element for a plant to complete its life cycle.

METHOD

1. Grow barley plants for 3 generations in nutrient solutions containing 0, 0.6, and 1.0 μM NiSO_4 .
2. Harvest seeds from 5–6 third-generation plants in each of the groups.
3. Determine the nickel concentration in seeds from each plant.
4. Germinate other seeds from the same plants on nickel-free medium and plot the success of germination against nickel concentration.

RESULTS

There was a positive correlation between seed germination and seed nickel concentration. There was significantly less germination at the lowest nickel concentrations.

CONCLUSION Barley seeds require nickel in order to germinate and thereby complete the life cycle.

36.2 RECAP

Mineral nutrients required by plants are classified as macronutrients and micronutrients, depending on the amount needed. Micronutrients are often needed in such minute amounts that only sophisticated chemical experiments can determine their essentiality.

- What are some specific mineral deficiency symptoms seen in plants? [See p. 757 and Table 36.1](#)
- Outline an experimental method for determining whether an element is essential to a plant. [See Figures 36.2 and 36.3](#)

As we have seen, all plants require nutrients for growth. Plants get nutrients in two ways. For plants growing in natural settings such as forests and fields, nutrients are derived from minerals in the soil. Crop plants, which often need large quantities of nutrients to support rapid growth, may be given nutrient supplements in the form of fertilizer. However, in either case, nutrition is not the only role the soil plays in the life of plants.

36.3 How Does Soil Structure Affect Plants?

Most terrestrial plants grow in soil. Soils provide:

- mechanical support
- mineral nutrients and water from the soil solution
- O_2 for root respiration

Soils also harbor many bacteria and other organisms; some of these are beneficial to plant life, but others are harmful. Some soils contain toxic levels of metal ions such as cadmium, chromium, and lead (see Chapter 39).

Soils are modified by natural phenomena, such as rain, temperature extremes, and the activities of plants and animals, and by the practices of humans—particularly agriculture. In this section, we examine the composition, structure, and formation of soils, as well as their role in plant nutrition.

Soils are complex in structure

Soils have living and nonliving components ([Figure 36.4](#)). The living components include plant roots as well as populations of bacteria, fungi, protists, and animals such as earthworms and insects. The nonliving portion of the soil includes rock fragments

36.4 The Complexity of Soil Soils favorable for plant growth contain both clay and larger mineral particles, as well as water, air, and organic matter. Other organisms are also present.

36.5 A Soil Profile The A, B, and C horizons can sometimes be seen in road cuts such as this one in Australia. The dark upper layer (the A horizon) is home to most of the living organisms in the soil.

ranging in size from large stones to sand to silt and finally to tiny particles of *clay* that are 2 μm or less in diameter. Soil also contains water and dissolved mineral nutrients, air spaces, and dead organic matter. The air spaces in soil contain O_2 .

Although soils vary greatly, almost all of them have a *soil profile* consisting of several recognizable horizontal layers, called **horizons**, lying on top of one another. Soil scientists recognize three major *horizons*—termed A, B, and C—in the profile of a typical soil (**Figure 36.5**).

Topsoil is the **A horizon**, which contains most of the soil's living and dead organic matter. Successful agriculture depends on the presence of a suitable A horizon; the A horizon is what blew away from the U.S. plains during the Dust Bowl (as we saw at the beginning of this chapter).

Topsoils vary greatly in their proportions of sand, silt, and clay, and this influences their ability to support plant growth. For example, mineral nutrients tend to be **leached** from the upper soil horizons—dissolved in rain or irrigation water and carried to deeper horizons, where they are unavailable to plant roots. Because sand particles are relatively large and cannot hold water, dissolved minerals are readily leached from sandy soil. Clay binds more water than sand does, and the charged surfaces of clay particles bind mineral ions that plant roots ultimately take up. But clay particles are tiny and pack tightly together, leaving little space for air. A **loam** is a soil that is an optimal mixture of sand, silt, and clay, and thus has sufficient levels of air, water, and available nutrients for plants. Loams also contain organic matter. Most of the best topsoils for agriculture are loams.

Below the A horizon is the **B horizon**, or **subsoil**, which is the zone of infiltration and accumulation of materials leached from

above. Farther down, the **C horizon** is the **parent rock**, also called bedrock, that is breaking down to form soil. Some deep-growing roots extend into the B horizon to obtain water and nutrients, but roots rarely enter the C horizon.

Soils form through the weathering of rock

Rocks are broken down into soil particles (**weathered**) in two ways: First, there is *mechanical weathering*, which is the physical breakdown of materials by wetting, drying, and freezing. Second there is *chemical weathering*, the alteration of the chemistry of the materials in the rocks. Several types of chemical weathering occur, all of which influence the availability of mineral nutrients:

- *Oxidation* by atmospheric oxygen
- *Hydrolysis* (reaction with water)
- Reaction with *acids* (particularly carbonic acid)

The parent rock and the weathering it undergoes determine the basic structure and chemical composition of a soil. However, a key soil characteristic for plants is the *availability* of nutrients, which must be dissolved in the soil solution for uptake by the plant. Chemical weathering results in clay particles covered with negatively charged chemical groups, which bind positively charged mineral nutrients (**Figure 36.6**). How do roots obtain these mineral nutrients?

Soils are the source of plant nutrition

Negatively charged clay particles form ionic bonds (see Section 2.2) with the positively charged ions (cations) of many minerals that are important for plant nutrition, such as potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}). To become available to plants or other organisms, these cations must be detached from the clay particles.

Recall that the root surface is covered with root hair cells (see Figure 34.11). Protein transporters in the plasma membrane of these cells actively pump protons (H^+) out of the cell. In addition, cellular respiration in the roots releases CO_2 , which dissolves in the soil water and reacts with it to form carbonic acid. This acid ionizes to form bicarbonate and free protons:

Proton-pumping by the root and ionization of carbonic acid both act to increase the proton concentration in the soil surrounding the root. The protons bind more strongly to clay particles than do mineral cations; in essence, they trade places with the cations in a process called **ion exchange** (see Figure 36.6). Ion exchange releases important cations into the soil solution, where they are available to be taken up by the roots. The capacity of a soil to support plant growth, called *soil fertility*, is determined in part by its ability to provide nutrients in this manner.

There is no comparable mechanism for binding and releasing negatively charged ions. As a result, important anions such as nitrate (NO_3^-) and sulfate (SO_4^{2-})—direct sources of nitrogen and sulfur, respectively—may leach rapidly from the A horizon.

36.6 Ion Exchange Plants obtain mineral nutrients from the soil primarily in the form of positive ions; potassium (K^+) is the example shown here.

Fertilizers and lime are used in agriculture

Agricultural soils are often deficient in one or more essential elements. Irrigation and rainwater leach mineral nutrients from the soil, and the harvesting of crops removes the nutrients that the crops took up from the soil during their growth. Unless the soil is replenished, crop yields will decrease. Mineral nutrients may be replaced by adding **fertilizers**: inorganic fertilizers of various types; or organic fertilizers, such as compost or rotted manure.

INORGANIC AND ORGANIC FERTILIZERS The three elements most commonly added to agricultural soils are nitrogen (N), phosphorus (P), and potassium (K). Commercial inorganic fertilizers are characterized by their “N-P-K” percentages. A 5-10-10 fertilizer, for example, contains 5 percent nitrogen, 10 percent phosphate (P_2O_5), and 10 percent potash (K_2O) by weight (of the nutrient-containing compound, not as weights of the elements N, P, and K). Sulfur, in the form of ammonium sulfate, is also occasionally added to soils.

Organic fertilizers such as manure or crop residues can also be used to supply mineral nutrients. Organic fertilizers have both advantages and disadvantages over inorganic fertilizers. Among the advantages:

- Organic fertilizers release nutrients slowly, which results in less leaching than occurs with a one-time application of an inorganic fertilizer.
- They contain residues of plant or animal materials that improve the structure of the soil, providing spaces for air movement, root growth, and drainage.

However, the nutrients in organic fertilizers are not in a form that is immediately available for absorption, as are the nutrients in inorganic fertilizers. Furthermore, unlike organic fertilizers, inorganic fertilizers can be formulated to meet the specific requirements of a particular soil and a particular crop.

pH EFFECTS ON NUTRIENTS The availability of nutrient ions, whether they are naturally present in the soil or added as fer-

tilizer, depends on soil pH. The proton concentration can affect the binding of nutrient cations to clay particles, as we saw earlier, and can also affect the solubility of other nutrients, such as iron, in the soil solution. The optimal soil pH for most crops is about 6.5, but so-called acid-loving crops such as blueberries prefer a pH closer to 4.

Rainfall and decomposition of organic substances lower the pH of soil, sometimes making it so acidic that plant growth is inhibited. Such acidification can be reversed by **liming**—the application of compounds commonly known as *lime*, such as calcium carbonate, calcium hydroxide, or magnesium carbonate. The addition of these compounds removes H^+ from the soil, and also increases the availability of calcium to plants.

Sometimes, on the other hand, a soil is not acidic enough for a crop. In this case, sulfur can be added in the form of elemental sulfur, which soil bacteria convert to sulfuric acid. Iron and some other elements are more available to plants at a slightly acidic pH. Because soil pH is so important for soil fertility, measuring pH is often the first step in deciding which amendments to add to soils for home gardens and agriculture.

SPRAY APPLICATION OF NUTRIENTS Spraying leaves with a nutrient solution is another effective way to deliver some essential elements to growing plants. Plants take up copper, iron, and manganese more readily from foliar (leaf) sprays than from the soil. Many foliar applications contain chemicals that partially dissolve the protective covering of leaf cells (the cuticle) to increase nutrient uptake.

Plants affect soil fertility and pH

The relationship between plants and soils is not a one-way affair—soils affect plants, but plants also affect soils. The soil that forms in a particular place depends not only on the underlying parent rock, mechanical weathering, and other such factors, but also on the particular plants that grow there. For example, dead plant matter provides most of the carbon-rich materials that break down to form **humus**—a dark-colored, organic soil component, each particle of which is too small to be recognizable with the naked eye. Soil bacteria and fungi produce humus by breaking down plant litter (such as fallen leaves and dead roots), animal feces, dead organisms, and other organic material. Humus is rich in mineral nutrients, especially nitrogen (from animal excrement). Humus also favors plant growth by trapping supplies of water and oxygen for absorption by roots.

Plants also affect the pH of the soil in which they grow. Roots maintain a balance of electric charges. If roots absorb more cations than anions, they excrete H^+ , thus lowering the soil pH. If they absorb more anions than cations, they excrete OH^- or HCO_3^- , raising the soil pH. Roots can also actively change the pH in their immediate vicinity by exuding organic acids, such as citric acid and malic acid, that acidify the soil, making it easier to take up certain ions such as ferric iron (Fe^{3+}). Looking at the big picture, we see that successful plant growth can help create conditions that favor further plant growth.

36.3 RECAP

Land plants live anchored in the soil and obtain water and mineral nutrients from it. Plants and soil interact in many ways. Plants can affect many aspects of the soil in which they grow, including mineral content and availability, pH, and the amount of humus. Many of these effects are beneficial to future plant growth.

- Explain how mechanical and chemical weathering form soil from rock. **See p. 760**
- How is soil fertility enhanced by the process of ion exchange? **See p. 760 and Figure 36.6**

Thus far we have focused on the uptake of nutrients in the soil by plant roots. An understanding of how plants acquire nutrients from the soil would be incomplete, however, without taking into account the involvement of *soil microbes*, including fungi and bacteria. In the next section we will focus on the intimate interactions of plants with these organisms, which are essential to the success of most terrestrial plants.

36.4 How Do Fungi and Bacteria Increase Nutrient Uptake by Plant Roots?

One gram of soil contains 6,000–50,000 bacterial *species* and up to 200 *meters* of fungal hyphae (the long branching cells of fungi), although both are largely invisible to the naked eye. In Chapter 39 we describe the strategies plants use to prevent infection by harmful soil microbes. It may surprise you that plants actively encourage a few species of fungi and bacteria to infect their roots and even invade root cells. In this section we describe the resulting “intracellular trading posts,” where products are exchanged to the mutual benefit of plants and a few very special soil microbes.

Mycorrhizae expand the root system of plants

The association of fungi with roots is so prevalent that it has its own name: **mycorrhizae** (singular, *mycorrhiza*) (from the Greek *mycos*, “fungus,” and *rhiza*, “root”). Recall from Chapter 30 that a multicellular fungus is called a **mycelium** (plural, *mycelia*) and that it is composed of rapidly growing individual tubular filaments called **hyphae** (singular, *hypha*). Two types of

mycorrhizae were introduced in Chapter 30 (see Section 30.2). In *ectomycorrhizae*, fungal hyphae wrap around the root (see Figure 30.11A) but do not penetrate the cells. In this section we will review features of a more widespread and intimate association: that of *arbuscular mycorrhizae*, where the fungal hyphae enter the root and form arbuscular (treelike) structures inside root cells (see Figure 30.11B). This is an evolutionarily ancient association. What is it about this interaction that makes it so enduring? What benefit does each partner derive?

In most cases, roots alone cannot nutritionally support vascular plant growth—they simply cannot reach all the nutrients available in the soil. Mycorrhizae expand the root surface area 10- to 1000-fold, increasing the amount of soil that can be scavenged for nutrients. In addition, because hyphae are much finer than root hairs, they can get into pores that are inaccessible to roots. In this way, mycorrhizae probe a vast expanse of soil for nutrients and deliver them into root cortical cells.

The primary nutrient that the plant obtains from a mycorrhizal interaction is phosphorus. In exchange, the fungus obtains an energy source, largely in the form of simple sugars. In fact, up to 20 percent of the photosynthate (the product[s] of photosynthesis) of terrestrial plants is directed to and consumed by arbuscular mycorrhiza fungi. Such associations are excellent examples of *mutualism*, an interaction between two species in which both species benefit (further discussed in Chapter 56). They are also examples of *symbiosis*, in which two different species live in close contact for a significant portion of their life cycles.

The events in the formation of arbuscular mycorrhiza are shown in **Figure 36.7**. Plant roots produce compounds called **strigolactones** that stimulate rapid growth of fungal hyphae toward the root. (We will return to strigolactones at the end of this chapter.) In response, fungi produce signals that stimulate expression of plant symbiosis-related genes. The products of some of these genes give rise to the *prepenetration apparatus* (PPA), which guides the growth of the fungal hyphae into the root cortex. The sites of nutrient exchange between fungus and plant are the *arbuscules*, which form within root cortical cells. Despite the intimacy of this association, the plant and fungal cytoplasm never mix—they are separated by two membranes, the fungal plasma membrane and the *periarbuscular membrane* (PAM), which is continuous with the plant plasma membrane. We will return to this structure and the features it shares with bacteria-induced root nodules in the next section.

Soil bacteria are essential in getting nitrogen from air to plant cells

The essential mineral nutrient most commonly in short supply, in both natural and agricultural situations, is nitrogen. This is surprising because elemental nitrogen (N_2) makes up almost four-fifths of Earth’s atmosphere. However, plants cannot use N_2 directly as a nutrient. The triple bond linking the two nitrogen atoms is extremely stable, and a great deal of energy is required to break it; thus N_2 is a highly unreactive substance. How, then, do plants obtain usable nitrogen for the synthesis of proteins and nucleic acids?

36.7 Formation of Arbuscular Mycorrhizae

Mycorrhizae develop by a highly coordinated process that involves signal exchanges between the plant and the fungus.

A few species of bacteria have an enzyme that enables them to convert N_2 into a more reactive and biologically useful form by a process called **nitrogen fixation**. These prokaryotic organisms—*nitrogen fixers*—convert N_2 to ammonia (NH_3). Although there are relatively few species of nitrogen fixers, and their biomass is small compared to that of the organisms that depend on them, these talented prokaryotes are essential to the biosphere as we know it.

Nitrogen fixers make all other life possible

By far the greatest share of total world nitrogen fixation is performed biologically by **nitrogen-fixing bacteria**, which fix approximately 170 million metric tons of nitrogen per year. About 80 million metric tons is fixed industrially by humans. Smaller amounts of nitrogen, about 20 million metric tons per year, are fixed in the atmosphere by nonbiological means such as lightning, volcanic eruptions, and forest fires. Rain brings these atmospherically formed products to the ground.

Several groups of bacteria fix nitrogen. In the oceans, various photosynthetic bacteria, including cyanobacteria, fix nitrogen. In fresh water, cyanobacteria are the principal nitrogen fixers. On land, free-living soil bacteria make some contribution to nitrogen fixation, but they fix only what they need for their own use and release the fixed nitrogen only when they die.

Important groups of nitrogen-fixing bacteria live in close association with plant roots. The plant obtains fixed nitrogen from the bacterium, and the bacterium obtains energy sources from the plant. As with arbuscular mycorrhizae, the relationship nitrogen-fixing bacteria have with plants is both mutualistic and symbiotic.

We will look at nitrogen-fixing symbioses in more detail later. But first: how does biological nitrogen fixation work?

Nitrogenase catalyzes nitrogen fixation

Nitrogen fixation is the *reduction* of nitrogen gas (see Section 9.1). It proceeds by the stepwise addition of three pairs of hydrogen atoms to N_2 (Figure 36.8). In addition to N_2 , these reactions require three things:

- A strong reducing agent to transfer hydrogen atoms (protons and electrons) to N_2 and to the intermediate products of the reaction
- A great deal of energy, which is supplied by ATP
- The enzyme **nitrogenase**, which catalyzes the reaction

Depending on the species of nitrogen fixer, either respiration or photosynthesis provides the necessary reducing agent and ATP.

Nitrogenase is strongly inhibited by oxygen, and many nitrogen fixers are anaerobes that live in environments with little or no O_2 . But rhizobia are aerobic and fix nitrogen in aerobic plant roots. How can nitrogenase function under these circumstances?

Plants typically house nitrogen-fixing bacteria in special root structures called **nodules**. Within a nodule, O_2 is maintained at a low level that is sufficient to support respiration, but not so high as to inactivate nitrogenase. This is possible because the cytoplasm of nodule cells contains a plant-produced protein called **leghemoglobin**, which is an O_2 carrier. Leghemoglobin is a close relative of hemoglobin, the red, oxygen-carrying pigment of animals, and is thus an evolutionarily ancient molecule. Some plant nodules contain enough of it to be bright pink inside. Leghemoglobin, with its iron-containing heme groups, transports enough oxygen to the nitrogen-fixing bacteria to support their respiration, while keeping free oxygen concentrations low enough to protect nitrogenase.

36.8 Nitrogenase Fixes Nitrogen Throughout the chemical reactions of nitrogen fixation, the reactants are bound to the enzyme nitrogenase. A reducing agent transfers hydrogen atoms to nitrogen, and eventually the final product—ammonia—is released. This reaction requires a large input of energy: about 16 ATPs are consumed per reaction.

Some plants and bacteria work together to fix nitrogen

Bacteria of several different genera, collectively known as **rhizobia** (singular, *rhizobium*), fix nitrogen in close, mutualistic association with the roots of plants in the legume family. The legumes include peas, soybeans, clover, alfalfa, and many tropical shrubs and trees. The bacteria infect the plant's roots, and in response the roots develop nodules that house the bacteria.

36.9 A Nodule Forms Rhizobia develop the ability to fix nitrogen only after entering a legume root. The diagrams show the sequence of events in nodule formation. The micrograph shows bacteroids of *Bradyrhizobium japonicum* in vesicles within a soybean root cell. A portion of an uninfected root cell is seen on the right.

Because of their ability to form nitrogen-fixing associations, legumes are often used in crop rotations; for example, farmers might plant clover or alfalfa occasionally to increase the available nitrogen content of the soil.

The legume–rhizobium association is not the only nitrogen-fixing symbiosis. Some cyanobacteria fix nitrogen in association with fungi (in lichens) or with ferns, cycads, or nonvascular plants. Rice farmers can increase crop yields by growing the water fern *Azolla*, with its symbiotic nitrogen-fixing cyanobacterium, in the flooded fields where rice is grown. Another group of bacteria, the filamentous actinobacteria, fix nitrogen in association with woody species such as alder and mountain lilacs.

Legumes and rhizobia communicate using chemical signals

Neither free-living rhizobia nor uninfected legumes can fix nitrogen. Only when the two are closely associated in root nodules does the reaction take place. The establishment of this symbiosis between a rhizobium and a legume requires a complex series of steps, with active contributions by both the bacterium and the plant root (**Figure 36.9**). First the root releases flavonoids and other chemical signals that attract soil-living rhizobia to the vicinity of the root. Flavonoids trigger the transcription of bacterial *nod* genes, the products of which synthesize Nod (nodulation) factors. These factors, secreted by the bacteria, cause cells

in the root cortex to divide, leading to the formation of a primary nodule meristem. This meristem gives rise to the plant tissue that constitutes the root nodule.

The bacteria enter the root via an infection thread and eventually reach cells in the interior of the root nodule. There the bacteria are released into the cytoplasm of the nodule cells, enclosed in plant-derived membrane vesicles. Inside the vesicles, the bacteria differentiate into **bacteroids**—the form of bacteria that can fix nitrogen.

The legume–rhizobium interaction is very specific. For example, only one species of rhizobium will form a nitrogen-fixing symbiosis with alfalfa; another rhizobium will only infect clover. The specificity of the interaction is determined in part by the specificity of the chemical signals exchanged by the plant and bacterium. The soil may not have the correct bacterium for a given legume crop, so farmers and gardeners often coat legume seeds with the appropriate rhizobium before planting.

There is increasing evidence that nodule formation depends on some of the same genes and mechanisms that allow mycorrhizae to develop. For example, both processes involve invagination of the plasma membrane to allow entry of the fungal hypha or rhizobia. The similarities of the structures formed during the development of mycorrhizae and nodules are especially striking considering that the symbioses involve members of two different *kingdoms* (fungi and bacteria) (**Figure 36.10**).

Biological nitrogen fixation does not always meet agricultural needs

Bacterial nitrogen fixation is not always sufficient to support the needs of agriculture. Traditional farmers used to plant dead fish along with corn; the decaying fish released nitrogen that the developing corn could use. Today farmers use inorganic nitrogen fertilizers produced through industrial nitrogen fixation to meet the food needs of a rapidly expanding population.

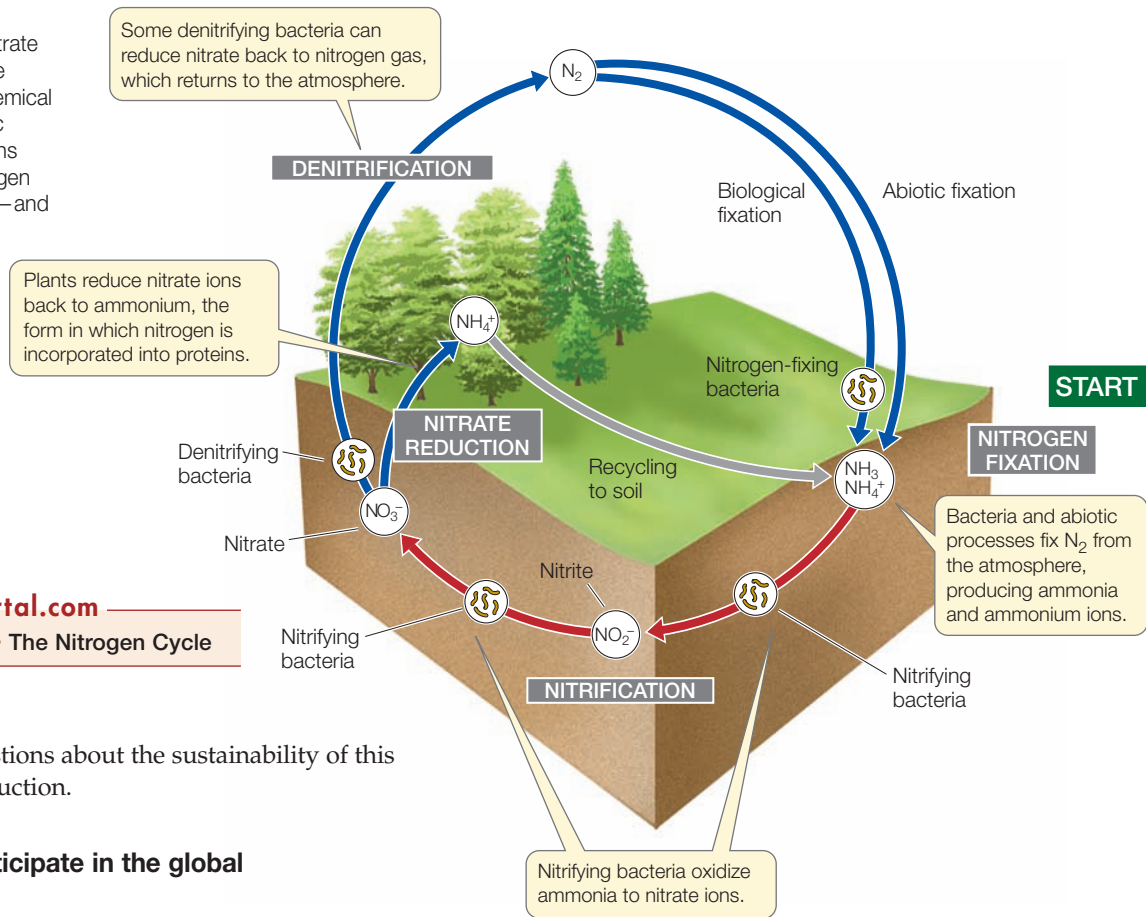

Most industrial nitrogen fixation is done by the *Haber process*, a chemical reduction that requires a great deal of energy. (Recall that biological nitrogen fixation consumes a lot of ATP—about 16 ATP per N fixed; see Figure 36.8.) At present in the United States, the manufacture of nitrogen-containing fertilizer takes more energy—primarily natural gas and hydroelectric—than does any other aspect of crop production. The rising cost and dwindling supply of energy

36.10 Intracellular Structures in Plant–Fungus and Plant–Rhizobium Symbioses Several steps in the development of mycorrhizae and nodules involve similar structures.

36.11 The Nitrogen Cycle

Nitrogen fixation, nitrification, nitrate reduction, and denitrification are components of an essential chemical cycle that converts atmospheric nitrogen gas into ammonium ions and nitrate ions—forms of nitrogen that can be taken up by plants—and returns N_2 to the atmosphere.

yourBioPortal.com

GO TO Web Activity 36.1 • The Nitrogen Cycle

sources raises serious questions about the sustainability of this approach to fertilizer production.

Plants and bacteria participate in the global nitrogen cycle

Nitrogen moves through the biosphere in a **global nitrogen cycle** (Figure 36.11), which includes four key steps:

1. *Fixation* of atmospheric N_2 to NH_3 and NH_4^+ by bacteria and by abiotic processes
2. *Nitrification* of these molecules to nitrate by bacteria
3. *Nitrate reduction* by plants
4. *Denitrification* of nitrate by bacteria back to N_2 , which is then released to the atmosphere to begin another cycle

The nitrogen released into the soil as a result of nitrogen fixation is primarily in the form of ammonia (NH_3) and ammonium ions (NH_4^+). Although ammonia can be toxic to plants if it accumulates in tissues, ammonium ions can be taken up safely at low concentrations. Soil bacteria called **nitrifiers** oxidize ammonia to nitrate ions (NO_3^-)—another form that plants can take up—by the process of **nitrification**. Soil pH affects which form of nitrogen is taken up by plants: nitrate ions are taken up preferentially under more acidic conditions, ammonium ions under more basic ones. To use nitrate, a plant must first reduce it to ammonium in a process called **nitrate reduction**. This occurs in two enzyme-catalyzed steps. The first step, from nitrate (NO_3^-) to nitrite (NO_2^-), takes place in the cytoplasm; the second, from nitrite (NO_2^-) to ammonia (NH_4^+), in the plastids. The plant uses the ammonia to manufacture amino acids, from which the plant's proteins and all its other nitrogen-containing compounds are formed. Animals cannot reduce nitrogen, and they depend on plants to supply them with reduced nitrogenous compounds.

The nitrogen cycle is essential for life on Earth: nitrogen-containing compounds constitute 5–30 percent of a plant's total dry weight. The nitrogen content of animals is even higher, and all of it arrives there by way of the plant kingdom.

36.4 RECAP

Two mutualistic interactions with soil microbes are critical to the success of terrestrial plants. Fungi and plants form mycorrhizae, which greatly increase the soil area that roots can scavenge for nutrients. Bacteria in soils and root nodules fix inert, atmospheric nitrogen into forms that plants and ultimately animals can use. Denitrification returns nitrogen from dead organisms and animal waste back to the atmosphere, continuing the global nitrogen cycle.

- What is exchanged between plants and fungi in mycorrhizae? **See p. 762**
- What, besides nitrogenase, is required to reduce nitrogen gas to a form plants can use? **See p. 763 and Figure 36.8**
- How is the formation of a root nodule on a legume similar to the formation of an arbuscular mycorrhiza? **See p. 765 and Figure 36.10**

Let's turn now to some special mechanisms for obtaining nutrients that have evolved in plant species with unusual lifestyles.

36.5 How Do Carnivorous and Parasitic Plants Obtain a Balanced Diet?

Most plants obtain their mineral nutrients from the soil solution (with the help of fungi), but some use other sources. Carnivorous and parasitic plants are examples of such plants.

Carnivorous plants supplement their mineral nutrition

Some plants augment their nitrogen supply by capturing and digesting flies and other insects. There are about 500 of these **carnivorous plant** species, the best known of which are Venus flytraps (genus *Dionaea*; **Figure 36.12A**), sundews (genus *Drosera*; **Figure 36.12B**), and pitcher plants (genus *Sarracenia*).

Carnivorous plants are typically found in boggy habitats that are acidic and nutrient deficient. To obtain extra nitrogen, these plants capture animals, digest their proteins, and absorb the amino acids. Pitcher plants have pitcher-shaped leaves that collect small amounts of rainwater. Insects and even small rodents are lured into the pitchers by bright colors or attractive scents and are prevented from leaving by stiff, downward-pointing hairs. The animals eventually die and are digested by a combination of plant enzymes and bacteria in the water. Sundews have leaves covered with hairs that secrete a clear, sticky, sugary liquid. Insects become stuck to these hairs, and more hairs curve over to further entrap them. Enzymes secreted by the plant digest the insects. Venus flytraps have specialized leaves with two halves that fold together. When an insect touches trigger hairs on a leaf, its two halves quickly come together, their spiny margins interlocking and imprisoning the insect before it can escape. The leaf then secretes enzymes that digest its prey.

The closing of the Venus flytrap's leaf is one of the fastest movements in the plant world, requiring only 0.1 sec. To find out how this happens, Dr. Lakshminarayanan Mahadevan and colleagues painted fluorescent dots on the surface of the flytrap's leaf surface and used high-speed cameras to record the trap snapping shut when its trigger hairs were touched. They then used computer analysis of the recorded dot movements to generate a mathematical model to help explain the movement. The researchers found that the first step is the elongation of cells on the outer surface of the leaf. The expansion of only one side of the leaf

causes it to snap from a convex into a concave shape, much like a contact lens flipping inside out.

Carnivorous plants do not need to feed on insects, but doing so helps them grow faster in their natural habitats. They use the additional nitrogen from the insects to make more proteins, chlorophyll, and other nitrogen-containing compounds.

Parasitic plants take advantage of other plants

Approximately 1 percent of flowering plant species derive some or all of their water, nutrients, and sometimes even photosynthate from other plants. In these **parasitic plants**, absorptive organs called **haustoria** have evolved that invade the host and tap into the vascular tissues in the root or stem.

Parasitic plants are divided into two broad classes based on their nutritional interactions with their hosts. **Hemiparasites** can still photosynthesize, but derive water and mineral nutrients from the living bodies of other plants. Perhaps the most familiar hemiparasites are the several genera of mistletoes. Mistletoes are green and carry on some photosynthesis, but they parasitize other plants for water and mineral nutrients and may derive photosynthetic products from them as well. Dwarf mistletoe (*Arceuthobium americanum*) is a serious parasite in forests of the western United States, destroying more than 3 billion board feet of lumber per year.

Holoparasites are completely parasitic and do not perform photosynthesis. They are taxonomically and morphologically diverse. Some, such as members of the dodder family, are plant-like in appearance, with small leaf remnants and flowers (**Figure 36.13**). Some holoparasites do not have leaves or stems because they spend most of their life cycle underground and only break the surface to flower.

Several parasitic plant species lack many of the genes normally present in the chloroplast genome (which in turn is only a remnant of the genome in the original endosymbiont from which the chloroplast evolved; see Sections 5.5 and 27.1). These genes, which are needed for photosynthesis, have been lost because there is no evolutionary pressure to retain them. Thus, while the parasitic lifestyle can be viewed as a free ride, for some

(A) *Dionaea muscipula*

(B) *Drosera rotundifolia*

36.12 Carnivorous Plants Some plants have adapted to nitrogen-poor environments by becoming carnivorous. (A) The Venus flytrap obtains nitrogen from the bodies of insects trapped inside the plant when its hinges snap shut. (B) Sundews trap insects on sticky hairs. Secreted enzymes will digest the carcass externally.

36.13 A Parasitic Plant Tendrils of dodder (genus *Cuscuta*) wrap around a goldenrod (genus *Solidago*). The parasitic dodder obtains water, sugars, and other nutrients through tiny, rootlike protuberances that penetrate the surface of the host plant.

plants it is also a one-way ticket, with no possibility of return to self-sufficiency.

The plant–parasite relationship is similar to plant–fungi and plant–bacteria associations

Plant–bacteria and plant–fungus relations both involve reciprocal signaling between the two species (see Figures 36.7 and 36.9). Parasitic plants also need to detect nearby plants so they can obtain their nutrients, but obviously this is to the disadvantage of the potential host plant. In one interesting case, a mechanism has evolved in a parasitic plant to recognize the chemical signals produced by plants to attract beneficial fungi.

The holoparasite *Striga* (witchweed) is a serious pest of cereal crops in Africa (see the opening story of Chapter 30). Earlier in this chapter, you learned that arbuscular fungi are attracted to plant roots by compounds called strigolactones. One of these same molecules was discovered over 60 years ago as an inducer of germination of some parasitic plants, including *Striga*. Scientists strongly suspect that this is no coincidence. The mycorrhizal interaction is ancient (over 400 million years old) and predates the evolution of parasitic plants. For this reason scientists hypothesize that a mechanism evolved in the ancestors of modern *Striga* to recognize a compound that was already produced by plants to attract soil microbes.

In *Striga* we thus find an example of “opportunistic evolution”—that is, the repurposing of preexisting processes rather than the invention of new processes from scratch. This is not the first time we have encountered this phenomenon in this chapter. Recall that the formation of nodules by rhizobia uses some of the same mechanisms utilized by arbuscular fungi to establish residence inside plant cells (see Figure 35.10), implying an evolutionary connection between the two symbioses.

36.5 RECAP

Carnivorous plants supplement their nutrition by extracting materials from animals. Rapid reflexes have evolved in some of these plants for trapping their prey. Parasitic plants, on the other hand, get some or all of their sustenance from other plants. Extreme holoparasites cannot function as autotrophs, having lost chloroplast genes coding for photosynthetic machinery. At least one parasitic plant responds to the same signaling molecule that the host plant uses to attract beneficial fungi.

- Why do carnivorous plants eat animals? **See p. 767**
- How do the needs of holoparasitic plants differ from those of carnivorous plants? **See p. 767**
- What characteristics are shared among plant–parasite, plant–fungus, and plant–bacteria associations?

CHAPTER SUMMARY

36.1 How Do Plants Acquire Nutrients?

- Plants are photosynthetic autotrophs that can produce all their organic molecules from carbon dioxide, water, and minerals, including a nitrogen source.
- **Mineral nutrients** are obtained from the **soil solution**.
- Root growth allows plants, which are sessile, to search for mineral resources.
- Microenvironments within the soil, such as acidic or alkaline areas, affect the direction of root growth.

36.2 What Mineral Nutrients Do Plants Require?

- Plants require 14 **essential elements**. Of these, six are **macronutrients** and eight are **micronutrients**. **Deficiency symptoms** suggest what essential element a plant lacks. **Review Table 36.1 and Figure 36.1**
- The essential elements were discovered by growing plants on **hydroponic solutions** that lacked individual elements. **Review Figures 36.2 and 36.3, ANIMATED TUTORIAL 36.1**

36.3 How Does Soil Structure Affect Plants?

- **Soils** contain water, air, and inorganic and organic substances. Soils have living (biotic) and nonliving (abiotic) components. **Review Figure 36.4**

- A soil typically consists of two or three horizontal zones called **horizons**. **Topsoil** forms the uppermost or **A horizon**. Topsoil tends to lose mineral nutrients through **leaching**. **Loams** are excellent agricultural topsoils, with a good balance of sand, silt, clay, and organic matter. **Review Figure 36.5**
- Soils form by mechanical and chemical **weathering** of rock. Chemical weathering imparts mineral nutrients to **clay** particles. Plant litter and other organic matter decomposes to form **humus**. Plants obtain some mineral nutrients through **ion exchange** between the soil solution and the surface of clay particles. **Review Figure 36.6**
- Farmers use **fertilizers** to make up for deficiencies in soil mineral nutrient content. **Liming** can reverse acidification.
- Plants can influence the characteristics, including the pH, of the soil in which they grow.

36.4 How Do Fungi and Bacteria Increase Nutrient Uptake by Plant Roots?

- **Mycorrhizae** are symbiotic root–fungus associations that greatly increase a plant’s absorption of water and minerals, especially phosphorus. They occur in 80 percent of plant species.
- The fungal **mycelia** invade root cortex cells and form arbuscules, which are the sites of nutrient exchange between the fungus and plant. **Review Figure 36.7**
- In the earliest stages of mycorrhiza formation, the **hyphae** of arbuscular fungi grow toward **strigolactones**, compounds that are produced by the plant roots.
- Some **nitrogen-fixing bacteria** live free in the soil; others live symbiotically as **bacteroids** within plant roots. In **nitrogen fixation**, nitrogen gas (N_2) is reduced to ammonia (NH_3) or ammonium ions (NH_4^+) in a reaction catalyzed by **nitrogenase**. **Review Figure 36.8**
- Nitrogenase requires anaerobic conditions, but the bacteroids in root **nodules** require oxygen, which is maintained at the proper level by **leghemoglobin**.

- The formation of a root nodule requires interaction between the root system of a legume and a **rhizobium**. **Review Figure 36.9**
- Several steps in the formation of root nodules and arbuscules are similar and probably involve some of the same plant genes. **Review Figure 36.10**
- In agriculture, biological nitrogen fixation must usually be supplemented with commercial nitrogen fertilizers made by the Haber process.
- Plants and bacteria interact in the **global nitrogen cycle**, which involves a series of reductions and oxidations of nitrogen-containing molecules. **Review Figure 36.11, WEB ACTIVITY 36.1**
- **Nitrification** by bacteria converts ammonia to nitrate ions in the soil. **Nitrate reduction** is carried out by plant enzymes, enabling plants to form their own nitrogen compounds. **Denitrification** returns nitrogen from animal wastes and dead organisms to the atmosphere.

36.5 How Do Carnivorous and Parasitic Plants Obtain a Balanced Diet?

- **Carnivorous plants** are autotrophs that supplement a low nitrogen supply by feeding on insects or other small animals.
- **Parasitic plants** draw on other plants to meet their needs, which may include minerals, water, or the products of photosynthesis.
- **Hemiparasites**, such as mistletoes, can still photosynthesize. Extreme **holoparasites** cannot function as autotrophs because they have lost chloroplast genes that code for components of the photosynthetic apparatus (which they no longer need).
- A strigolactone—a compound in the same category of compounds plants use to attract mycorrhizal fungi—also induces the germination of some parasitic plants, including *Striga*.
- Scientists hypothesize that a mechanism evolved in the ancestors of modern *Striga* to recognize a compound that was already produced by plants to attract arbuscular fungi.

SELF-QUIZ

- Macronutrients
 - are so called because they are more essential than micronutrients.
 - include manganese, boron, and zinc, among others.
 - function as catalysts.
 - are required in concentrations of at least 1 gram per kilogram of plant dry matter.
 - are obtained by the process of photosynthesis.
- Which of the following is *not* an essential mineral element for plants?
 - Potassium
 - Magnesium
 - Calcium
 - Lead
 - Phosphorus
- Fertilizers
 - are often characterized by their N-P-O percentages.
 - are not required if crops are removed frequently enough.
 - restore needed mineral nutrients to the soil.
 - are needed to provide carbon, hydrogen, and oxygen to plants.
 - are needed to destroy soil pests.
- In a typical soil,
 - the topsoil tends to lose mineral nutrients by leaching.
 - there are four or more horizons.
 - the C horizon consists primarily of loam.
 - the dead and decaying organic matter gathers in the B horizon.
 - more clay means more air space and thus more oxygen for roots.
- Which of the following is *not* true for arbuscules?
 - They are an ancient association between plants and fungi.
 - They expand the effective root area of plants and allow more efficient water uptake.
 - They are a significant source of fixed nitrogen for plants.
 - They are a significant source of phosphorous for plants.
 - Most land plants have them.
- Nitrogen fixation is
 - performed only by plants.
 - the oxidation of nitrogen gas.
 - catalyzed by the enzyme nitrogenase.
 - a single-step chemical reaction.
 - possible because N_2 is a highly reactive substance.

7. Nitrification is
 - a. performed only by plants.
 - b. the reduction of ammonium ions to nitrate ions.
 - c. the reduction of nitrate ions to nitrogen gas.
 - d. catalyzed by the enzyme nitrogenase.
 - e. performed by certain bacteria in the soil.
8. Which of the following is an early step in the formation of *both* arbuscules and root nodules?
 - a. Invasion of a plant root by a fungus
 - b. Invasion of a plant root by a bacterium
 - c. Strigolactones produced by the root are recognized by the microbe
 - d. Root cells are invaded but there is no direct contact between plant and microbe cell contents
 - e. Root cells are invaded and there is direct contact between plant and microbe cell contents
9. Which of the following is a parasite?
 - a. Venus flytrap
 - b. Pitcher plant
 - c. Sundew
 - d. Dodder
 - e. Tobacco
10. All carnivorous plants
 - a. are parasites.
 - b. depend on animals as a source of carbon.
 - c. are incapable of photosynthesis.
 - d. depend on animals as their sole source of phosphorus.
 - e. obtain supplemental nitrogen from animals.

FOR DISCUSSION

1. Methods for determining whether a particular element is essential have been known for more than a century. Since these methods are so well established, why was the essentiality of some elements discovered only recently?
2. If a Venus flytrap were deprived of soil sulfates and hence made unable to synthesize the amino acids cysteine and methionine, would it die from lack of protein? Explain.
3. Soils are dynamic systems. What changes might result when land is subjected to heavy irrigation for agriculture after being relatively dry for many years? What changes in the soil might result when a virgin deciduous forest is cut down and replaced by crops that are harvested each year? Even though the countries share the same island, why are hurricanes frequently accompanied by the loss of life in Haiti but not in the Dominican Republic?
4. We mentioned that important positively charged ions are held in the soil by clay particles, but other, equally important, negatively charged ions are leached deeper into the soil's B horizon. Why doesn't leaching cause an electrical imbalance in the soil? (Hint: think of the ionization of water.)
5. The biosphere of Earth as we know it depends on the existence of a few species of nitrogen-fixing prokaryotes. What do you think might happen if one of these species were to become extinct? If all of them were to disappear?
6. Holoparasitic plants have lost many of the morphological and genetic traits necessary for an autotrophic lifestyle. From an evolutionary point of view, how do you think this happened? (Hint: think about selection pressures.)

ADDITIONAL INVESTIGATION

Some mutant *Arabidopsis* plants that are very bushy (their shoots are more highly branched than wild-type plants) cannot make strigolactones because of a mutation in a gene necessary for strigolactone biosynthesis. If an investigator applies strigo-

lactones to the plants, they grow normally. What does this experiment suggest about the role of strigolactones in plant growth? How does this add to the story of strigolactones as signals for arbuscules and parasitic plants?

WORKING WITH DATA (GO TO yourBioPortal.com)

Is Nickel an Essential Element for Plant Growth? In this hands-on exercise, you will critically examine the experimental approach used by Patrick Brown and his colleagues to show that barley plants require nickel for their life cycle (Figure 36.3).

Analyzing data from the original paper, you will calculate the critical value, the tissue concentration below which growth is significantly reduced.

Saving millions of lives by regulation of plant development

There is no Nobel Prize for agriculture as there is for medicine, the other branch of applied biology. This is not because plant biology is unimportant; it is because agriculture was not mentioned in the will of the prize's benefactor, Alfred Nobel. But a Nobel prize was awarded in this field: plant geneticist Norman Borlaug received the Peace Prize for research on wheat that has been estimated to have saved a billion lives.

In their constant search for ways to help farmers produce more food for a growing population, biologists have developed crop plants whose physiology allows them to produce more grain per plant (higher yield). However, when a plant produces a lot of seeds, the sheer weight of the load may cause the stem to bend over, or even break. This makes harvesting the seeds impossible: think of how

hard it would be to get enough food for your family if you had to pick up seeds on the ground, some of which had already sprouted.

In 1945, the U.S. Army temporarily occupied Japan, which it had defeated in World War II. During the war, Japan, an island nation, was blockaded and could not import food. How had they been able to grow enough grain to feed their people? The answer lay in the fields: the Japanese had bred genetic strains of rice and wheat with short, strong stems that could bear a high yield of grain without bending or breaking. This innovation made an impression on an agricultural advisor who happened to be among the first wave of U.S. occupiers, and seeds of the Japanese strains were sent back to the U.S.

A decade later, Borlaug, who was working in Mexico at the time, began genetic crosses of what were known as semi-dwarf wheat plants from Japan with varieties that had genes conferring rapid growth, adaptability to varying climates, and resistance to fungal diseases. The results were genetic strains of wheat that gave record yields, first in Mexico and then in India and Pakistan in the 1960s. At about the same time and using a similar strategy, scientists in the Philippines developed semi-dwarf rice with equally spectacular results. People who had lived on the edge of starvation now produced enough food. Countries that had been relying on food aid from

Norman Borlaug Seen here in a field of semi-dwarf wheat, plant geneticist Norman Borlaug carried out a program of genetic crosses that led to high-yielding varieties and saved millions from starvation.

Semi-Dwarf Rice The short variety of rice can give higher yields of grain than its taller counterpart (right). The difference is that the latter can respond to the hormone gibberellin.

other countries were now growing so much grain that they could export the surplus. The development of these semi-dwarf grains began what was called the “Green Revolution.”

It is only recently that plant biologists have discovered why semi-dwarf wheat and rice have short stems. In normal plants a hormone called gibberellin stimulates stem elongation. But in the semi-dwarf plants, a mutation affects the signal transduction mechanism for gibberellin so that the stem cells do not respond to it and growth is reduced. The lives of countless people have been saved by a disruption of hormone signaling.

IN THIS CHAPTER we will give a brief overview of the life of a flowering plant and its developmental stages. We will explore the nature of the environmental cues, photoreceptors, and hormones (including gibberellin) that regulate plant growth and development. We will also consider the multiple roles and interactions of these different elements.

CHAPTER OUTLINE

- 37.1** How Does Plant Development Proceed?
- 37.2** What Do Gibberellins Do?
- 37.3** What Does Auxin Do?
- 37.4** What are the Effects of Cytokinins, Ethylene, and Brassinosteroids?
- 37.5** How Do Photoreceptors Participate in Plant Growth Regulation?

37.1 How Does Plant Development Proceed?

As Chapter 34 describes, plants are sessile organisms that must seek out resources above and below the ground. Features that maximize the ability of plants to obtain the resources that they need to grow and reproduce include:

- *Meristems*. Plants have permanent collections of stem cells (undifferentiated, constantly dividing cells) that allow them to continue growing throughout their lifetimes (see Section 34.4).
- *Post-embryonic organ formation*. Unlike animals, plants can initiate development of new organs such as leaves and flowers throughout their lifetimes.
- *Differential growth*. Plants can allocate their resources so that they grow more of the organs that will benefit them most; for example, more leaves to harvest more sunlight or more roots to obtain more water and nutrients.

To use growth for maximal advantage, plants must continuously monitor their environment and redirect their growth as appropriate. Under normal circumstances a plant’s environment is never completely stable. For example, the amount of light changes from day to night and from season to season. In addition, other plants are often vying for what light there is, and plants modulate their growth to compete with their neighbors for this precious resource. As you will see in this chapter, several mechanisms have evolved in plants to sense their environment and trigger appropriate growth responses.

The *development* of a plant—the series of progressive changes that take place throughout its life—is regulated in many ways. Key factors involved in regulating plant growth and development are:

- *Environmental cues*, such as day length
- *Receptors* that allow a plant to sense environmental cues, such as photoreceptors that absorb light, and chemoreceptors that signal the presence of pathogens (see Chapter 39)
- *Hormones*—chemical signals that mediate the effects of the environmental cues, including those sensed by receptors
- The plant’s *genomes*, which encode regulatory proteins and enzymes that catalyze the biochemical reactions of development

We will explore these regulatory mechanisms in more detail later in this chapter. But first let’s look at the initial steps of plant development—from seed to seedling—and the types of internal and external cues that guide them.

In early development, the seed germinates and forms a growing seedling

If all developmental activity is suspended in a seed, even when conditions appear to be suitable for its growth, the seed is said to be **dormant**. Cells in dormant seeds do not divide, expand, or differentiate. For the embryo to begin developing, seed dormancy must be broken by one of the mechanisms discussed later in this section.

As the seed begins to **germinate**—to develop into a seedling—it takes up water. The growing embryo then obtains chemical building blocks—carbohydrate, amino acid, and lipid monomers—for its development by digesting the polysaccharides, fats, and proteins stored in the seed. As we will see later, the embryos of some plant species secrete hormones that direct the mobilization of these reserves. Germination is completed when the **radicle** (embryonic root) emerges from the seed coat. The plant is then called a **seedling**.

If the seed germinates underground, the new seedling must elongate rapidly (in the right direction!) and cope with a period of life in darkness or dim light. A series of photoreceptors direct this stage of development and prepare the seedling for growth in the light.

Early shoot development varies among the flowering plants.

Figure 37.1 shows the shoot development patterns of monocots and eudicots.

Environment cues can initiate seed germination

The seeds of some plant species are capable of germinating as soon as they have matured. All they need for germination is water. But the seeds of many species are dormant at maturity. Seed

storage and dormancy may last for weeks, months, years, or even centuries, as we saw in the opening story of Chapter 29: in 2005 a botanist was able to germinate a date palm seed recovered from a 2000-year-old storage bin at Masada in Israel. The mechanisms that maintain seed dormancy are numerous and diverse, but three principal strategies dominate:

- *Exclusion of water or oxygen* from the embryo by an impermeable seed coat
- *Mechanical restraint* of the embryo by a tough seed coat
- *Chemical inhibition* of germination

Seed dormancy must be broken before germination can begin. The dormancy of seeds with impermeable seed coats can be broken if the coat is abraded as the seed tumbles across the ground or through a creek bed or passes through the digestive tract of an animal. Cycles of freezing and thawing can also aid in making the seed coat permeable, as can soil microorganisms. Fire can end seed dormancy by melting waterproof wax in seed coats, allowing water to reach the embryo. Fire can also release mechanical restraint by cracking the seed coat. *Leaching*—the dissolving and diffusing away of water-soluble chemical inhibitors by prolonged exposure to water—is another way in which dormancy can be broken.

GO TO Web Activity 37.1 • Monocot Shoot Development
AND Web Activity 37.2 • Eudicot Shoot Development

37.1 Patterns of Early Shoot Development (A) In grasses and some other monocots, growing shoots are protected by a coleoptile until they reach the soil surface. (B) In most eudicots, the growing point of the shoot is protected within the cotyledons. (C) In some eudicots, the cotyledons remain in the soil, and the apex is protected by the first true leaves.

Seed dormancy affords adaptive advantages

What are the potential advantages of seed dormancy? For many plant species, dormancy ensures survival during unfavorable conditions and results in germination when conditions are more favorable for growth. To avoid germination in the dry days of late summer, for example, some seeds require exposure to a long cold period (winter) before they will germinate. Other seeds will not germinate until a certain amount of time has passed, regardless of how they are treated. Among other things, this strategy prevents germination while the seeds are still attached to the parent plant. Plants whose seeds need fire to break dormancy avoid competition with other plants by germinating only where an area has been cleared by fire. Dormancy also helps seeds to survive long-distance dispersal, allowing plants to colonize new territory.

The dormancy of some seeds is broken by exposure to light. These seeds, which germinate only at or near the surface of the soil, are generally tiny and have few food reserves. Seedlings from such seeds would not have enough food to reach the light if they germinated deep in the soil. Conversely, the germination of some other seeds is inhibited by light; these seeds germinate only when deeply buried. Light-inhibited seeds are often large and well-stocked with nutrients.

Dormancy may also increase the likelihood of a seed germinating in a favorable ecological setting. Some cypress trees, for example, grow in standing water, and their seeds germinate only if germination inhibitors are leached away by water (**Figure 37.2**).

Seed germination begins with the uptake of water

Seeds begin to germinate when dormancy is broken and environmental conditions are satisfactory. The first step in germination is the uptake of water, called **imbibition** (from *imbibe*, “to

37.2 Breaking dormancy The seeds of bald cypress, a tree adapted to moist or wet environments, germinate only after being leached by water, which increases the chances that they will germinate in a location suitable for their growth.

drink in”). A dormant seed contains very little water; only 5 to 15 percent of a seed’s weight is water compared to 80 to 95 percent for most other plant parts. Seeds also contain polar macromolecules, such as cellulose and starch, that attract and bind polar water molecules. Consequently a seed has a very negative water potential (see Section 35.1), and will take up water if the seed coat is permeable. The force exerted by imbibing seeds, which expand several-fold in volume, demonstrates the magnitude of seed water potential. Imbibing cocklebur seeds can exert a pressure of up to 1,000 atmospheres (approximately 100 kilopascals or 15,000 pounds per square inch)!

As a seed takes up water, it undergoes metabolic changes: enzymes are activated upon hydration, RNA and then proteins are synthesized, the rate of cellular respiration increases, and other metabolic pathways are activated. In many seeds, there is no initiation of the cell division cycle during the early stages of germination. Instead, growth results solely from the expansion of small preformed cells. DNA is synthesized only after the radicle begins to grow and ruptures the seed coat.

The embryo must mobilize its reserves

To fuel its metabolic activities, the embryo must use the reserves of energy and raw materials stored in the seed. Until the young plant is able to photosynthesize, it depends on these reserves, which are stored in the **cotyledons** (see Figure 37.1) or in the **endosperm** (the specialized nutritive tissue) of the seed. The principal reserve of energy and carbon in many seeds, such as wheat, is starch. Other seeds, such as sunflower, store fats or oils. Usually the seed holds amino acid reserves in the form of proteins, rather than as free amino acids.

Before they can be used to support growth of the embryo, starch, lipids, and proteins must be broken down by enzymes into monomers. Starch breakdown yields glucose for energy metabolism and for the synthesis of cellulose and other cell wall constituents. Digestion of stored proteins provides the amino acids the embryo needs to synthesize its own proteins. Lipids are broken down into glycerol and fatty acids, both of which can be metabolized for energy. Glycerol and fatty acids can also be converted to glucose, which permits fat-storing plants to make all the building blocks they need for growth.

Several hormones and photoreceptors help regulate plant growth

This survey of the early stages of plant development illustrates the many internal and external cues that influence plant growth. A plant’s responses to these cues are initiated and maintained by two types of regulators: *hormones* and *photoreceptors*.

Hormones are regulatory molecules that act at very low concentrations at sites often distant from where they are produced. Unlike animals, which usually produce each hormone in specific cells

within the body, plants produce hormones in many types of cells. Each plant hormone plays multiple regulatory roles, affecting several different aspects of plant development (Table 37.1). Interactions among these hormones can be complex. Several hormones regulate plant growth from seedling to adult. Other hormones are involved in the plant's defenses against herbivores and microorganisms (discussed in Chapter 39).

Photoreceptors, like hormones, are involved in many developmental processes in plants. However, unlike plant hormones, which are small molecules, plant photoreceptors consist of *pigments* (molecules that absorb light) associated with proteins. Light acts directly on photoreceptors, which in turn regulate developmental processes that need to be responsive to light, such as the many changes that occur as a young seedling germinates and emerges from the soil.

Signal transduction pathways are involved in all stages of plant development

Plants, like other organisms, make extensive use of *signal transduction pathways*, sequences of biochemical reactions by which a cell generates a response to a stimulus (see Chapter 7). Cell signaling in plant development generally involves a receptor (for a hormone or for light) and a signal transduction pathway, and concludes with a cellular response that is relevant to development. Protein kinase cascades often amplify responses to signals in plants, as they do in other organisms (see Figure 7.12). We will look at several plant signal transduction pathways in more detail in the remaining sections of this chapter.

No matter what cues regulate development, the plant's genome ultimately determines the limits of plant development.

The genome encodes the master plan, but its interpretation depends on conditions in the environment. For several decades biologists focused on identifying the hormones and photoreceptors that control plant development, but recent advances in molecular genetics have now made it possible to explore the underlying processes that regulate development, such as signal transduction pathways.

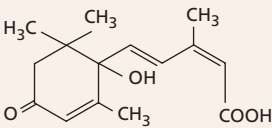

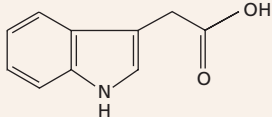

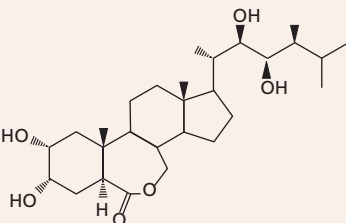

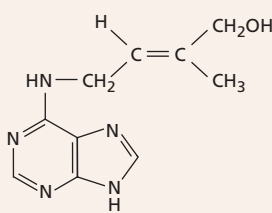

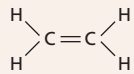

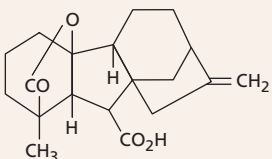

Studies of *Arabidopsis thaliana* have increased our understanding of plant signal transduction

Many recent advances in understanding plant growth and development have come from work with *Arabidopsis thaliana*, a weed in the mustard family. This plant is used as a model organism by researchers because its body and seeds are tiny, its nuclear genome is unusually small for a flowering plant (125 million base pairs), and it flowers and forms many seeds (up to 10,000 per plant) within weeks of germination. Furthermore, its genomes (nuclear, plastid, and mitochondrial) are fully sequenced, so researchers have an accounting of all genes in the plant.

In Chapter 19, we describe how genetics can be used to identify the steps along a developmental pathway. You will recall the theme of these experiments: *if a mutation for a certain biochemical process disrupts a developmental event, then the biochemical process must be essential for that developmental event*. Similarly, genetics can be used to dissect pathways for receptor activation and signal transduction in

TABLE 37.1

Plant Growth Hormones

HORMONE	STRUCTURE	TYPICAL ACTIVITIES
Absciscic acid*		Maintains seed dormancy; closes stomata
Auxins (e.g., indole-3-acetic acid)		Promote stem elongation, adventitious root initiation, and fruit growth; inhibit axillary bud outgrowth, leaf abscission, and root elongation
Brassinosteroids		Promote stem and pollen tube elongation; promote vascular tissue differentiation
Cytokinins		Inhibit leaf senescence; promote cell division and axillary bud outgrowth; affect root growth
Ethylene		Promotes fruit ripening and leaf abscission; inhibits stem elongation and gravitropism
Gibberellins		Promote seed germination, stem growth, and fruit development; break winter dormancy; mobilize nutrient reserves in grass seeds

*See Chapter 38.

plants: if proper signaling does not occur in a mutant strain, the mutant gene must be involved in the signal transduction process. Mapping the mutant gene and characterizing its molecular phenotype is a starting point for understanding the signaling pathway.

One technique for identifying genes involved in a plant signal transduction pathway is illustrated in **Figure 37.3**. Called a **genetic screen**, the process involves creating a collection of mutants and identifying those individuals that are likely to have a defect in the pathway being studied. Genes can be randomly mutated in two ways:

- Insertion of a transposon (see Section 17.2)
- Point mutation by a chemical mutagen, usually ethyl methane sulfonate

In both cases, a large number of mutated plants are then examined for a specific phenotype, usually a characteristic that is easy to see or measure (e.g., height). The growth conditions and plant characteristics used for the screen are carefully chosen to maximize the chances that the selected plants will have a defect in the pathway of interest. Once mutant plants have been selected, their genotypes and phenotypes are compared to those of wild-type plants. *Arabidopsis* mutants with altered developmental patterns have provided a wealth of new information about the hormones present in plants and the mechanisms of hormone and photoreceptor action.

37.1 RECAP

Plant development is under the control of external cues in the environment as well as internal hormones. In both cases, signal transduction pathways regulate plant development. Genetic screens have been useful in describing signal transduction pathways in the model plant *Arabidopsis thaliana*. Seed dormancy often precedes seed germination.

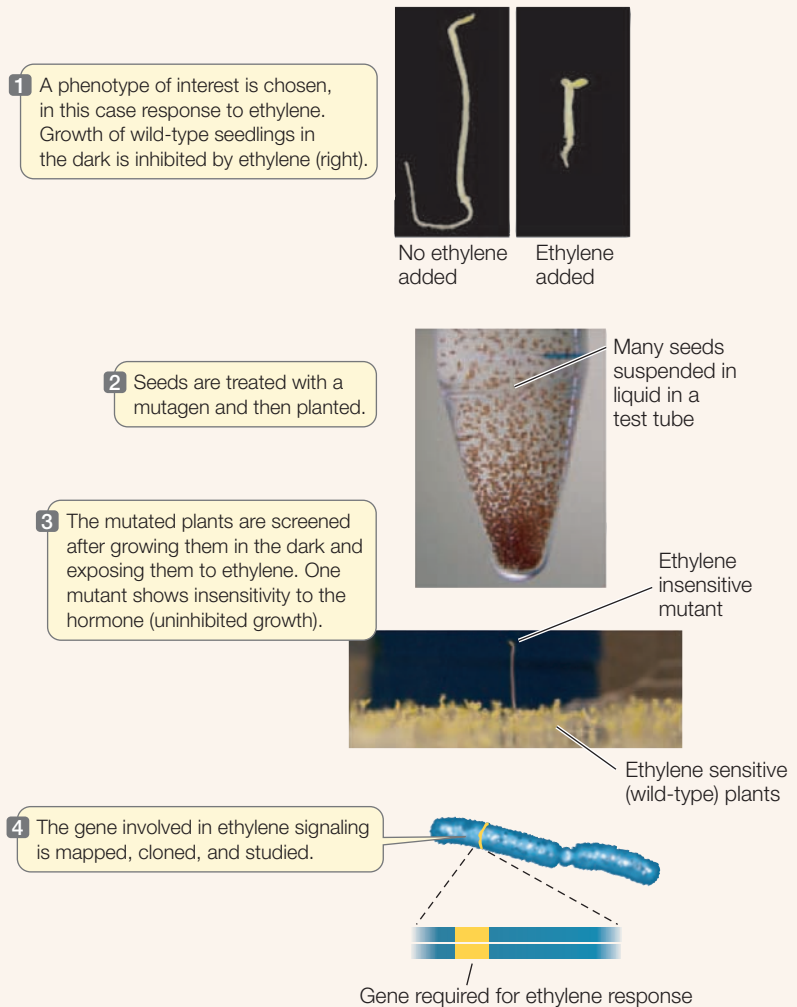

- Describe how monocots and eudicots differ in early development. **See p. 773 and Figure 37.1**
- Under what circumstances is seed dormancy advantageous? **See p. 774**
- What fuels the metabolic activities of a young plant embryo before it is able to commence photosynthesis? **See p. 774**
- What is a genetic screen and how can it be used to analyze the regulation of plant development? **See p. 776 and Figure 37.3**

You have now seen the early stages of plant development and growth, and how the environment influences these processes. Plant hormones are central to the internal regulation of development, a subject to which we now turn. We will describe how hormones were discovered and what physiological effects they

TOOLS FOR INVESTIGATING LIFE

37.3 A Genetic Screen

Genetics of the model plant *Arabidopsis thaliana* can be used to identify the steps of a signal transduction pathway. If a mutant strain does not respond to a hormone (in this case, ethylene), the corresponding wild-type gene must be essential for the pathway (in this case, ethylene response). This method has been instrumental to scientists in understanding plant growth regulation.

have on plants. We will emphasize how genetic screens and other methods have led to a deeper molecular understanding of the action of plant hormones.

37.2 What Do Gibberellins Do?

In Asia, rice farmers have known about “foolish seedling disease” (*bakanae* in Japanese) for centuries. Seedlings affected by this disease grow more rapidly than their healthy neighbors, but this rapid growth gives rise to tall, spindly plants that die before producing rice grains, having expended most of their energy on vegetative growth. At first, the disease was attributed to an inherited defect in the plants themselves. But by the twentieth century it was clear that it is caused by infection with the

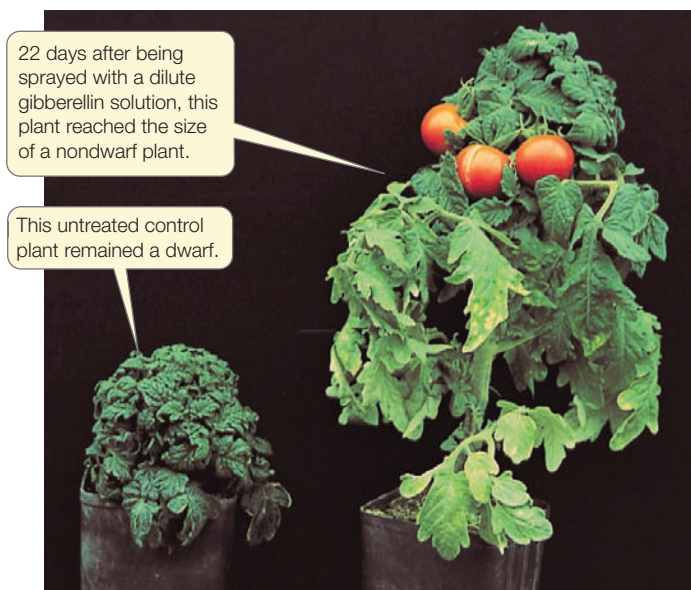

ascomycete fungus *Gibberella fujikuroi*. How does the infection cause the disease?

The mystery of foolish seedling disease was solved in 1925 by Japanese biologist Eiichi Kurosawa. He hypothesized that the fungus must release a molecule that overstimulates plant growth. To isolate it, he grew the fungus in a liquid medium and then removed the fungus from the medium by filtration. He heated the filtered medium to kill any remaining fungus, but found that the resulting heat-treated filtrate was still capable of inducing rapid growth in rice seedlings. Medium that had never contained the fungus did not have this effect. This experiment established that *G. fujikuroi* produces a growth-promoting chemical substance, which Kurosawa called a **gibberellin**. Soon, gibberellin was isolated and its chemical nature described (see Table 37.1).

Gibberellins are plant hormones

Once externally applied gibberellin was shown to affect rice plant growth, a question arose: *does a plant make the same or similar molecules to regulate its own growth?* Biologists used a genetic approach to answer this question, by studying mutant strains of corn and tomato that were dwarfs—they had abnormally short stems. The stems hardly grew, even though other parts of the plants appeared normal. Because this was the exact opposite of the effect of *too much* gibberellin (in the fungus-infected rice plants), the biologists hypothesized that the dwarf mutants had *too little* gibberellin. This hypothesis was tested in two ways:

- Gibberellin was applied to the dwarf plants. As a result, they grew to normal height (**Figure 37.4**).
- The levels of gibberellin were measured in wild-type and dwarf plants, and the wild-type plants had much more gibberellin.

37.4 The Effect of Gibberellins on Dwarf Plants Both of the dwarf tomato plants in this photograph were the same size when the one on the right was treated with gibberellins.

These experiments clearly showed that gibberellin is made by plants and acts to stimulate stem elongation. Numerous chemically related gibberellins exist, all belonging to a family of common plant metabolites called *diterpenoids*.

Gibberellins have many effects on plant growth and development

The functions of gibberellins can be inferred from the effects of experimentally decreasing gibberellins or blocking their action at various points in plant development. Such experiments reveal that gibberellins have multiple roles in regulating plant growth.

FRUIT GROWTH Gibberellins and other hormones regulate the growth of fruits. Grapevines that produce seedless grapes develop smaller fruit than varieties that produce seed-bearing grapes. Biologists wanting to explain this phenomenon removed seeds from immature seeded grapes and found that this prevented normal fruit growth, suggesting that the seeds are sources of a growth regulator. Biochemical studies showed that developing seeds produce gibberellins, which diffuse out into the immature fruit tissue. Spraying young seedless grapes with a gibberellin solution causes them to grow as large as seeded ones, and this is now a standard commercial practice (**Figure 37.5**).

MOBILIZATION OF SEED RESERVES Early in seed germination hydrolytic enzymes are produced to break down stored reserves of starch, proteins, and lipids. Just after imbibition in germinating seeds of barley and other cereals, the embryo secretes gibberellins. The hormones diffuse through the endosperm to a surrounding tissue called the **aleurone layer**, which lies underneath the seed coat. The gibberellins trigger a cascade of events in the aleurone layer, causing it to syn-

37.5 Gibberellin and Fruit Growth Spraying developing seedless grapes with gibberellins (right) increases their size compared to untreated fruit (left).

37.6 Embryos Mobilize Their Reserves During seed germination in cereal grasses, gibberellins trigger a cascade of events that result in the conversion of starch and protein reserves into monomers that can be used by the developing embryo.

synthesize and secrete enzymes that digest proteins and starch stored in the endosperm (**Figure 37.6**). These observations have practical importance: in the beer brewing industry, gibberellins are used to enhance the “malting” (germination) of barley and the breakdown of its endosperm, producing sugar that is fermented to alcohol.

STEM ELONGATION The effects of gibberellins on wild-type plants are not as dramatic as those seen on dwarf plants. However, gibberellins are indeed active in wild-type plants, because inhibitors of gibberellin synthesis cause a reduction in stem elongation. Such inhibitors can be put to practical uses. For example, plants such as chrysanthemums that are grown in greenhouses tend to get too tall; but leggy plants, unfortunately, do not appeal to consumers. Flower growers thus spray such plants with gibberellin synthesis inhibitors to control their height. Some wheat crops are similarly sprayed to keep them short, so they do not fall over when they produce grain—this is essentially a chemically induced version of the semi-dwarf genetic varieties described in the opening story of this chapter. In some plants, such as cabbage, the normal growth habit is to be a squat, leafy head near the ground. When environmental signals are right, however, the plant “bolts,” quickly producing a tall stem with flowers. This response is mediated by gibberellins.

Gibberellins act by initiating the breakdown of transcriptional repressors

The molecular mechanisms underlying gibberellin action have been worked out with the help of genetic screens. Biologists started by identifying mutant plants whose growth and devel-

GO TO Web Activity 37.3 • Events of Seed Germination

opment are *insensitive* to gibberellins; that is, they are *not* affected by added gibberellins. Several such mutants have been found—both natural mutant strains and induced mutants selected from genetic screens—and they fall into two general categories:

- *Excessively tall plants.* These plants resemble wild-type plants given an excess of gibberellin, and get no taller when given extra gibberellin. They are also tall even when treated with inhibitors of gibberellin synthesis. Their gibberellin response is always “on,” even in the absence of the hormone. It is presumed that the normal allele for the mutant gene codes for an *inhibitor* of the gibberellin signal transduction pathway. In wild-type plants, the pathway is “off” but in the mutant plants, the pathway is “on” and the plant grows tall.
- *Dwarf plants.* These plants resemble dwarf tomato or maize plants that are deficient in gibberellin synthesis, but they do not respond to added gibberellin. In these mutants the gibberellin response is always “off,” regardless of the presence of the hormone.

The two types of mutations described above *affect the same protein*, which turns out to be a *repressor* of a transcription factor that stimulates the expression of growth-promoting genes. The repressor protein has two important domains, explaining how mutations in the same protein can have seemingly opposite effects:

- *One region of the repressor protein binds to the transcription complex to inhibit transcription.* This is the region mutated in the excessively tall plants: the growth-promoting genes are always “on” because the repressor does not bind to the transcription complex.
- *Another part of the repressor protein causes it to be removed from the transcription complex.* This is the region mutated in the

37.7 How Gibberellin Works Gibberellin acts to stimulate gene transcription by inactivating a repressor protein, a common mechanism for plant hormone action.

dwarf plants: the growth-promoting genes are always “off” because the repressor is always bound to the complex.

How does gibberellin act in this system? *Gibberellin acts by removing the repressor from the transcription complex (Figure 37.7).* It does this by binding to a receptor protein, which in turn binds to the repressor. Binding of the gibberellin–receptor complex stimulates poly-ubiquitination of the repressor, targeting it for breakdown in the proteasome (see Figure 16.24). The gibberellin receptor contains a region called an **F-box** that facilitates protein–protein interactions necessary for protein breakdown. While animal genomes have few F-box containing proteins, plant genomes have hundreds, an indication that this type of gene regulation is common in plants. As you will see, this regulatory mechanism underlies the effects of another important plant hormone: auxin.

37.2 RECAP

Gibberellins are plant hormones that affect stem growth, fruit size, seed germination, and many other aspects of plant development; the effects vary from species to species.

- How were gibberellins shown to be plant hormones? **See p. 777**
- How do gibberellins contribute to the germination of barley seeds? **See Figure 37.6**
- Explain how gibberellins work at the molecular level. **See pp. 778–779 and Figure 37.7**

Most other hormones, like the gibberellins, have multiple effects within the plant, and they often interact with one another to regulate developmental processes. In controlling stem elongation, for example, gibberellins interact with another hormone, auxin, to which we now turn.

37.3 What Does Auxin Do?

Auxin was discovered as a result of investigations into **phototropism**, the growth of plants toward light (as in shoots) or away from it (as in roots). Ever the curious biologist, Charles Darwin wanted to know how plants bend toward a source of light. In 1880, he and his son Francis published the results of their experiments on what part of a plant senses light.

yourBioPortal.com

GO TO Animated Tutorial 37.1 • Tropisms

The Darwins worked with canary grass (*Phalaris canariensis*) seedlings grown in the dark. A young grass seedling has a **coleoptile**—a cylindrical sheath a few cells thick that protects the delicate shoot as it pushes through the soil (see Figure 37.1A). When the seedling breaks through the soil surface, the coleoptile soon stops growing, and the shoot emerges unharmed. The coleoptiles of grasses are phototropic—they grow toward the light.

To find the light-receptive region of the coleoptile, the Darwins “blindfolded” the coleoptiles of dark-grown canary grass seedlings in various places, and then illuminated them from one side (**Figure 37.8**). The coleoptile grew toward the light whenever its tip was exposed. If the top millimeter or more of the coleoptile was covered, however, the coleoptile showed no phototropic response. Thus, the Darwins were able to conclude that the tip contains the photoreceptor that responds to light. The actual bending toward the light, however, takes place in a growing region a few millimeters below the tip. Therefore, the Darwins reasoned, *some type of signal must travel from the tip of the coleoptile to the growing region.* Later, others demonstrated that this signal is a chemical substance by showing that it can move through certain permeable materials, such as gelatin, but not through impermeable materials, such as a metal sheet.

INVESTIGATING LIFE

37.8 The Darwins' Phototropism Experiment

Charles Darwin and his son Francis wanted to know how plants bend toward the light. They grew canary grass seedlings (coleoptiles) in the dark. To discover what part of the coleoptile responds to light, they covered up ("blindfolded") different regions of each coleoptile and then exposed the seedlings to light from one side. The Darwins discovered that the tip of the seedling senses the light and that growth occurs below the tip. Their observations led them to hypothesize the existence of a growth-promoting signal produced by the coleoptile tip.

HYPOTHESIS Only part of the coleoptile senses the light that triggers phototropism.

METHOD

1 Grow seedlings in the dark.

2 "Blindfold" the seedlings in different places and expose to light on one side.

RESULTS

3 Coleoptiles responded to light only when the tip was exposed.

CONCLUSION The part of the coleoptile that senses light is in the tip, and it sends a signal from the tip to the growing region.

INVESTIGATING LIFE

37.9 Went's Experiment

Previous experiments had indicated that the tip of a coleoptile produces a growth-inducing substance. Went verified this conclusion by placing agar blocks containing the substance contained within coleoptile tips on one side of a decapitated coleoptile. In the absence of light, the coleoptile bent away from the side with the substance. The substance was later identified as auxin.

HYPOTHESIS A growth hormone can be isolated from a coleoptile tip.

METHOD

Experiment

- 1 Remove the coleoptile tip and place on agar.
- 2 Place the agar on one edge of another decapitated coleoptile.
- 3 The coleoptile curves away from the agar as it grows.

RESULTS

Control

- 1 For the control, remove the coleoptile tip.
- 2 Place a plain agar block on one edge of the coleoptile.
- 3 The coleoptile does not curve.

CONCLUSION A growth hormone diffused from the tip into the agar, and from the agar into another plant. It had an effect on the growth of the plant similar to that of a coleoptile tip.

GO TO Animated Tutorial 37.2 • Went's Experiment

In the 1920s, the Dutch botanist Frits Went followed up on the Darwins' experiment. He removed coleoptile tips and placed their cut surfaces on a block of agar. Then he placed pieces of that agar on decapitated coleoptiles—positioned to cover only one side (**Figure 37.9**). As they grew, the coleoptiles curved away from the side with the agar, showing that the agar contained a substance that stimulated elongation of cells on that side of the coleoptile. This substance had diffused into the agar block from the isolated coleoptile tips. Eventually, the hormone indole-3-acetic acid (see Table 37.1) was isolated from similar agar blocks and was nicknamed *auxin* (from the Latin “to increase”).

Auxin transport is polar and requires carrier proteins

The experiments we have just described showed that in coleoptiles auxin movement is strictly *polar*—that is, it is unidirectional along a line from apex to base. Auxin transport is polar in other organs as well. For example, in a leaf petiole, which connects the leaf blade to the stem, auxin moves from the leaf blade end toward the stem. In roots, auxin moves unidirectionally toward the root tip. How does this directional transport occur?

Polar transport depends on four biochemical conditions that should be familiar from earlier chapters (**Figure 37.10**):

- **Diffusion across a plasma membrane.** Polar molecules diffuse across the plasma membrane less readily than nonpolar molecules.
- **Membrane protein asymmetry.** Active transport carriers for auxin are located only at the basal (bottom) end of the plasma membrane.

37.10 Polar Transport of Auxin Proton pumps set up a chemiosmotic gradient directing A⁻ toward the basally placed auxin active transport carriers, leading to a net movement of auxin in a basal direction.

- **Proton pumping/chemiosmosis.** An ATP-driven proton pump removes H⁺ from the cell, thereby increasing the intracellular pH and decreasing the pH in the cell wall. Proton pumping also sets up an electrochemical gradient, with potential energy to drive the transport of auxin by the carriers noted above.
- **The ionization of a weak acid.** Indole-3-acetic acid (which, recall, is the chemical name for auxin; see Table 37.1) is a weak acid:

When the pH is low, the increased H⁺ concentration drives this reaction to the right and HA (non-ionized auxin) is the predominant form. When the pH is higher, there is more A⁻ (ionized auxin).

Auxin transport mediates responses to light and gravity

While polar auxin transport distributes the hormone along the longitudinal axis of the plant, *lateral* (side-to-side) redistribution of auxin is responsible for plant movements. This redistribution is carried out by auxin carrier proteins that move from the base of the cell to one side; because of this, auxin exits the cell only on that side of the cell, rather than at the base, and moves sideways within the tissue.

When light strikes a grass coleoptile on one side, auxin at the tip moves laterally toward the shaded side. The asymmetry thus established is maintained as polar transport moves auxin down the coleoptile, so that in the growing region below, the auxin concentration is highest on the shaded side. Cell elongation is thus speeded up on that side, causing the coleoptile to bend toward the light (**phototropism**; **Figure 37.11A**). If you have noticed a houseplant bending toward a window, you have observed phototropism.

Light is not the only signal that can cause redistribution of auxin. Auxin moves to the lower side of a shoot that has been tipped sideways, causing more rapid growth in the lower side and, hence, an upward bending of the shoot. Such growth in a direction determined by gravity is called **gravitropism** (**Figure 37.11B**). The upward gravitropic response of shoots is defined as *negative gravitropism*; that of roots, which bend downward, is *positive gravitropism*.

How does a plant cell sense light and gravity and respond with an asymmetric distribution of auxin? Different mechanisms have been proposed:

- **The phototropic response.** As you will see later in the chapter, plants have a membrane receptor called phototropin that absorbs blue light. This receptor was discovered in a genetic screen in *Arabidopsis* for mutant plants that failed to bend toward light. When the receptor is activated, a signal transduction pathway results in redistribution of auxin transport carriers so that the hormone is transported to the cells on the shaded side. This results in bending toward light (see Figure 37.11).
- **The gravitropic response.** Some types of plant cells contain starch that is stored in large plastids called amyloplasts. These plastids tend to settle on the downward side of a cell

(A) Phototropism

1 Auxin moves to the shaded side within the tip.

2 The redistributed auxin moves down the coleoptile.

3 A higher auxin concentration causes more rapid growth on the shaded side. The tip curves toward the light.

**(B) Negative gravitropism of shoot**

37.11 Plants Respond to Light and Gravity (A) Phototropism and (B) gravitropism occur in shoot apices in response to a redistribution of auxin.

in response to gravity. How gravity-induced plastid movement is sensed is not well understood, but it may be through disturbance of endoplasmic reticulum membranes on the downward side of the cell. This in turn triggers auxin transport to the bottom side of the root or shoot, which causes bending in the appropriate direction.

Auxin affects plant growth in several ways

Like the gibberellins, auxin has many roles in plant development. It affects the vegetative and reproductive growth of plants in a number of ways.

ROOT INITIATION Cuttings from the shoots of some plants can produce roots and develop into entire new plants. For this to occur, certain undifferentiated cells in the interior of the shoot, originally destined to function only in food storage, must set off on a new mission: they must change their cell fate and become organized into the apical meristem of a new root. These changes are similar to those that take place in the pericycle of a root when

**37.12 Changes Occur when a Leaf Is About to Fall**

The breakdown of cells in the abscission zone of the petiole causes the leaf to fall.

a lateral root forms (see Figure 34.13A). Shoot cuttings of many species can be made to develop roots by dipping the cut surfaces into an auxin solution. These observations suggest that in an intact plant the plant's own auxin plays a role in the initiation of lateral roots. Commercial preparations that enhance the rooting of plant cuttings typically contain synthetic auxins.

LEAF ABSCISSION In contrast to its stimulatory effect on root initiation, auxin inhibits the detachment of old leaves from stems. This detachment process, called **abscission**, is the cause of autumn leaf fall. Most leaves consist of a blade and a petiole that attaches the blade to the stem. Abscission results from the breakdown of a specific part of the petiole, the *abscission zone* (Figure 37.12). If the blade of a leaf is cut off, the petiole falls from the plant more rapidly than if the leaf had remained intact. If the cut surface is treated with an auxin solution, however, the petiole remains attached to the plant, often longer than an intact leaf would have. The timing of leaf abscission in nature appears to be determined in part by a decrease in the movement through the petiole of auxin produced in the blade.

APICAL DOMINANCE Auxin helps maintain **apical dominance**, a phenomenon in which apical buds inhibit the growth of axillary buds (see Figure 34.1), resulting in the growth of a single main stem with minimal branching. A diffusion gradient of auxin from the apical tip of the shoot down the stem results in lower branches receiving less auxin and therefore branching more. The effect of the auxin gradient is apparent in conifers: next time you see a decorated tree during the winter holidays, think of auxin and apical dominance.

Apical dominance can be demonstrated by an experiment with a young seedling. If the plant remains intact, the stem elongates and the axillary buds remain inactive. Removal of the apical bud—the major site of auxin production—results in growth of the axillary buds. If the cut surface of the stem is treated with auxin, however, the axillary buds do not grow. The apical buds of branches also exert apical dominance: the axillary buds on the branch are inactive unless the apex of the branch is removed. That is why gardeners prune shrubs to encourage branching.

In the experiments on leaves and stems just discussed, removal of a particular part of the plant elicits a response—abscission or loss of apical dominance—and that response is prevented by treatment with auxin. These results are consistent with other data showing that the excised part of the leaf or stem is an auxin source and that auxin in the intact plant delays the abscission of leaves and helps maintain apical dominance.

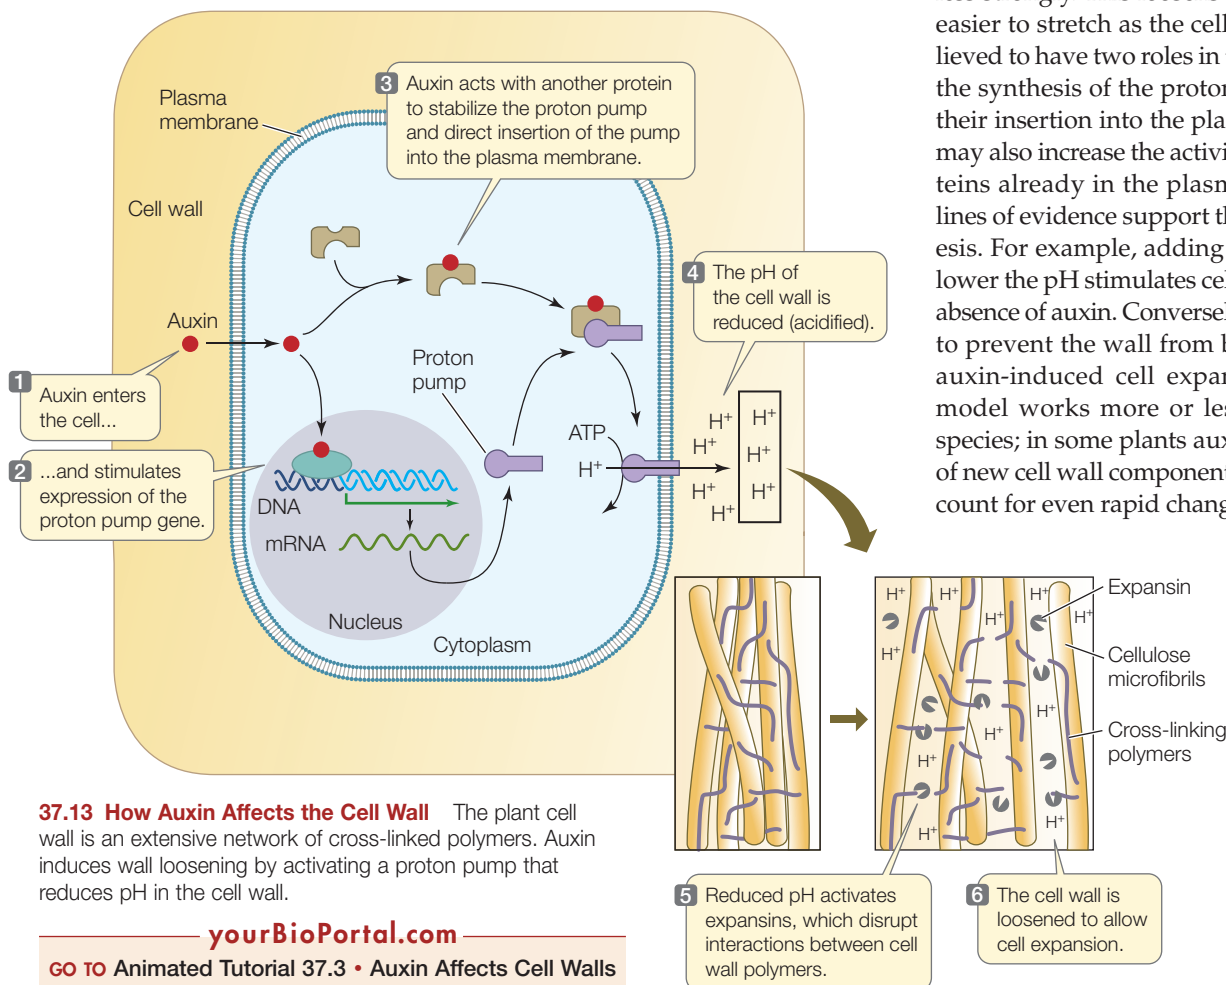

FRUIT DEVELOPMENT Fruit development normally depends on prior fertilization of the ovule (egg), but in many species treatment of an unfertilized ovary with auxin or gibberellins causes **parthenocarp**y—fruit formation without fertilization. Parthenocarpic fruits form spontaneously in some cultivated varieties of plants, including seedless grapes, bananas, and some cucumbers.

CELL EXPANSION The expansion of plant cells is what causes plant growth. Because the plant cell wall normally prevents expansion of the protoplast (see Section 35.1), the cell wall plays a key role in controlling the rate and direction of plant cell growth. Auxin acts on cell walls to regulate this process.

The expansion of a plant cell is driven primarily by the uptake of water, which enters the cytoplasm of the cell and accumulates in its central vacuole (see Section 35.1). Growth of the vacuole accounts for most of the increase in volume of a growing cell, and the vacuole often makes up more than 90 percent of the volume of a mature cell. As the vacuole expands, it presses the cytoplasm against the cell wall, and the wall resists this force (the basis of turgor pressure). The cell wall is an extensively cross-linked network of polysaccharides and proteins, dominated by cellulose fibrils (see Figure 34.5). If the cell is to expand, some adjustments must be made in the wall structure to allow the wall to “give” under turgor pressure. Think of a balloon (the cell surrounded by a membrane) inside a box (the cell wall). How does the cell wall “box” loosen to allow expansion?

The **acid growth hypothesis** offers a possible explanation for auxin-induced cell expansion (**Figure 37.13**). The hypothesis holds that protons (H^+) are pumped from the cytoplasm into the cell wall, lowering the pH of the wall and activating enzymes called *expansins* that catalyze changes in the cell wall structure

such that the polysaccharides adhere to each other less strongly. This loosens the cell wall, making it easier to stretch as the cell expands. Auxin is believed to have two roles in this process: to increase the synthesis of the proton pumps, and to guide their insertion into the plasma membrane. Auxin may also increase the activity of proton pump proteins already in the plasma membrane. Several lines of evidence support the acid growth hypothesis. For example, adding acid to the cell wall to lower the pH stimulates cell expansion even in the absence of auxin. Conversely, when a buffer is used to prevent the wall from becoming more acidic, auxin-induced cell expansion is blocked. The model works more or less well depending on species; in some plants auxin stimulates secretion of new cell wall components quickly enough to account for even rapid changes in growth rate.

(A) Repression: Auxin absent**(B) Activation: Auxin present**

37.14 Signal Transduction Pathway for Auxin As with gibberellins (see Figure 37.7), the auxin response involves the release from inhibition of transcription.

At the molecular level, auxin and gibberellins act similarly

Given that auxin induces so many different physiological responses in plants, biologists expected that the hormone might act through several different signal transduction pathways. However, genetic screens have revealed a single, relatively simple mechanism that accounts for many of auxin's actions. This mechanism is similar to that involved in the action of gibberellins (see Figure 37.7).

Like gibberellin, auxin acts by countering the inhibition of genes involved in the cellular response to the hormone. In the absence of auxin, a repressor blocks transcription of these genes. Auxin binds to a receptor, which then binds to the repressor. This stimulates addition of ubiquitin to the repressor and causes it to be degraded by the proteasome (**Figure 37.14**), thereby allow-

ing transcription. The molecular response takes longer, and is longer-lasting than the rapid acid growth response in the cell wall.

37.3 RECAP

Auxin regulates stem elongation (cell expansion) and mediates phototropism and gravitropism; it also plays roles in apical dominance, leaf abscission, and root initiation. The acid growth hypothesis explains auxin-induced cell wall loosening. Similar molecular mechanisms explain the effects of auxin and gibberellin on gene expression.

- What is the evidence for polar transport of auxin and how does it occur? **See pp. 779–780 and Figures 37.9 and 37.10**
- Explain why, even though auxin moves *away* from the lighted side of a coleoptile tip, the coleoptile bends *toward* the light. **See p. 781 and Figure 37.11**
- How does auxin cause cell wall loosening? **See p. 783 and Figure 37.13**
- What are the similarities between the signal transduction pathways for auxin and gibberellin? **See p. 784 and Figures 37.7 and 37.14**

How can a single hormone, such as auxin or a gibberellin, have so many effects? As we have seen, a single signal transduction pathway may affect more than one gene. We learn about other important plant hormones in the next section, and they, too, have multiple effects.

37.4 What Are the Effects of Cytokinins, Ethylene, and Brassinosteroids?

Like animal cells, plant cells differentiate after they form from undifferentiated stem cells (called meristem cells in plants). But unlike animal cells, which generally do not divide after differentiation, plant cells retain the ability to divide. For example, in leaf abscission (see Figure 37.12) differentiated parenchyma cells in the petiole resume division, forming a specialized, weak layer of cells. Also, cells of the phloem and cortex can resume division and form secondary meristems. What stimulates these cells to divide? An answer came from studies of cells isolated from the plant and cultured in the laboratory.

Cytokinins are active from seed to senescence

Like bacteria and yeast, plant cells such as parenchyma cells can be grown in a liquid or solidified growth medium containing sugars and salts. The cells will divide continuously until they run out of nutrients. In the early days of plant cell culturing, scientists experimented with many supplements to determine the optimal chemical environment for growth. The best supplement was coconut milk, the fluid that surrounds the developing embryo in coconut fruit. Investigators suspected that a molecule in the fluid must stimulate plant cell division.

A clue to the identity of the molecule came when Folke Skoog at the University of Wisconsin tested various pure substances that might substitute for coconut milk. DNA was among the substances tested, and it did not work; however, heating DNA at high pressure in an autoclave produced a mixture that strongly promoted plant cell division. A derivative of adenine called *kinetin* was identified as the active ingredient. Because it stimulated cell division (cytokinesis), it was called a **cytokinin**.

Kinetin does not exist in cells, but it gave scientists a hint as to what type of molecule might be the active ingredient in coconut milk. In 1963, an adenine derivative called **zeatin** was extracted from corn endosperm, the “coconut milk of corn” (see Table 37.1). Since then, over 150 different cytokinins have been isolated, and most are derivatives of adenine.

Cytokinins have a number of different effects, in many cases interacting with auxin:

- Adding an appropriate combination of auxin and cytokinins to a growth medium induces rapid proliferation of cultured plant cells.
- Cytokinins can cause certain light-requiring seeds to germinate even when kept in constant darkness.
- In cell cultures, a high cytokinin-to-auxin ratio promotes the formation of shoots; a low ratio promotes the formation of roots.
- Cytokinins usually inhibit the elongation of stems, but they cause lateral swelling of stems and roots (the fleshy roots of radishes are an extreme example).
- Cytokinins stimulate axillary buds to grow into branches; the auxin-to-cytokinin ratio controls the extent of branching (bushiness) of a plant.
- Cytokinins delay the senescence of leaves. If leaf blades are detached from a plant and floated on water or a nutrient solution, they quickly turn yellow and show other signs of senescence. If instead they are floated on a solution containing a cytokinin, they remain green and senesce much more slowly. Roots contain abundant cytokinins, and cytokinin transport to the leaves delays senescence.

Cytokinin signaling appears to act through a pathway that includes proteins with amino acid sequences similar to proteins in *two-component systems* in bacteria (see Figure 7.3). Indeed, this system was one of the first of its kind discovered in eukaryotes. The two components in such a system are:

- A *receptor* that can act as a protein kinase, phosphorylating itself as well as a target protein
- A *target protein*, generally a transcription factor, that can act as an *effector*

Genetic screens in *Arabidopsis* for abnormalities in the response to cytokinin have identified the receptor (AHK; *Arabidopsis* histidine kinase) and target effector (ARR; *Arabidopsis* response regulator), the latter acting as a transcription factor when phosphorylated. The cytokinin signal transduction pathway also includes a third protein (AHP; *Arabidopsis* histidine phosphotransfer protein), which transfers phosphates from the receptor to the effector (Figure 37.15). The plant genome has over 20 genes that are expressed in response to this signaling pathway.

37.15 The Cytokinin Response Pathway Plant cells respond to cytokinins using a signal transduction pathway related to bacterial two-component systems.

Ethylene is a gaseous hormone that hastens leaf senescence and fruit ripening

Whereas the cytokinins delay senescence, another plant hormone promotes it: the gas **ethylene** (see Table 37.1), which is sometimes called the senescence hormone. Ethylene can be produced by all parts of the plant, and, like all plant hormones, it has several effects.

Back when streets were lit by gas rather than by electricity, leaves on trees near street lamps dropped earlier than those on trees farther from the lamps. We now know why: ethylene, a combustion product of the illuminating gas, caused the early abscission. While auxin delays leaf abscission, ethylene strongly promotes it; thus the balance of auxin and ethylene controls abscission.

FRUIT RIPENING By promoting senescence, ethylene also speeds the ripening of fruit. As a fruit ripens, it loses chlorophyll and its cell walls break down; ethylene promotes both of these processes. Ethylene also causes an increase in its own production. Thus, once ripening begins, more and more ethylene forms, and because it is a gas, it diffuses readily throughout the fruit and even to neighboring fruits on the same or other plants. The old saying “one rotten apple spoils the barrel” is true. That rotten apple is a rich source of ethylene, which speeds the ripening and subsequent rotting of the other fruit in a barrel or other confined space.

Farmers in ancient times poked holes in developing figs to make them ripen faster. We now know that wounding causes an increase in ethylene production by the fruit and that the raised ethylene level promotes ripening. Today commercial shippers and storers of fruit hasten ripening by adding ethylene to storage chambers. This use of ethylene is the single most important use of a natural plant hormone in agriculture and commerce. Ripening can also be delayed by the use of “scrubbers” and adsorbents that remove ethylene from the atmosphere in fruit storage chambers. This strategy can even be used in the home. Many supermarkets sell plastic bags designed to keep fruits fresh; the bags are impregnated with a substance that binds ethylene.

As flowers senesce, their petals may abscise, decreasing their value in the cut-flower industry. Growers and florists often immerse the cut stems of ethylene-sensitive flowers in dilute solutions of silver thiosulfate before sale. Silver salts inhibit ethylene action by interacting directly with the ethylene receptor—thus they delay senescence, keeping flowers “fresh” for longer.

STEM GROWTH Although it is associated primarily with senescence, ethylene is active at other stages of plant development, as well. The stems of many eudicot seedlings form an **apical hook** that protects the delicate shoot apex while the stem grows through the soil (**Figure 37.16**). The apical hook is maintained through an asymmetrical production of ethylene gas, which inhibits the elongation of cells on the inner surface of the hook. Once the seedling breaks through the soil surface and is exposed to light, ethylene synthesis stops, and the cells of the inner surface are no longer inhibited. These cells now elongate, and the hook unfolds, raising the shoot apex and the expanding leaves into the sun.

Ethylene also inhibits stem elongation in general, promotes lateral swelling of stems (as do the cytokinins), and decreases the sensitivity of stems to gravitropic stimulation. Together,

37.16 The Apical Hook of a Eudicot Asymmetrical production of ethylene is responsible for the apical hook of this bean seedling. The ethylene concentration was highest on the right side, so more rapid growth on the left caused and maintained the hook.

these three phenomena constitute the *triple response*, a well-characterized stunted growth habit observed when plants are treated with ethylene.

THE ETHYLENE SIGNAL TRANSDUCTION PATHWAY The mechanism of ethylene action has been worked out by analyzing *Arabidopsis* mutants that have ethylene-related defects. Some of these mutants do not respond to applied ethylene, and others act as if they have been exposed to ethylene even though they have not. Researchers studied the mutant genes and compared their protein products to other known proteins; thus they worked out some of the details of the signal transduction pathway through which ethylene acts (**Figure 37.17**).

The pathway includes two membrane proteins in the endoplasmic reticulum. The first is an ethylene receptor (labeled A in the figure) and the second is a channel protein (C). In the absence of ethylene, a protein kinase (B) keeps C inactive by phosphorylation. When receptor A binds ethylene it inactivates B. Without B to inactivate it, C activates a transcription factor (D), which then moves into the nucleus, where it turns on the genes that produce ethylene’s effects in the cell. In other words, ethylene turns off the “off” signal.

Brassinosteroids are plant steroid hormones

In animals, steroid hormones such as cortisol and estrogen are formed from cholesterol (see Figure 3.22). Animal steroids are widespread and have been well studied for many decades. In contrast, plant steroid hormones are a relatively recent discovery. In the 1970s, biologists isolated a steroid (see Table 37.1) from the pollen of rape, a member of the Brassicaceae (mustard family). When applied to various plant tissues, this **brassinosteroid** stimulated cell elongation, pollen tube elongation, and vascular tissue differentiation, but it inhibited root elongation. Since then, dozens of chemically related, growth-affecting brassinosteroids have been found in plants.

37.17 The Signal Transduction Pathway for Ethylene This diagram shows the roles of four proteins (A, B, C, and D) in the signal transduction pathway through which ethylene exerts its many effects.

Mutant plants that either do not make brassinosteroids or have defects in brassinosteroid reception and signal transduction are usually dwarf, infertile, and slow to develop. These effects can be reversed by adding small amounts of brassinosteroids, indicating that brassinosteroids are true hormones. These hormones have diverse effects, which vary among plants. Brassinosteroids can:

- enhance cell elongation and cell division in shoots
- promote xylem differentiation
- promote growth of pollen tubes during reproduction
- promote seed germination
- promote apical dominance and leaf senescence

The signaling pathway for these plant steroids differs sharply from those for steroid hormones in animals. In animals, steroids diffuse through the plasma membrane and bind to receptors in the cytoplasm. In contrast, the receptor for brassinosteroids is an integral protein in the plasma membrane

37.18 The Brassinosteroid Signal Transduction Pathway Begins at the Plasma Membrane Unlike the receptors for animal steroid hormones, the brassinosteroid (BR) receptor is a membrane protein. The signal transduction pathway concludes by activating certain genes.

(Figure 37.18). Binding of a brassinosteroid by the receptor inactivates a protein kinase that would otherwise inactivate a transcription factor. The genes activated by this pathway code

for proteins involved in cell expansion and, significantly, the response to light. As we will see, light has profound effects on plant development.

RECAP 37.4

Cytokinins, ethylene, and brassinosteroids work in concert with auxin and gibberellins to mediate plant development. Their signaling pathways vary from a simple two-component receptor–effector system (cytokinin) to inhibition of an inhibitor of an effector (ethylene and brassinosteroids).

- How do cytokinins interact with auxin to regulate a plant's development? **See p. 785**
- What is the role of ethylene in fruit ripening? How is this knowledge used commercially? **See p. 786**
- Describe how the signaling pathways for cytokinins and brassinosteroids differ. **See p. 787 and Figures 37.15 and 37.18**

A plant's response to light—the energy source for photosynthesis—is crucial to its survival. We saw how the Darwins' pioneering investigations of phototropism led to the discovery of auxin. Let's now look more closely at how plants sense and respond to light.

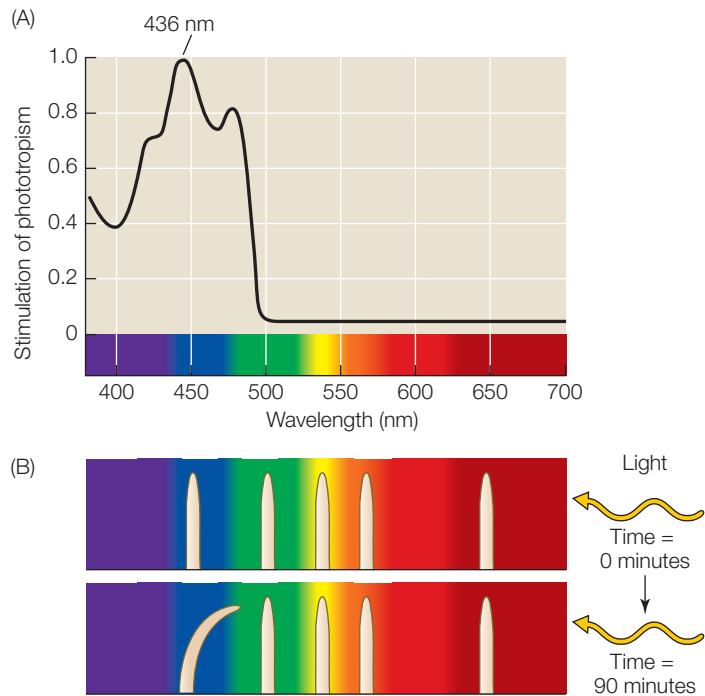

37.5 How Do Photoreceptors Participate in Plant Growth Regulation?

Plants respond to two aspects of light: (1) its *quality*—that is, the wavelengths of light that can be absorbed by molecules in the plant; and (2) its *quantity*—that is, the intensity and duration of light exposure.

Chapter 10 describes photosynthesis: how chlorophyll and other pigments absorb light at certain wavelengths (quality), and how light intensity affects photosynthetic rate (quantity). Here, we consider how light affects plant development. Earlier in this chapter, we described phototropism and how auxin mediates a plant stem's bending toward light. In addition to phototropism, light influences seed germination, shoot elongation, the initiation of flowering, and many other important aspects of plant development. Several photoreceptors take part in these processes. Three or more types of **blue-light receptors** mediate the effects of higher-intensity blue light, and **phytochrome** mediates the effects of red light.

Phototropins, cryptochromes, and zeaxanthin are blue-light receptors

Charles and Francis Darwin showed that the apical tip of a growing coleoptile receives light as a signal and then redistributes auxin to stimulate cell elongation below the tip on the shaded side. You may recall from Chapter 10 that an *action spectrum* involves exposing plants to different wavelengths of light to determine what wavelengths are most effective in driving

37.19 Action Spectrum for Phototropism (A) The action spectrum for bending of a coleoptile toward light is similar to the absorption spectrum for the receptor, phototropin. (B) After 90 minutes, only the coleoptiles exposed to blue light bend.

a given process (e.g., photosynthesis). For photosynthesis, such studies showed that the most effective wavelengths are those absorbed by chlorophylls (see Figure 10.6). When an action spectrum was obtained for phototropism of coleoptiles, blue light (peak 436 nm) was found to be the most effective at inducing the coleoptile to curve (**Figure 37.19**). What is the blue-light-absorbing receptor/pigment? Biologists have used a genetic approach to answer this question, once again employing the model plant *Arabidopsis*.

Researchers recovered blue-light-insensitive *Arabidopsis* mutants from a genetic screen and identified the gene for a blue-light receptor protein located in the plasma membrane called **phototropin**. Phototropin protein has a flavin mononucleotide associated with it that absorbs blue light, leading to a change in the shape of the protein. This change exposes an active site for a protein kinase, which in turn initiates a signal transduction cascade that ultimately results in stimulation of cell elongation by auxin.

Phototropin is also involved in chloroplast movements in relation to light, and participates with another type of blue-light receptor, the plastid pigment **zeaxanthin**, in the light-induced opening of stomata (see Figure 35.9).

Yet another class of blue-light receptors is the **cryptochromes**, which absorb blue and ultraviolet light. These yellow pigments are located primarily in the plant cell nucleus and affect seedling development and flowering. The exact mechanism of cryptochrome action is not yet known. Strong blue light inhibits cell elongation through the action of cryptochromes, although the most rapid responses are mediated by phototropins.

Phytochromes mediate the effects of red and far-red light

A number of physiological and developmental events in plants are controlled by light, a process called **photomorphogenesis**. For example:

- A bean seedling germinating below ground has an elongated stem, a pale yellow, folded leaf, and a hook that protects the leaf (see Figures 37.2 and 37.16)—it is **etiolated**. As the seedling reaches the surface of the soil, it undergoes several light-induced changes: the apical hook straightens, the rudimentary leaf unfolds, and chlorophyll is made so that photosynthesis can begin. Even very dim light will induce these changes.
- Lettuce seeds spread on the soil will germinate only in response to light. Even just a flash of dim light will suffice.
- Adult cocklebur plants flower when they are exposed to long nights. If there is a brief light flash in the middle of the night, they do not flower.

Action spectra of the above processes show that they are induced by red light (650–680 nm). This indicates that plants must have a photoreceptor pigment that absorbs red light and initiates photomorphogenesis.

What is especially remarkable about these red light responses is that *they are reversible by far-red light* (710–740 nm). For example, if lettuce seeds are exposed to brief, alternating periods of red and far-red light in close succession, they respond only to the final exposure. If it is red, they germinate; if it is far-red, they remain dormant (**Figure 37.20**). This reversibility of the effects of red and far-red light regulates many other aspects of plant development, including flowering and seedling growth.

The basis for the effects of red and far-red light resides in a bluish photoreceptor pigment protein in the cytosol of plants called **phytochrome**. Phytochrome exists in two interconvertible “isoforms” or states. The molecule undergoes a conformational change upon absorbing light at particular wavelengths. The default or “ground” state, which absorbs principally red light, is called P_r . When P_r absorbs a photon of red light it is converted into P_{fr} . The P_{fr} form preferentially absorbs far-red light; when it does so, it is converted back to P_r .

INVESTIGATING LIFE

37.20 Sensitivity of Seeds to Red and Far-Red Light

Lettuce seeds will germinate if exposed to a brief period of light. An action spectrum indicated that red light was most effective in promoting germination, but far-red light would reverse the stimulation if presented right after the red light flash. Harry Borthwick and his colleagues asked what would be the effect of repeated alternating flashes of red and far-red light. In each case, the final exposure determined the germination response. This observation led to the conclusion that a single, photoreversible molecule was involved. That molecule turned out to be phytochrome.

HYPOTHESIS The effects of red and far-red light on lettuce seed germination are mutually reversible.

METHOD Expose lettuce seeds to alternate periods of red light **R** for 1 minute and far-red light **FR** for 4 minutes.

R **R/FR** ... **R/FR/R/FR/R/FR/R** **R/FR/R/FR/R/FR/R/FR**

RESULTS

CONCLUSION Red light and far-red light reverse each other's effects.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

P_{fr} , not P_r , is the active form of phytochrome—the form that triggers important biological processes in various plants. As we have seen, these processes include seed germination, shoot development after etiolation, and flowering.

For a plant in nature, the ratio of red to far-red light determines whether a phytochrome-mediated response will occur. For example, during daylight, the ratio is about 1.2:1; because there is more red than far-red light, the P_{fr} form predominates. But for a plant growing in the shade of other plants, the ratio is as low as 0.13:1, and phytochrome is mostly in the P_r form. The low ratio of red to far-red light in the shade results from absorption of red light by chlorophyll in the leaves overhead, so less of the red light gets through to the plants below. Shade-intolerant species respond by stimulating cell elongation in the stem and thus growing taller to escape the shade. Shade cast by other plants also prevents germination of seeds that require red light to germinate (see Figure 37.20). The reflective properties of the soil can also affect the red to far-red ratio—and thus plant behavior. For example, cotton seedlings grow more slowly on soils (such as clay) that reflect more red than far-red light.

Phytochrome stimulates gene transcription

How does phytochrome, or more specifically, P_{fr} , work? Phytochrome is a cytoplasmic protein composed of two subunits (**Figure 37.21**). Each subunit has a protein chain and a nonprotein pigment from the plastid called a *chromophore*. In *Arabidopsis*, there is a gene family that encodes five slightly different phytochromes, each functioning in different photomorphogenic responses.

Gene transcription is stimulated when P_r is converted to the P_{fr} isoform. When P_r absorbs red light, the chromophore changes shape, which leads to a change in the conformation of the protein itself from the P_r form to the P_{fr} form. Conversion to the P_{fr} form exposes two important regions of the phytochrome protein (see Figure 37.21), both of which affect transcriptional activity:

- Exposure of a *nuclear localization sequence* (see Figure 14.20) results in movement of P_{fr} from the cytosol to the nucleus. Once in the nucleus, P_{fr} binds to transcription factors and thereby stimulates expression of genes involved in photomorphogenesis.
- Exposure of a *protein kinase* domain causes P_{fr} protein to phosphorylate itself and other proteins involved in red-light signal transduction, resulting in changes in the activity of transcription factors.

The effect of activating these transcription factors is quite large: In *Arabidopsis*, phytochrome affects an amazing 2,500 genes (10 percent of the entire genome!) by either increasing or de-

creasing their expression. Some of these genes are related to other hormones. For example, when P_{fr} is formed in seed germination, genes for gibberellin synthesis are activated and genes for gibberellin breakdown are repressed. As a result, gibberellins accumulate and seed reserves are mobilized.

Circadian rhythms are entrained by light reception

The timing and duration of biological activities in living organisms are governed in all eukaryotes and some prokaryotes by what is commonly called a “biological clock”—an oscillator within cells that alternates back and forth between two states at roughly 12-hour intervals. The major outward manifestations of this clock are known as **circadian rhythms** (Latin *circa*, “about,” and *dies*, “day”). Think of your own life: in all probability you sleep at night, and you are awake during the day. In plants, circadian rhythms influence, for example, the opening (during the day) and closing (at night) of stomata in *Arabidopsis*, and the raising toward the sun (during the day) and lowering (at night) of leaves in bean plants. From these two examples, it is obvious that circadian rhythms are ecologically useful adaptations, in that they relate the plant’s physiology to its environment.

Two qualities characterize circadian rhythms, as well as other regular biological cycles: the **period** is the length of one cycle, and the **amplitude** is the magnitude of the change over the course of a cycle. The circadian rhythms of plants have several noteworthy characteristics:

- The period of a circadian rhythm is remarkably insensitive to temperature, although lowering the temperature may drastically reduce the amplitude.
- Circadian rhythms are highly persistent; they may continue for days, even in the absence of environmental cues, such as light–dark periods.
- Circadian rhythms can be *entrained*, within limits, by light–dark cycles that do not exactly correspond to 24 hours. That is, the period of a rhythm can be made to coincide (within limits) with that of the light–dark cycle to which the organism is exposed.

37.21 Phytochrome Stimulates Gene Transcription Phytochrome is composed of two polypeptide chains, each with a chromophore pigment. This pair of polypeptides undergoes a conformational change upon absorbing light. When phytochrome absorbs red light, it converts to the P_{fr} form, which activates transcription of phytochrome-responsive genes.

Consider what happens when a person abruptly moves across many time zones: what was the night becomes the day, and gradually the person's sleep–wakefulness circadian rhythm entrains to the new environmental cues. Similar entrainment occurs in plants adapting to day length as the seasons progress during the year. The action spectrum for plant entrainment indicates that phytochrome (and to a lesser extent, blue-light receptors) is very likely involved. At sundown phytochrome is mostly in the active P_{fr} form. But as the night progresses, P_{fr} gradually gets converted back to the inactive P_r form. By dawn phytochrome is mostly in the P_r state, but as daylight begins, it rapidly converts to P_{fr} . The switch to the P_{fr} state resets the plant's biological clock. However long the night, the clock is still reset at dawn every day. Thus while the total period measured by the clock is consistent, the clock adjusts to changes in day length over the course of the year.

37.5 RECAP

Light controls a number of physiological and developmental events in plants, a process called photomorphogenesis. Pigment photoreceptors such as phototropin, cryptochromes, and phytochrome mediate the effects of light on plant growth and development. Phytochrome exists in two interconvertible states; conversion from one state to the other is controlled by the ratio of red to far-red light. Circadian rhythms are influenced by light reception.

- Give the evidence for blue-light receptors in plants. **See p. 788 and Figure 37.19**
- Why does red light affect seed germination differently from far-red light? **See p. 789 and Figure 37.20**
- What are circadian rhythms? How are they related to photoreception? **See p. 790**

Photoreceptors also play a regulatory role in flowering. In addition to light, another environmental cue—temperature—regulates flowering. We will examine these topics and others in the next chapter, which focuses on reproduction in flowering plants.

CHAPTER SUMMARY

37.1 How Does Plant Development Proceed?

- As sessile organisms, plants maximize their ability to grow by using meristems, forming new organs and growing throughout life.
- The environment, photoreceptors, hormones, and the plant's genome all regulate plant development.
- Seed **dormancy**, which has adaptive advantages, is maintained by a variety of mechanisms. In nature, dormancy is broken by, for example, abrasion, fire, leaching, and low temperatures. When dormancy ends and the seed **imbibes** water, it **germinates** and develops into a **seedling**. **Review Figure 37.1, WEB ACTIVITIES 37.1 and 37.2**
- Plants have several hormones, each of which regulates multiple aspects of development. Interactions among these hormones are often complex. **Review Table 37.1**
- **Hormones and photoreceptors** act through signal transduction pathways to regulate seedling development. Before the germinating embryo can begin photosynthesis, it relies on energy reserves in the **cotyledons** or the **endosperm**.
- **Genetic screens** using the model organism *Arabidopsis thaliana* have contributed greatly to our understanding of signaling in plants. **Review Figure 37.3**

37.2 What Do Gibberellins Do?

- The embryos of cereal seeds secrete **gibberellins**, which cause the **aleurone layer** to synthesize and secrete digestive enzymes that break down macromolecules stored in the endosperm. **Review Figure 37.6, WEB ACTIVITY 37.3**
- Dozens of gibberellins exist. These hormones regulate the growth of stems and some fruits.
- Gibberellins act through the breakdown of transcriptional repressors. **Review Figure 37.7**

37.3 What Does Auxin Do?

SEE ANIMATED TUTORIAL 37.1

- In **coleoptiles**, **auxin** is made in cells at the tip and moves down to the growing region. **Review Figures 37.8 and 37.9, ANIMATED TUTORIAL 37.2**
- Auxin transport is polar. Auxin active transport carriers—membrane proteins confined to the basal ends of cells—cause auxin to move from the tip to the base of the shoot. **Review Figure 37.10**
- Lateral movement of auxin, mediated by auxin transport carriers, is responsible for **phototropism** and **gravitropism**. **Review Figure 37.11**
- Auxin plays roles in root formation, leaf **abscission**, **apical dominance**, and **parthenocarpic fruit development**. Certain synthetic auxins are used as selective herbicides.
- The **acid growth hypothesis** explains how auxin promotes cell expansion by disrupting interactions between cell wall microfibrils. **Review Figure 37.13, ANIMATED TUTORIAL 37.3**
- The molecular mechanism underlying auxin action is similar to that of gibberellin; as long as auxin is not bound to its receptor, transcription is repressed. When the auxin–receptor complex binds to a transcriptional repressor, the repressor is degraded and transcription is initiated. **Review Figure 37.14**

37.4 What Are the Effects of Cytokinins, Ethylene, and Brassinosteroids?

- **Cytokinins** are adenine derivatives. They promote plant cell division, promote seed germination in some species, inhibit stem elongation, promote lateral swelling of stems and roots, stimulate the growth of axillary buds, promote the expansion of leaf tissue, and delay leaf senescence.

- **Cytokinins** act on plant cells by a signal transduction pathway that is similar to bacterial two-component systems. **Review Figure 37.15**
- A balance between auxin and **ethylene** controls leaf abscission. Ethylene promotes senescence and fruit ripening. It causes the formation of a protective **apical hook** in eudicot seedlings. In stems, it inhibits elongation, promotes lateral swelling, and causes a loss of gravitropic sensitivity.
- Ethylene acts on cells by a protein kinase pathway located in the endoplasmic reticulum. **Review Figure 37.17**
- Dozens of different **brassinosteroids** affect cell elongation, pollen tube elongation, vascular tissue differentiation, and root elongation. Some effects of light are mediated by changes in the action and levels of brassinosteroids. These steroids act at a plasma membrane receptor. **Review Figure 37.18**

37.5 How Do Photoreceptors Participate in Plant Growth Regulation?

- **Phototropins** are blue-light photoreceptors for phototropism and chloroplast movements. **Zeaxanthin** acts in conjunction with the phototropins to mediate the light-induced opening of stomata. **Cryptochromes** are blue-light photoreceptors that control seedling development, stem elongation, and floral initiation.
- **Phytochromes** exist in the cytosol in two interconvertible forms, P_r and P_{fr} . The relative amounts of these two forms are a function of the ratio of red to far-red light. Phytochromes affect seedling growth, flowering, and etiolation. **Review Figure 37.20**
- The phytochrome signal transduction pathway affects transcription in two different ways; the P_{fr} form interacts directly with some transcription factors, and influences transcription indirectly through interactions with protein kinases. **Review Figure 37.21**
- **Circadian rhythms** are activities that occur on a near-24-hour cycle. Light can entrain these activities through photoreceptors such as phytochrome.

SELF-QUIZ

- Which of the following is *not* an advantage of seed dormancy?
 - It makes the seed more likely to be digested by birds that disperse it.
 - It counters the effects of year-to-year variations in the environment.
 - It increases the likelihood that a seed will germinate in the right place.
 - It favors dispersal of the seed.
 - It may result in germination at a favorable time of year.
- Which of the following does *not* occur in seed germination?
 - Imbibition of water
 - Metabolic changes
 - Growth of the radicle
 - Mobilization of nutrient reserves
 - Extensive mitotic divisions
- To mobilize its nutrient reserves, a germinating barley seed
 - becomes dormant.
 - undergoes senescence.
 - secretes gibberellins into its endosperm.
 - converts glycerol and fatty acids into lipids.
 - takes up proteins from the endosperm.
- The gibberellins
 - are responsible for phototropism and gravitropism.
 - are gases at room temperature.
 - are produced only by fungi.
 - cause flowering in plants.
 - inhibit the synthesis of digestive enzymes by barley seeds.
- In coleoptile tissue, auxin
 - is transported from base to tip.
 - is transported from tip to base.
 - can be transported toward either the tip or the base, depending on the orientation of the coleoptile with respect to gravity.
 - is transported by simple diffusion, with no preferred direction.
 - is not transported, because auxin is used where it is made.
- Which process is *not* directly affected by auxin?
 - Apical dominance
 - Leaf abscission
 - Synthesis of digestive enzymes by barley seeds
 - Root initiation
 - Cell elongation
- Signal transduction for both auxin and gibberellins involves
 - binding of the hormone to a nuclear receptor.
 - degradation of a repressor of gene transcription.
 - production of a small molecule second messenger.
 - light absorption followed by chemical changes.
 - breakdown of the hormone.
- Which statement about cytokinins is *not* true?
 - They promote cell division in tissue cultures.
 - They delay the senescence of leaves.
 - They usually promote the elongation of stems.
 - They act by a receptor with protein kinase activity.
 - They were discovered as a breakdown product of DNA.
- Ethylene
 - causes the triple response in seedlings growing underground.
 - is liquid at room temperature.
 - delays the ripening of fruits.
 - generally promotes stem elongation.
 - inhibits the swelling of stems, in opposition to cytokinin's effects.
- Phytochrome
 - is the only photoreceptor pigment in plants.
 - exists in two forms interconvertible by light.
 - is a pigment that is colored red or far-red.
 - is a green-light receptor.
 - is the photoreceptor for phototropism in coleoptiles.

FOR DISCUSSION

1. Describe the circumstances under which it would be advantageous for a species to have the dormancy of its seeds broken by fire.
2. Cocklebur fruits contain two seeds each that are kept dormant by two different mechanisms. Why might having two mechanisms of dormancy be advantageous to cockleburs?
3. Supermarkets sell plastic bags that are impregnated with activated charcoal, which binds gases. The bags are designed to keep fruit fresh. How do they work?
4. Corn stunt virus causes a great reduction in the growth rate of infected corn plants. Diseased plants take on a dwarfed form. Since their appearance is reminiscent of the genetically dwarfed corn, you suspect that the virus may inhibit the synthesis of gibberellins by corn plants. Describe two experiments you might conduct to test this hypothesis, only one of which should require chemical measurement.

ADDITIONAL INVESTIGATION

The semi-dwarf wheat and rice plants that led to the Green Revolution described in the chapter opening have mutations in the signal transduction pathway for gibberellins. You wish to use genetic engineering to make corn plants that are semi-dwarf.

- a. How would you do a genetic screen to identify the genes in corn involved in gibberellin signaling?
- b. Assuming that the signal transduction pathway is similar to that in *Arabidopsis*, what gene would you select for inactivation?
- c. Besides short stature, what other effects would you expect for the signal transduction mutant strain? How would you use other hormones to overcome them?

WORKING WITH DATA (GO TO yourBioPortal.com)

The Darwins' Phototropism Experiment In this exercise based on Figure 37.8, you will read excerpts from a book by Charles Darwin, *The Power of Movement in Plants*, in which he describes the experiments he and his son Francis undertook

that ultimately led to the isolation by others of the plant hormone auxin. You will see how they planned their experiments and controls, and analyze the results.

The language of flowers

In the recent film *Kate and Leopold*, a Victorian English nobleman named Leopold is transplanted to modern-day New York, where he meets and falls in love with Kate. At one point, Leopold sees a bundle of flowers at a florist's shop and is amazed that this bouquet would be given to a woman. It's all wrong, he explains: the lavender implies distrust; the orange lily stands for extreme hatred. Better to send amaryllis, which symbolizes great beauty.

During the Victorian era in England (1837–1891) floral symbolism reached its peak of popularity. Social convention discouraged open displays of emotion, so flowers were often used to convey messages people dared not speak aloud. This botanical language was so elaborate

that dictionaries were written to describe the specific “meanings” of flowers and their colors.

A student at Cambridge University might “tell” a woman that she was beautiful with a calla lily. He might indicate he would be patient by presenting her with a daisy. If the woman found her suitor attractive, she could tell him so with a camellia; a geranium, on the other hand, would say, “Let’s just be friends.” Colors had meaning, too. A red rose symbolized love, while yellow was associated with jealousy and white with innocence.

By the early twentieth century the rules of social communication were sufficiently relaxed that intricate floral communication was no longer necessary. Nevertheless, certain flowers continue to have symbolic meaning. Poppies are worn in the British Commonwealth to memorialize soldiers who died in battle. Lilies are often used at funerals to symbolize life and, for Christians, resurrection. The Hindu god Vishnu is often shown with a lotus flower, symbolizing that he is the pure source of all creation.

Floral symbolism flourishes even in the United States. Consider the poinsettia, *Euphorbia pulcherrima*, a bright red shrub native to Central America that was used by the Aztecs as a source of red dye. The plant was brought to the U.S. by the first U.S. ambassador to Mexico, John Roberts Poinsett, an amateur botanist. Some years later a much shorter strain of the plant was developed by a Californian plant breeder named Paul Ecke. By 1950, his son, Paul Ecke, Jr., began promoting this now portable plant as a holiday decoration, blanketing television specials with offers of free plants during the period between Thanksgiving and Christmas. The campaign was successful: over 100 million poinsettia plants are now sold in the U.S. during the winter holidays every year, making it the best-selling potted plant.

Floral Message A girl holds a single flower, perhaps wondering what message it conveys.

Flowers Have Diverse Forms and Meanings

The language of flowers still had some popularity in the early twentieth century, as demonstrated by these Edwardian postcards.

You may be surprised to learn that the brightly colored poinsettia “flowers” are not flowers at all. The red (or sometimes pale yellow) parts of the plant that we most notice and appreciate are actually leaves. The poinsettia has a single tiny yellow female flower, without petals, surrounded by male flowers.

The main task of flowers is not to convey messages to humans. Flowers are reproductive equipment: they produce gametophytes, female and male, which in turn produce the gametes that give rise to the next sporophyte generation. Wildflowers (those not “improved” by plant breeders) may have pleasing shapes and colors, but these are in aid not of poetry but of pollination, which is crucial to angiosperm reproduction.

IN THIS CHAPTER we contrast sexual and asexual reproduction in plants, focusing on the details of sexual reproduction. We consider angiosperm gametophytes, pollination, double fertilization, embryo development, and the roles of fruits in seed dispersal. We examine the transition from the vegetative state to the flowering state, a key event in angiosperm development. We conclude by considering the role of asexual reproduction in nature and in agriculture.

CHAPTER OUTLINE

- 38.1** How Do Angiosperms Reproduce Sexually?
- 38.2** What Determines the Transition from the Vegetative to the Flowering State?
- 38.3** How Do Angiosperms Reproduce Asexually?

38.1 How Do Angiosperms Reproduce Sexually?

Flowers—the hallmark of angiosperms—contain sex organs; thus it is no surprise that almost all angiosperms reproduce sexually. But many reproduce asexually as well; some even reproduce asexually most of the time. What are the advantages and disadvantages of these two kinds of reproduction?

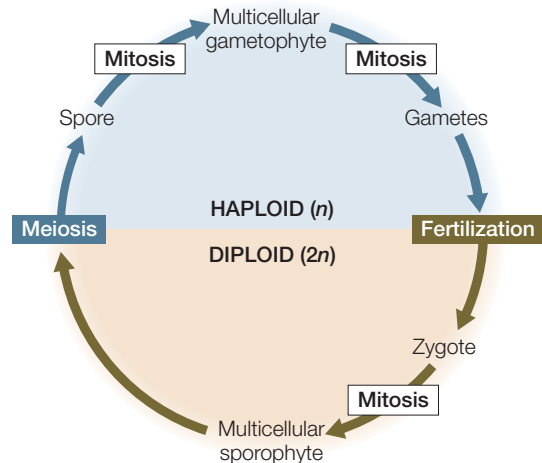

The relative benefits of sexual versus asexual production are a matter of whether genetic recombination will be advantageous. As we have seen, sexual reproduction produces new combinations of genes and diverse phenotypes (see Section 11.4). Asexual reproduction, in contrast, produces a clone of genetically identical individuals.

Many plants can reproduce either sexually or asexually. For example, strawberry plants can reproduce perfectly well by flowers and seeds (sexual reproduction), but they also reproduce asexually by a stem called a *runner* that spreads over the surface of the soil, sprouting new plants at intervals. For the strawberry plant it might be advantageous to reproduce sexually when possible; this generates genetic diversity, and the seeds that are produced facilitate dispersal to far-flung sites. However, too much diversity can be a drawback for farmers, and they generally propagate this crop asexually to deliver predictably plump and tasty strawberries to the market.

We will return to asexual reproduction later in this chapter. Our concern for now is sexual reproduction.

The flower is an angiosperm's structure for sexual reproduction

Sexual reproduction involves mitosis and meiosis, and the alternation of haploid and diploid generations (see Chapter 11):

In angiosperms, the plant that we see in nature is a sporophyte and male and/or female gametophytes are contained in the

flowers. A complete flower consists of four concentric groups of organs arising from modified leaves: the *carpels*, *stamens*, *petals*, and *sepals*.

The parts of the flower are usually borne on a stem tip, and derive from a meristem. The differentiation of the meristem into the various organs of the flower is controlled by specific transcription factors (see Figure 19.14). As we discussed in the introductory essay for this chapter, flower parts are very diverse in form.

The carpels and stamens are, respectively, the female and male sex organs. Flowers usually have both stamens and carpels; such flowers are termed *perfect* (Figure 38.1A). *Imperfect* flowers, on the other hand, are those with only male or only female sex organs. Male flowers have stamens but not carpels,

(A) Perfect: lily

(B) Imperfect monoecious: corn

and female flowers have carpels but not stamens. Some plants, such as corn, bear both male and female flowers on an individual plant; such species are called **monoecious** (“one house”) (Figure 38.1B). In **dioecious** species, on the other hand, individual plants bear either male-only or female-only flowers; an example is bladder campion (Figure 38.1C).

Flowering plants have microscopic gametophytes

Figure 38.2 offers a detailed look at the gametophytes central to angiosperm reproduction. The haploid gametophytes—the gamete-producing structures—develop from haploid spores in the flower:

- Female gametophytes (megagametophytes), which are called **embryo sacs**, develop in megasporangia.
- Male gametophytes (microgametophytes), which are called **pollen grains**, develop in microsporangia.

FEMALE GAMETOPHYTE Locate the ovule in the flower shown in Figure 38.2. Within the ovule, a megasporocyte—a cell within the megasporangium—divides meiotically to produce four haploid megaspores. In most flowering plants, all but one of these megaspores then undergo apoptosis. The surviving megaspore usually goes through three mitotic divisions without cytokinesis, producing eight haploid nuclei, all initially contained within a single cell—three nuclei at one end, three at the other, and two in the middle. Subsequent cell wall formation leads to an elliptical, seven-celled megagametophyte with a total of eight nuclei:

- At one end of the elliptical megagametophyte are three tiny cells: the **egg** and two cells called *synergids*. The egg is the female gamete, and the synergids participate in fertilization

38.1 Perfect and Imperfect Flowers (A) A lily is an example of a perfect flower, meaning one that has both male and female sex organs. (B) Imperfect flowers are either male or female. Corn is a monoecious species: both types of imperfect flowers are borne on the same plant. (C) Bladder campion is a dioecious species; some bladder campion plants bear male imperfect flowers while others bear female imperfect flowers.

(C) Imperfect dioecious: bladder campion

by attracting the pollen tube and receiving the sperm nuclei prior to their movement to the egg and central cell.

- At the opposite end of the megagametophyte are three antipodal cells, which eventually degenerate.
- In the large central cell are two **polar nuclei**, which together combine with a sperm nucleus.

38.2 Sexual Reproduction in Angiosperms The embryo sac is the female gametophyte; the pollen grain is the male gametophyte. The male and female nuclei meet and fuse within the embryo sac. Angiosperms have double fertilization, in which a zygote and an endosperm nucleus form from separate fusion events—the zygote from one sperm and the egg, and the endosperm from the other sperm and two polar nuclei.

yourBioPortal.com

GO TO Animated Tutorial 38.1 • Double Fertilization

The embryo sac (megagametophyte) is the entire seven-cell, eight-nucleus structure.

MALE GAMETOPHYTE The pollen grain (microgametophyte) consists of fewer cells and nuclei than the embryo sac. The development of a pollen grain begins when a microsporocyte within the anther divides meiotically. Each resulting haploid microspore develops a spore wall, within which it normally undergoes one mitotic division before the anthers open and release these two-celled pollen grains. The two cells are the tube cell and the generative cell. Further development of the pollen grain, which we will describe shortly, is delayed until the pollen arrives at a stigma (the receptive part of the carpel). In angiosperms, the transfer of pollen from the anther to the stigma is referred to as **pollination**.

Pollination in the absence of water is an evolutionary adaptation

As Chapter 28 describes, the union of gametes in aquatic plants is accomplished in the water. Fertilization of mosses and ferns also requires at least a film of water for movement of gametes. While there are mechanisms to ensure fertilization if and when the two gametes meet, fertilization is clearly a low-probability event. The evolution of pollen made it possible for male gametes to reach the female gametophyte without an aqueous conduit. With this selective advantage, pollen-bearing plants were able to colonize the land.

In the first land plants, wind was the primary vehicle by which pollen reached its destination, and many plant species are wind-pollinated today. Wind-pollinated flowers have sticky or featherlike stigmas, and they produce pollen grains in great numbers. Pollen transport by wind is, however, a relatively chancy means of achieving pollination, explaining why about 75 percent of all angiosperms rely upon animals—including insects, birds, and bats—for pollen transport. Pollen transport by animals greatly increases the probability that pollen will get to the female gametophyte. Suitably pigmented, shaped, and scented flowers attract the pollinating animal, resulting in a pollen transfer from flower to flower within the same plant species (**Figure 38.3**).

Flower color is one of several adaptations that attract pollinators. Bees, for example, are attracted to blue and yellow flowers (bees cannot sense red but are attracted to patterns exhibited by pigments visible in ultraviolet light; see Figure 56.10). Many birds, on the other hand, are attracted to red flowers (bird-pollinated plants also are often shaped to fit their

pollinator's beak.) In both cases, the animals may derive nutrition from the flowers in the form of carbohydrate-rich nectar and/or pollen—a mutually beneficial situation.

Flowering plants prevent inbreeding

You may recall from discussions of Mendel's work (see Section 12.1) that some plants can reproduce sexually by both cross-pollination and self-pollination. Self-pollination increases the chances of successful pollination, but leads to homozygosity, which reduces genetic diversity. Because diversity is the raw material of evolution by natural selection, homozygosity can be selectively disadvantageous. Most plants have evolved mechanisms that prevent self-fertilization. The two primary means to prevent self-fertilization are (1) physical separation of male and female gametophytes, and (2) genetic self-incompatibility.

SEPARATION OF MALE AND FEMALE GAMETOPHYTES Self-fertilization is prevented in dioecious species, which bear only male or female flowers on a particular plant. Pollination in dioecious species is accomplished only when one plant pollinates another. In monoecious plants, which bear both male and female flowers on the same plant, the physical separation of the male and female flowers is often sufficient to prevent self-fertilization. Some monoecious species prevent self-fertilization by staggering the development of male and female flowers so they do not bloom at the same time, making these species functionally dioecious.

GENETIC SELF-INCOMPATIBILITY A pollen grain that lands on the stigma of the same plant will fertilize the female gamete (review Figure 38.2) *only if the plant is self-compatible*, meaning capable of self-pollination. To prevent self-fertilization, many plants are

38.3 Flowers and Pollinators (A) Flies are attracted to some flowers (in this case, the tropical plant *Stapelia gigantea*) by chemicals emitted from the flower. (B) Other flowers, such as these *Cavendishia* sp. flowers, have red pigments and a shape that attracts certain birds.

38.4 Self-Incompatibility In a self-incompatible plant, pollen is rejected if it expresses an *S* allele that matches one of the *S* alleles of the stigma and style. Self pollen may (A) fail to germinate or (B) its pollen tube may die before reaching an ovule. In either case, the egg cannot be fertilized by a sperm from the same plant.

self-incompatible, which depends upon the ability of a plant to determine whether pollen is genetically similar or genetically different from “self.” Rejection of “same-as-self” pollen prevents self-fertilization. How does it occur?

Self-incompatibility in plants is controlled by a cluster of tightly linked genes called the *S* locus (for self-incompatibility). The *S* locus encodes proteins in the pollen and style that interact during the recognition process. A self-incompatible species typically has many alleles of the *S* locus, and when the pollen carries an allele that matches one of the alleles of the recipient pistil, the pollen is rejected. Depending on the type of self-incompatibility system, the rejected pollen either fails to germinate or is prevented from growing through the style (**Figure 38.4**); either way, self-fertilization is prevented.

A pollen tube delivers sperm cells to the embryo sac

When a functional pollen grain lands on the stigma of a compatible pistil, it germinates. A key event is water uptake by pollen from the stigma: pollen loses most of its water as it matures. Germination involves the development of a **pollen tube** (**Figure 38.5**). The pollen tube either traverses the spongy tissue of the style or, if the style is hollow, grows on the inner surface of the style until it reaches an ovule. The pollen tube typically grows at the rate of 1.5–3 mm/hr, taking just an hour or two to reach its destination, the female gametophyte.

The growth of the pollen tube is guided in part by a chemical signal in the form of a small protein produced by the synergids within the ovule. If one synergid is destroyed, the ovule

38.5 Pollen Tubes Begin to Grow Staining pollen with a fluorescent dye allows them to be seen through a fluorescence microscope. These pollen grains have landed on the stigmas of a crocus.

still attracts pollen tubes, but destruction of both synergids renders the ovule unable to attract pollen tubes, and fertilization does not occur. The attractant appears to be species-specific: in some cases, isolated female gametophytes attract only pollen tubes of the same species.

Angiosperms perform double fertilization

In most angiosperm species, the mature pollen grain consists of two cells, the tube cell and the generative cell. The larger tube cell encloses the much smaller generative cell. Guided by the tube cell nucleus, the pollen tube eventually grows through the style tissue and reaches the embryo sac. The generative cell, meanwhile, has undergone one mitotic division and cytokinesis to produce two haploid **sperm cells** (**Figure 38.6, steps 1 and 2**).

Two fertilization events now occur. One of the two synergids degenerates when the pollen tube arrives and the two sperm cells are released into its remains. (**Figure 38.6, step 3**). Each sperm cell then fuses with a different cell of the embryo sac (**Figure 38.6, steps 4 and 5**). One sperm cell fuses with the egg cell, producing the diploid zygote. The nucleus of the other fuses with the two polar nuclei in the central cell, forming a **triploid (3n) nucleus**. While the zygote nucleus begins mitotic division to form the new sporophyte embryo, the triploid nucleus undergoes rapid mitosis to form a specialized nutritive tissue, the **endosperm**. The endosperm will later be digested by the developing embryo as a source of nutrients, energy, and carbon-based anabolic building blocks (since it often begins its development

underground and thus cannot perform photosynthesis right away). The remaining cells of the male and female gametophytes, the antipodal cells, and the remaining synergid eventually degenerate, as does the pollen tube nucleus.

Double fertilization is so named because it involves two nuclear fusion events:

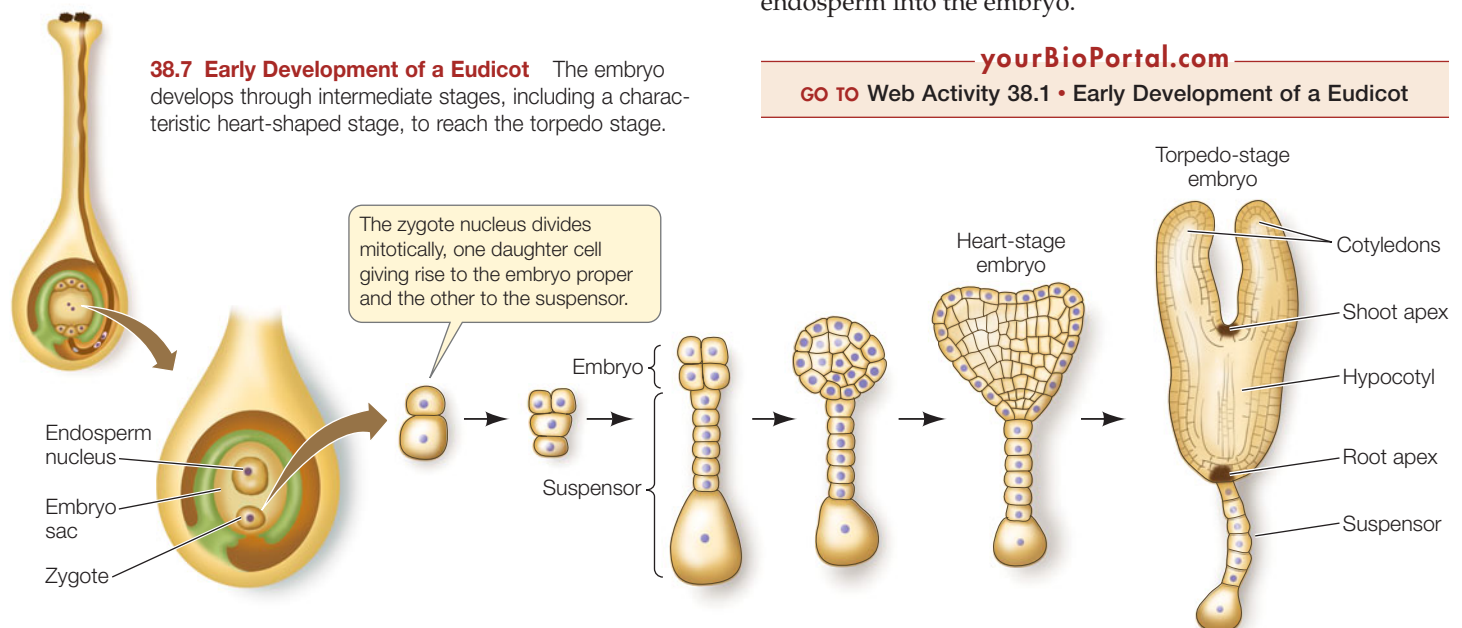

- One sperm nucleus fuses with the egg cell nucleus.
- The other sperm nucleus fuses with the two polar nuclei.

The fusion of a sperm cell nucleus with the two polar nuclei to form endosperm is one of the defining characteristics of angiosperms.

Embryos develop within seeds

Fertilization initiates the highly coordinated growth and development of the embryo, endosperm, integuments, and carpel. The *integuments*—tissue layers immediately surrounding the megasporangium—develop into the seed coat, and the carpel ultimately becomes the wall of the fruit that encloses the seed.

The first step in the formation of the embryo is a mitotic division of the zygote that gives rise to two daughter cells. These two cells face different fates. An asymmetrical (uneven) distribution of cytoplasm within the zygote causes one daughter cell to produce the embryo proper and the other daughter cell to produce a supporting structure, the **suspensor** (Figure 38.7). The suspensor pushes the embryo against or into the endosperm, thereby facilitating the transfer of nutrients from the endosperm into the embryo.

yourBioPortal.com

GO TO Web Activity 38.1 • Early Development of a Eudicot

The asymmetrical division of the zygote establishes polarity as well as the longitudinal axis of the new plant. A long, thin suspensor and a more spherical or globular embryo are distinguishable after just four mitotic divisions. The suspensor soon ceases to elongate, and the primary meristems and first organs begin to form within the embryo.

In eudicots, the initially globular embryo develops into the characteristic heart stage as the cotyledons (“seed leaves”) start to grow. Further elongation of the cotyledons and of the main axis of the embryo gives rise to the torpedo stage, during which some of the internal tissues begin to differentiate (see Figure 34.7). Between the cotyledons is the shoot apex; at the other end of the axis is the root apex. Each of the apical regions contains a cluster of meristematic cells that continue to divide to give rise to new organs throughout the life of the plant.

During seed development, large amounts of nutrients are moved in from other parts of the parent plant, and the endosperm accumulates starch, lipids, and proteins. In many species, the cotyledons absorb the nutrient reserves from the surrounding endosperm and grow very large in relation to the rest of the embryo (**Figure 38.8A**). In others, the cotyledons remain thin (**Figure 38.8B**) and draw on the reserves in the endosperm as needed when the seed germinates.

In the late stages of embryonic development, the seed loses water—sometimes as much as 95 percent of its original water content. This helps the seed remain viable during the time between the seed’s dispersal from the parent plant and its eventual germination.

What keeps seeds viable when they have lost water? It appears that as water leaves, sugars and certain protective proteins become more concentrated inside the seeds, creating a very viscous fluid similar to glass. The membranes and proteins of the cells inside the seed retain their integrity in this viscous state. Once the embryo has become desiccated, it is incapable of further development; it remains dormant until internal and external conditions are right for germination (as we saw in Section 37.1).

38.8 Variety in Angiosperm Seeds In some seeds, such as kidney beans (A), the nutrient reserves of the endosperm are absorbed by the cotyledons. In others, such as corn (B), the reserves in the endosperm will be drawn upon after germination.

Seed development is under hormonal control

Chapter 37 describes the role of the hormone gibberellin in the mobilization of stored macromolecules in the seed endosperm during germination. The development of seeds is under the control of a different hormone, **abscisic acid (ABA)**. Most plant tissues make this hormone, and like other plant hormones it has multiple effects (see Table 37.1). (Unfortunately, its name is misleading, because it does not directly control leaf abscission.) During early seed development the ABA level is low, and it rises as the seed matures. This increase stimulates the endosperm to synthesize seed storage proteins. It also stimulates the synthesis of proteins that prevent cell death as the seeds dry.

ABA also keeps the developing seed from germinating on the plant before it dries. Premature germination, termed **vivipary**, is undesirable in seed crops (such as wheat) because the grain is damaged if it has started to sprout. Viviparous seedlings are also unlikely to survive if they remain attached to the parent plant and are unable to establish themselves in the soil. Mutants of corn that are insensitive to ABA have viviparous seeds, indicating the importance of ABA in preventing precocious germination.

The general effect of ABA in preventing germination extends to seed dormancy. Seeds stay dormant if their ABA level is high and germinate when the level goes down, as usually occurs as dormancy is broken.

Fruits assist in seed dispersal

In angiosperms the ovary wall—together with its seeds—develops into a fruit after fertilization has occurred. Fruits have two main functions:

- They protect the seed from damage by animals and infection by microbial diseases
- They aid in seed dispersal

A **fruit** may consist of only the mature ovary and seeds, or it may include other parts of the flower. Some species produce fleshy, edible fruits such as peaches and tomatoes, while the fruits of other species are dry or inedible.

Fruits are clearly important for carrying seeds, with their embryos, away from the parent plant. Why has this characteristic been selected for during evolution? As products of sexual reproduction, seeds are genetically diverse, and dispersal spreads this diversity around. But if a plant has successfully grown to reproduce, its environment would presumably be favorable for the next generation, too. Some offspring do indeed stay near the parent, as is the case in many tree species, where the seeds essentially fall to the ground. However, this strategy has several disadvantages. If the species is a perennial, offspring that germinate near their parent will be competing with their parent for resources, which may be too limited to support a dense population. Furthermore, even though the local conditions were good enough for the parent to produce at least some seed, there is no guarantee that conditions will still be good the next year, or that they won’t be even better elsewhere. Thus, in many cases, seed dispersal is vital to a species’ survival.

38.9 Dispersing Fruit (A) A milkweed seed pod. Silky filaments catch the wind currents and carry the brown seeds with them. (B) Animals who rub up against the “hook-and-loop” surface of burdock fruit walk away with it attached to their fur, thus making the animals unwitting agents of dispersal. This feature of the fruit is said to have inspired the invention of Velcro.

(A) *Asclepias syriaca*(B) *Arctium* sp.

Some fruits help disperse seeds over substantial distances, increasing the probability that at least a few of the many seeds produced by a plant will find suitable conditions for germination and growth to sexual maturity. Various plants, including milkweed and dandelion, produce a fruit with a “parachute” that may be blown some distance from the parent plant by the wind (**Figure 38.9A**). Still other fruits move by hitching rides with animals—either on them, as with burrs stuck to an animal’s fur (or to your hiking socks) (**Figure 38.8B**), or inside them, as with berries eaten by birds. Water disperses some fruits; coconuts have been known to travel thousands of miles between islands. Seeds swallowed whole along with fruits such as berries travel through the animal’s digestive tract and are deposited some distance from the parent plant. In some species, seeds must pass through an animal in order to break dormancy.

sented in Chapter 37. The next section covers the rest of the angiosperm life cycle—the transition from the vegetative to the flowering state—and how this transition is regulated.

38.2 What Determines the Transition from the Vegetative to the Flowering State?

The act of flowering is one of the major events in a plant’s life. It represents a reallocation of energy and materials away from making more plant parts (vegetative growth) to making flowers and gametes (reproductive growth). Once a plant is old enough, it can respond to internal or external signals to initiate reproduction. This can happen right at maturity as part of a predetermined developmental program (as in a dandelion plant in the summer) or in response to environmental cues such as light or temperature (as with most ornamental flowers).

Plants fall into three categories depending upon when they mature and initiate flowering, and what happens after they flower:

- **Annuals** complete their lives in one year. This class includes many crops important to the human diet, such as corn, wheat, rice, and soybean. When the environment is suitable, they grow rapidly, with little or no secondary growth. After flowering, they use most of their materials and energy to develop seeds and fruits, and the rest of the plant withers away.
- **Biennials** take two years to complete their lives. They are much less common than annuals and include carrots, cabbage, onions, and Queen Anne’s lace. Typically, biennials produce just vegetative growth during the first year and store carbohydrates in underground roots (carrot) and stems (onion). In the second year, they use most of the stored carbohydrates to produce flowers and seeds rather than vegetative growth, and the plant dies after seeds form.
- **Perennials** live three or more—sometimes many more—years. Maple trees, whose leaves symbolize Canada, can live up to 400 years. Perennials include many trees and shrubs, as well as wildflowers. Typically these plants flower every year, but stay alive and keep growing for another season; the reproductive cycle repeats each year. However, some perennials (e.g., century plant) grow vegetatively for many years, flower once, and die.

38.1 RECAP

Flowers contain the organs for sexual reproduction in angiosperms. Plants that use pollen for reproduction have several selective advantages, among them the ability to accomplish fertilization without water, which allowed plants to colonize land. After fertilization, the flower develops into seed(s) and fruit. The selective advantages of seeds and fruits include long-term viability and multiple modes of dispersal.

- What are the relationships between an ovule and an ovary, and between a fruit and a seed? **See p. 796 and Figure 38.2**
- How do plants prevent self-pollination? **See pp. 798–799 and Figure 38.4**
- Describe the roles of the two sperm nuclei in double fertilization. **See p. 799 and Figure 38.6**
- How is plant development controlled by the hormone abscisic acid? **See p. 801**

We have now traced the sexual life cycle of angiosperms from the flower, to the fruit, to the dispersal of seeds. Seed germination and the vegetative development of the seedling are pre-

38.10 Flowering and the Apical Meristem A vegetative apical meristem (A) grows without producing flowers. Once the transition to the flowering state is made (B), inflorescence meristems give rise to bracts and to floral meristems (C), which become the flowers.

be **floral meristems**, each of which gives rise to a flower.

Each floral meristem typically produces four consecutive whorls or spirals of organs—the sepals, petals, stamens, and carpels discussed earlier in the chapter—separated by very short internodes, keeping the flower compact (**Figure 38.10C**). In contrast to vegetative apical meristems and some inflorescence meristems, floral meristems are responsible for *determinate growth*—growth of limited duration, like that of leaves.

A cascade of gene expression leads to flowering

How do apical meristems become floral meristems or inflorescence meristems, and how do inflorescence meristems give rise to floral meristems? How does a floral meristem give rise, in short order, to four different floral organs (sepals, petals, stamens, and carpels)? How does each flower come to have the correct number of each of the floral organs? Numerous genes are expressed and interact to produce these results. We'll refer here to some of the genes whose actions have been most thoroughly studied in *Arabidopsis* and snapdragons (*Antirrhinum*) (see Figure 38.10):

- Expression of a group of **meristem identity genes** initiates a cascade of further gene expression that leads to flower formation. The expression of the genes *LEAFY* and *APETALA1* is both necessary and sufficient for flowering. How do we know this? There are two types of evidence, genetic and molecular. For example, a mutated allele of the gene *APETALA1* leads to continued vegetative growth, even if all other conditions are suitable for flowering. On the other hand, if the wild-type *APETALA1* gene is coupled to an active promoter and introduced into an apical meristem, the plant will flower regardless of the environment. This is powerful evidence that *APETALA1* plays a role in switching meristem cells from a vegetative to a reproductive fate.
- Meristem identity gene products trigger the expression of **floral organ identity genes**, which work in concert to specify the successive whorls of the flower (see Figure 19.14). Floral identity genes are homeotic genes whose products are transcription factors that determine whether cells in the floral meristem will be sepals, petals, stamens, or carpels. An example is the gene *AGAMOUS*, which causes florally determined cells to form stamens and carpels in the “ABC” system described in Section 19.5.

How is this cascade of events initiated? Depending on the species, plants respond to either internal or external cues. Among external clues, the best studied are photoperiod (day

No matter what type of life cycle they have, angiosperms all make the transition to flowering. This transition entails significant developmental changes, to which we now turn.

Apical meristems can become inflorescence meristems

The first visible sign of a transition to the flowering state may be a change in one or more apical meristems in the shoot system. As described in Chapter 34, meristems have a pool of undetermined cells. During vegetative growth, an apical meristem continually produces leaves, axillary buds, and stem tissues (**Figure 38.10A**) in a kind of unrestricted growth called *indeterminate growth* (see Section 34.4).

Flowers may appear singly or in an orderly cluster that constitutes an **inflorescence**. If a vegetative apical meristem becomes an **inflorescence meristem**, it ceases production of leaves and axillary buds and produces other structures: smaller leafy structures called bracts, as well as new meristems in the angles between the bracts and the stem (**Figure 38.10B**). These new meristems may also be inflorescence meristems, or they may

length) and temperature. We begin with photoperiod, as it has a fascinating history and clear experimental support.

Photoperiodic cues can initiate flowering

In 1920, W. W. Garner and H. A. Allard of the U.S. Department of Agriculture studied the behavior of a newly discovered mutant tobacco plant. The mutant, named Maryland Mammoth, had large leaves and exceptional height (**Figure 38.11**). Normally tobacco is an annual that flowers in the summer and then stops growing. In contrast, Maryland Mammoth plants remained vegetative and continued to grow.

Garner and Allard now tried to figure out why the mutant plants did not flower in the summer. It wasn't that they *could not flower*: the scientists found that the plants would flower in December in the greenhouse under natural light. To determine what induces flowering in December, they tested several likely environmental variables, such as temperature. The key variable proved to be day length. By moving plants between light and dark rooms at different times to vary the day length artificially, the scientists were able to establish a direct link between flowering and day length.

Maryland Mammoth plants did not flower if exposed to more than 14 hours of light per day, but flowering commenced once the daylight period became shorter than 14 hours, as in December. Thus the **critical day length** for Maryland Mammoth tobacco is 14 hours (**Figure 38.12**). Control of an organism's responses by the length of day or night is called **photoperiodism**.

Plants vary in their responses to photoperiodic cues

Plants that flower in response to photoperiodic stimuli fall into two main classes:

- **Short-day plants (SDPs)** flower only when the day is shorter than a critical maximum. They include poinsettias and chrysanthemums, as well as Maryland Mammoth tobacco. Thus, for example, we see chrysanthemums in nurseries in the fall, and poinsettias in winter, as noted in the opening of this chapter.
- **Long-day plants (LDPs)** flower only when the day is longer than a critical minimum. Spinach and clover are examples of LDPs. For example, spinach tends to flower and become bitter in the summer, and is therefore normally planted in early spring.

While there are variations on these two patterns, photoperiodic control of flowering serves an important role: it synchronizes the flowering of plants of the same species in a local population, and this promotes cross-pollination and successful reproduction.

The length of the night is the key photoperiodic cue determining flowering

The terms “short-day plant” and “long-day plant” became entrenched before scientists determined that *photoperiodically sen-*

38.11 Mammoth Plant Wild-type tobacco (left) is much smaller than the Maryland Mammoth mutant of the same age (right), which does not respond to an environmental cue to stop growing and flower.

38.12 Day Length and Flowering By artificially varying the day length in a 24-hour period, Garner and Allard showed that the flowering of Maryland Mammoth tobacco is initiated when the days become shorter than a critical length. Maryland Mammoth tobacco is thus called a short-day plant. Henbane, a long-day plant, shows an inverse pattern of flowering.

INVESTIGATING LIFE

38.13 Night Length and Flowering

Short-day plants (SDP) flower only when the day is shorter than a critical maximum. But what environmental cue initiates SDP flowering: day length or night length? To find out, Karl Hamner and James Bonner carried out greenhouse experiments using cocklebur, a SDP.

HYPOTHESIS Short-day plants measure day length.

METHOD Divide plants into two groups. Expose groups to different light conditions: one group to a constant daylight period and varied periods of darkness, the other to varied periods of daylight and fixed periods of darkness.

RESULTS

CONCLUSION The data do not support the hypothesis. Short-day plants measure the length of the night and thus could more accurately be called long-night plants.

FURTHER INVESTIGATION: How would you perform these experiments using long-day plants and what would be the results?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

Working with cocklebur, an SDP, Hamner and Bonner ran a series of experiments using two sets of conditions:

- One group of plants was exposed to a constant light period—either shorter or longer than the critical day length—and the dark period was varied.
- A second group of plants was exposed to a constant dark period—and the light period was varied.

Plants flowered under all treatments in which the dark period exceeded 9 hours, regardless of the length of the light period. Hamner and Bonner thus concluded that the length of the *night* is critical to flowering. For cocklebur, the **critical night length** is about 9 hours. It is thus more accurate to call cocklebur a “long-night plant” than a short-day plant.

In cocklebur, a single long night is sufficient to trigger full flowering some days later, even if the intervening nights are short. Most plants are less sensitive than cocklebur and require from two to several nights of appropriate length to induce flowering. For some plants a single shorter night in a series of long ones inhibits flowering, even if the short night comes only one day before flowering would have commenced.

Through other experiments Hamner and Bonner gained some insight into how plants measure night length. They grew SDPs and LDPs under a variety of light/dark conditions. In some experiments, the dark period was interrupted by a brief exposure to light; in others, the light period was interrupted briefly by darkness. Interruptions of the light period by darkness had no effect on the flowering of either short-day or long-day plants. Even a brief interruption of the dark period by light, however, completely nullified the effect of a long night. An SDP flowered *only if the long nights were uninterrupted*. The investigators hypothesized that something must accumulate during that long night that could be broken down by a flash of light in the middle of the night.

To find out what that “something” might be, Hamner and Bonner tested flashes of interrupting light at various wavelengths. You may recall from Section 37.5 that several photoreceptors play roles in regulating plant growth, and that these are sensitive to different wavelengths. In the interrupted-night experiments, the most effective wavelengths of light were in the red range (**Figure 38.14**), and the effect of a red-light interruption of the night could be fully reversed by a subsequent exposure to far-red light, indicating that a phytochrome is the photoreceptor. Where does this occur and what happens downstream from the reception? Once again, elegant experiments provided the answer.

The flowering stimulus originates in a leaf

Early experiments indicated that reception of the photoperiodic stimulus occurs within the leaf. For example, in spinach, an LDP, flowering would occur if the leaves were exposed to long-day periods of light while the bud meristem was masked to simulate short days. Flowering could *not* occur when its leaves were masked to simulate short days while the bud was exposed to long-day periods of light.

sitive plants actually measure the length of the night (darkness), rather than the length of the day. This was demonstrated by Karl Hamner of the University of California at Los Angeles and James Bonner of the California Institute of Technology (Figure 38.13).

INVESTIGATING LIFE

38.14 Interrupting the Night

Knowing that plants measure night duration, the question became whether the dark hours to which a plant is exposed must be continuous. Using SDPs and LDPs as test subjects, Hamner and Bonner interrupted the night with light of different wavelengths.

HYPOTHESIS Red light participates in the photoperiodic timing mechanism.

METHOD Grow plants under short-day conditions, but interrupt the night with light of different wavelengths.

Short-day plants	Light/dark combinations	Long-day plants
Flowering		No flowering

RESULTS

No flowering		Flowering
Flowering		No flowering
Flowering		No flowering
No flowering		Flowering
Flowering		No flowering
Flowering		No flowering

CONCLUSION When plants are exposed to red (R) and far-red (FR) light in alternation, the final treatment determines the effect. Phytochrome is the photoreceptor.

FURTHER INVESTIGATION: How would you show that interrupting the day with a brief period of darkness had no effect on flowering?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

GO TO Animated Tutorial 38.2 • The Effect of Interrupted Days and Nights

These “masking” experiments were extended to SDP plants as well (Figure 38.15). Because the receptor of the stimulus (in the leaf) is physically separated from the tissue on which the stimulus acts (the bud meristem), the inference can be drawn that a systemic signal travels from the leaf through the plant’s tissues to the bud meristem. Other evidence that a diffusible chemical travels from the leaf to the bud meristem signal includes the following:

- If a photoperiodically induced leaf is immediately removed from a plant after the inductive dark period, the plant does not flower. If, however, the induced leaf remains attached to the plant for several hours, the plant will flower. This re-

INVESTIGATING LIFE

38.15 The Flowering Signal Moves from Leaf to Bud

The receptor for photoperiod, phytochrome, is in the leaf but flowering occurs in the bud meristem. To investigate whether there is a diffusible substance that travels from leaf to bud, James Knott exposed only the leaf to the photoperiodic stimulus.

HYPOTHESIS The leaves measure the photoperiod.

METHOD Grow cocklebur plants under long days and short nights. Mask a leaf on some plants and see if flowering occurs.

RESULTS

If even one leaf is masked for part of the day—thus shifting that leaf to short days and long nights—the plant will flower.

CONCLUSION The leaves measure the photoperiod. Therefore, some signal must move from the induced leaf to the flowering parts of the plant.

FURTHER INVESTIGATION: How would you show experimentally that the flowering signal is the same in different species of plants?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

sult suggests that something is synthesized in the leaf in response to the inductive dark period, and then moves out of the leaf to induce flowering.

- If two or more cocklebur plants are grafted together and if one plant is exposed to inductive long nights and its graft

partners are exposed to noninductive short nights, all the plants flower.

- In several species, if an induced leaf from one species is grafted onto another, noninduced plant of a different species, the recipient plant flowers.

Although the transmissible signal was long ago given a name, **florigen** ("flower inducing"), the nature of the signal has only recently been explained.

Florigen is a small protein

The characterization of florigen was made possible by genetic and molecular studies of the model organism *Arabidopsis*, an LDP. Three genes are involved (Figure 38.16):

- **FT (FLOWERING LOCUS T)** codes for florigen. A small protein (20 kDa molecular weight), FT can travel through plasmodesmata. FT is synthesized in phloem companion cells of the leaf and diffuses into the adjacent sieve elements, where it enters the phloem flow to the apical meristem. If FT is coupled to an active promoter and expressed at high levels in the shoot meristem, flowering is induced even in the absence of an appropriate photoperiodic stimulus.
- **CO (CONSTANS)** codes for a transcription factor that activates the synthesis of FT. Like FT, CO is expressed in leaf companion cells. If CO is experimentally overexpressed in the leaf, flowering is induced. Overexpression of CO in the apical meristem does not, however, induce flowering, indicating

that its essential activity is in the leaf. CO protein is expressed all the time but is unstable; an appropriate photoperiodic stimulus stabilizes CO so that there is enough to turn on FT synthesis.

- **FD (FLOWERING LOCUS D)** codes for a protein that binds to FT protein when it arrives in the apical meristem. The FD protein is a transcription factor that when complexed with FT protein, activates promoters for meristem identity genes, such as *APETALA1* (see Figure 38.10). The expression of FD primes meristem cells to change from a vegetative fate to a reproductive fate once florigen arrives.

Before florigen was isolated, grafting experiments indicated that many different plant species could be induced to flower by the same chemical signal. A photoperiod-induced leaf from one species can induce flowering when grafted onto an uninduced plant of another species. Results of molecular experiments confirm that the *FT* gene is involved in photoperiod signaling in many species:

- Transgenic plants (e.g., tobacco and tomato) that express the *Arabidopsis* *FT* gene at high levels flower regardless of day length.
- Transgenic *Arabidopsis* plants that express high levels of *FT* homologs from other plants (e.g., rice and tomato) flower regardless of day length.

While the molecular basis of the action of florigen has been elucidated, commercial applications of this knowledge have been harder to realize. It was hoped that florigen might be a very small molecule, like auxin or gibberellin that could be sprayed on economically important plants to induce flowering

at will. The fact that florigen is a protein that cannot readily enter cells from the outside environment makes the development of commercial florigen treatments unlikely.

We have considered the photoperiodic regulation of flowering, from photoreceptors in the leaf to florigen that travels from the induced leaf to the sites of flower formation. In some plant species, however, flowering is induced by other stimuli.

Flowering can be induced by temperature or gibberellin

TEMPERATURE In some plant species, notably certain cereal grains, the environmental signal for flowering is cold temperature, a phenomenon called **vernalization** (Latin *vernus*, “spring”). In both wheat and rye, we distinguish two categories of flowering behavior. Spring wheat, for example, is a typical annual plant: it is sown in the spring and flowers in the same year. Winter wheat is sown in the fall, grows to a seedling, overwinters (often covered by snow), and flowers the following summer. If winter wheat is not exposed to cold in its first year, it will not flower normally the next year.

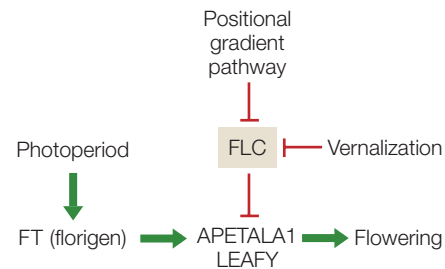

How vernalization leads to flowering has been elucidated from model organisms such as *Arabidopsis*. In strains of *Arabidopsis* that require vernalization to flower (Figure 38.17), a gene called *FLC* (FLOWERING LOCUS C) encodes a transcription factor that blocks the FT–FD florigen pathway (see Figure 38.16) by inhibiting expression of FT and FD. Cold temperature inhibits the synthesis of FLC protein, allowing FT and FD proteins to be expressed and flowering to proceed. Similar proteins control some steps in vernalization in cereals.

GIBBERELLIN *Arabidopsis* plants do not flower if they are genetically deficient in the hormone gibberellin, or if they are treated with an inhibitor of gibberellin synthesis. These observations implicate gibberellins in flowering. Direct application of gibberellins to buds in *Arabidopsis* results in activation of the meristem identity gene *LEAFY*, which in turn promotes the transition to flowering.

Some plants do not require an environmental cue to flower

A number of plant species and strains do not require a photoperiod, vernalization, or gibberellin to flower, but instead flower on cue from an “internal clock.” For example, flowering in some strains of tobacco will be initiated in the terminal bud when the stem has grown four phytomers in length (recall that stems are composed of repeating units called phytomers; see Figure 34.1). If such a bud and a single adjacent phytomer is removed and planted, the cutting will flower because the bud has already received the cue for flowering. But the rest of the shoot below the bud that has been removed will not flower because it is only three phytomers long. After it grows an additional phytomer, it flowers. These results suggest that there is something about the *position* of the bud (atop four phytomers of stem) that determines its transition to flowering.

The bud might “know” its position by the concentration of some substance that forms a positional gradient along the length of the plant. Such a gradient could be formed if the root makes a diffusible inhibitor of flowering whose concentration diminishes with plant height. When the plant reaches a certain height, the concentration of the inhibitor would become sufficiently low at the tip of the shoot to allow flowering. What this inhibitor might be is unclear, but there is evidence that it acts by decreasing the amount of FLC, allowing the FT–FD pathway to proceed (just as cold acts on FLC in vernalization). A positional gradient that acts on FLC would be consistent with other mechanisms affecting flowering, which all converge on *LEAFY* and *APETALA1*:

38.17 Vernalization A genetic strain of *Arabidopsis* (winter-annual *Arabidopsis*) requires vernalization for flowering. Without it, the plant is large and vegetative (left), but with the cold period it is smaller and flowers (right).

38.2 RECAP

Flowering of some angiosperms is controlled by night length, a phenomenon called photoperiodism. Gibberellins can induce flowering in some species, as can exposure to low temperatures (vernalization). Some species flower when their stems have grown by a certain amount, independent of environmental cues. All pathways to flowering converge on the meristem identity genes.

- What are the differences between apical meristems, inflorescence meristems, and floral meristems? What genes control the transitions between them? **See p. 803 and Figure 38.10**
- Explain why “short-day plant” is a misleading term. **See p. 805 and Figure 38.13**
- What is the evidence for florigen? What is its molecular mechanism of action? **See p. 807 and Figures 38.15 and 38.16**

We have seen how environmental factors interact with genes to control flowering in angiosperms. The function of flowers is sexual reproduction, which maintains beneficial genetic variation in a population. Many angiosperms, however, also benefit from being able to reproduce asexually.

38.3 How Do Angiosperms Reproduce Asexually?

Although sexual reproduction takes up most of the space in this chapter, asexual reproduction accounts for many of the individual plants present on Earth. This fact suggests that in some circumstances asexual reproduction must be advantageous.

We have noted that genetic recombination is one of the advantages of sexual reproduction. Self-fertilization is a form of sexual reproduction, but offers fewer opportunities for genetic recombination than does cross-fertilization. A diploid, self-fertilizing plant that is heterozygous for a certain locus can produce both kinds of homozygotes for that locus plus the heterozygote among its progeny, but it cannot produce any progeny carrying alleles that it does not itself possess. Nevertheless many self-fertilizing plant species produce viable and vigorous offspring.

Asexual reproduction eliminates genetic recombination altogether. A plant that reproduces asexually produces progeny genetically identical to the parent (clones). What, then, is the advantage of asexual reproduction? If a plant is well adapted to its environment, asexual reproduction allows it to pass on to all its progeny a superior combination of alleles, which might otherwise be separated by sexual recombination.

Many forms of asexual reproduction exist

Stems, leaves, and roots are considered *vegetative organs* and are distinguished from flowers, the reproductive parts of the plant. Asexual reproduction is often accomplished through the modification of a vegetative organ, which is why the term **vegetative reproduction** is sometimes used to describe asexual reproduction in plants. Another type of asexual reproduction, *apomixis*, involves flowers but no fertilization.

VEGETATIVE REPRODUCTION Often the stem is the organ that is modified for vegetative reproduction. As noted earlier, strawberries produce horizontal stems, called *stolons* or runners, which grow along the soil surface, form roots at intervals, and establish potentially independent plants. Asexual reproduction by *tip layers* is accomplished when the tips of upright branches sag to the ground and develop roots, as in blackberry and forsythia.

Some plants, such as potatoes, form enlarged fleshy tips of underground stems, called *tubers*, that can produce new plants (from the “eyes”). *Rhizomes* are horizontal underground stems that can give rise to new shoots. Bamboo is a striking example of a plant that reproduces vegetatively by means of rhizomes. A single bamboo plant can give rise to a stand—even a forest—of plants constituting a single, physically connected entity.

Whereas stolons and rhizomes are horizontal stems, bulbs and corms are short, vertical, underground stems. Lilies and onions form bulbs (**Figure 38.18A**), short stems with many fleshy, highly modified

(A) *Allium* sp.

(B)

38.18 Vegetative Organs Modified for Reproduction (A) Bulbs are short stems with large leaves that store nutrients and can give rise to new plants. (B) In *Kalanchoe*, new plantlets can form on leaves.

leaves that store nutrients. These storage leaves make up most of the bulb. Bulbs are thus large underground buds. They can give rise to new plants by dividing or by producing new bulbs from axillary buds. Crocuses, gladioli, and many other plants produce corms, underground stems that function very much as bulbs do. Corms are disclike and consist primarily of stem tissue; they lack the fleshy modified leaves that are characteristic of bulbs.

Stems are not the only vegetative organs modified for asexual reproduction. Leaves may also be the source of new plantlets, as in some succulent plants of the genus *Kalanchoe* (Figure 38.18B). Many kinds of angiosperms, ranging from grasses to trees such as aspens and poplars, form interconnected, genetically homogeneous populations by means of suckers—shoots produced by roots. What appears to be a whole stand of aspen trees, for example, may be a clone derived from a single tree by suckers. This is why the leaves of a whole stand of aspens typically turn yellow at the same time.

Plants that reproduce vegetatively often grow in physically unstable environments such as eroding hillsides. Plants with stolons or rhizomes, such as beach grasses, rushes, and sand verbena, are common pioneers on coastal sand dunes. Rapid vegetative reproduction enables these plants, once introduced, not only to multiply but also to survive burial by the shifting sand; in addition, the dunes are stabilized by the extensive network of rhizomes or stolons that develops. Vegetative reproduction is also common in some deserts, where the environment is often not suitable for seed germination and the establishment of seedlings.

APOMIXIS Some plants produce flowers but use them to reproduce asexually rather than sexually. Dandelions, blackberries, some citrus, and some other plants reproduce by the asexual production of seeds, called **apomixis**. As described earlier, in alternation of generations meiosis typically reduces the number of chromosomes in gametes by half, and fertilization restores the sporophytic (diploid) number of chromosomes in the zygote. In a female gametophyte undergoing apomixis, either meiosis begins and the chromosomes do not undergo meiosis II, or meiosis does not occur at all. In either case, the resulting gamete is diploid. Cells within the ovule simply develop into the embryo and the ovary wall develops into a fruit. The result of apomixis is a fruit with seeds that are genetically identical to the parent plant.

Apomixis would be considered an oddity of the plant reproductive world were it not for its potential use in propagating crop plants. You may recall from Chapter 12 that many crop plants (such as corn) are grown as hybrids because the progeny of a cross between two inbred lines are often superior to either of their parents. The explanation for this phenomenon, called *hybrid vigor*, is not completely understood. One hypothesis attributes the superiority of hybrids to the suppression of undesirable recessive alleles from one parent by dominant alleles from the other. Another hypothesis states that certain advantageous combinations of alleles can be obtained by crossing two inbred strains.

Unfortunately, once a farmer has obtained a hybrid with desirable characteristics, (s)he cannot use those plants for further crosses with themselves (selfing) to get more seeds for the next generation. You can imagine the genetic chaos when a hybrid, which is heterozygous at many of its loci (e.g., *AaBbCcDdEe*, etc.), is crossed with itself: there will be many new combinations of alleles (e.g., *AabbCCDdee*, etc.), resulting in highly variable progeny. The only way to reliably reproduce the hybrid is to maintain populations of the original parents to cross again each year.

However, if a hybrid carried a gene for apomixis, it could reproduce asexually, and its offspring would be genetically identical to itself. So the search is on for a gene for apomixis that could be introduced into desirable crops and allow them to be propagated indefinitely. (A recently published detective novel, *Day of the Dandelion*, explores this idea.)

Researchers recently found a strain of *Arabidopsis* that exhibits apomixis as a result of a mutation in a single gene called *dyad*. In normal plants, *dyad* is essential for chromosome organization, specifically synapsis, during meiosis I (see Figure 11.17). In the apomictic strain, meiosis I resembles mitosis, and the chromosomes replicate again before what would be meiosis II. The result is diploid cells that are genetically identical to the parent instead of the genetically recombined haploid gametes that normally result from meiosis. Scientists are trying to isolate and transfer such apomictic genes into corn and other cereal crops with the hope that plant breeders can use apomixis to propagate plants with desirable hybrid traits (such as high yields, and disease- and insect-resistance) without compromising their hybrid vigor.

Vegetative reproduction has a disadvantage

Vegetative reproduction is highly efficient in an environment that is stable over the long term. A change in the environment, however, can leave an asexually reproducing species at a disadvantage.

A striking example is provided by the demise of the English elm, *Ulmus procera*, which was apparently introduced into England as a clone by the ancient Romans. This tree reproduces asexually by suckers and is incapable of sexual reproduction. In 1967, Dutch elm disease first struck the English elms. After two millennia of clonal growth, the population lacked genetic diversity, and no individuals carried genes that would protect them against the disease. Today the English elm is all but gone from England.

Vegetative reproduction is important in agriculture

Farmers and gardeners take advantage of some natural forms of vegetative reproduction. They have also developed new types of asexual reproduction by manipulating plants. One of the oldest methods of vegetative reproduction used in agriculture consists of simply making cuttings of stems, inserting them in soil, and waiting for them to form roots and thus become autonomous plants. The cuttings are usually encouraged to root

38.19 Grafting Grafting—attaching a piece of a plant to the root or root-bearing stem of another plant—is a common horticultural technique. The “host” root or stem is the **stock**; the upper grafted piece is the **scion**. In the photo, a Bing cherry scion is being grafted onto a hardier stock.

by treatment with a plant hormone, auxin, as described in Section 37.3.

Horticulturists reproduce many woody plants by **grafting**—attaching a bud or a piece of stem from one plant to the root or root-bearing stem of another plant. The part of the resulting plant that comes from the root-bearing “host” is called the **stock**; the part grafted on is the **scion** (Figure 38.19).

For a graft to succeed, the vascular cambium of the scion must associate with that of the stock. By cell division, both cambiums form masses of wound tissue. If the two masses meet and connect, the resulting continuous cambium can produce xylem and phloem, allowing transport of water and minerals to the scion and of photosynthate to the stock. Grafts are most often successful when the stock and scion belong to the same or closely related species. Much fruit grown for market in the United States is produced on grafted trees. Another example is wine grapes. The roots of most grape strains are susceptible to soil pests, and so grape varieties are grafted onto root stocks that have pest resistance.

Scientists in universities and commercial laboratories have been developing new ways to produce useful plants through tissue culture. Because many plant cells are totipotent, cultures of undifferentiated tissue can give rise to entire plants, as can small pieces of tissue cut directly from a parent plant. Tissue cultures sometimes are used commercially to produce new plants. This is common in the forestry industry, where uniformity of trees is desirable.

Culturing tiny bits of apical meristem can produce plants free of viruses. Because apical meristems lack developed vascular tissues, viruses tend not to enter them. Treatment with hormones causes a single apical meristem to give rise to 20 or more shoots; thus, a single plant can give rise to millions of genetically identical plants within a year by repeated meristem

culturing. Using this approach, strawberry and potato producers are able to start each year’s crop from virus-free plants.

38.3 RECAP

Angiosperms may reproduce asexually by means of modified stems, roots, or leaves, or by apomixis. Asexual reproduction is advantageous when a plant has a superior genotype well adapted to its environment, but decreases the genetic diversity of plant populations.

- How does apomixis differ from sexual reproduction? **See p. 810**
- Explain how vegetative reproduction of plants is advantageous to humans. **See pp. 810–811**

We have seen how angiosperms reproduce sexually and asexually. A disadvantage of asexual reproduction is that its genetic inflexibility may leave a population unable to cope with new challenges. In the next chapter we focus on the mechanisms that have evolved in plants to cope with biological and physical challenges in their environment.

CHAPTER SUMMARY

38.1 How Do Angiosperms Reproduce Sexually?

- Sexual reproduction promotes genetic diversity in a population. The flower is an angiosperm’s structure for sexual reproduction.
- Flowering plants have microscopic gametophytes. The megagametophyte is the **embryo sac**, which typically contains eight nuclei in a total of seven cells. The microgametophyte is the **pollen grain**, which usually contains two cells. **Review Figure 38.2, ANIMATED TUTORIAL 38.1**
- Following **pollination**, the pollen grain delivers **sperm cells** to the embryo sac by means of a **pollen tube**.
- Most angiosperms exhibit **double fertilization**: one sperm nucleus fertilizes the **egg**, forming a zygote, and the other

sperm nucleus unites with the two **polar nuclei** to form a triploid **endosperm**. **Review Figure 38.6**

- Plants have both physical and genetic methods of preventing inbreeding. Physical separation of the gametophytes and genetic **self-incompatibility** prevent self-pollination.
- The zygote develops into an embryo (with an attached **suspensor**), which remains quiescent in the seed until conditions are right for germination. **Review Figure 38.7, WEB ACTIVITY 38.1**
- Ovules develop into seeds, and the ovary wall and the enclosed seeds develop into a **fruit**.
- The hormone **abscisic acid** promotes seed development and dormancy.

38.2 What Determines the Transition from the Vegetative to the Flowering State?

- In **annuals** and **biennials**, flowering and seed formation usually leads to death of the rest of the plant. **Perennials** live a long time and typically reproduce repeatedly.
- For a vegetatively growing plant to flower, an apical meristem in the shoot system must become an **inflorescence meristem**, which in turn must give rise to one or more **floral meristems**. These events are under the influence of **meristem identity genes** and **floral organ identity genes**. **Review Figure 38.10**
- Some plants flower in response to **photoperiod**. **Short-day plants** flower when the nights are longer than a **critical night length** specific to each species; **long-day plants** flower when the nights are shorter than a critical night length. **Review Figure 38.13**
- The mechanism of photoperiodic control involves phytochromes and a biological clock. **Review Figure 38.14, ANIMATED TUTORIAL 38.2**

- A flowering signal, called **florigen**, is formed in a photoperiodically induced leaf and is translocated to the sites where flowers will form. **Review Figures 38.15 and 38.16**
- In some angiosperm species, exposure to low temperatures—**vernalization**—is required for flowering; in others internal signals (one of which is gibberellin in some plants) induce flowering. All of these stimuli converge on the meristem identity genes.

38.3 How Do Angiosperms Reproduce Asexually?

- Asexual reproduction allows rapid multiplication of organisms that are well suited to their environment.
- **Vegetative reproduction** involves the modification of a vegetative organ—usually the stem—for reproduction.
- Some plant species produce seeds asexually by **apomixis**.
- Horticulturists often **graft** different plants together to take advantage of favorable properties of both **stock** and **scion**. **Review Figure 38.19**

SELF-QUIZ

- Sexual reproduction in angiosperms
 - is by way of apomixis.
 - requires the presence of petals.
 - can be accomplished by grafting.
 - gives rise to genetically diverse offspring.
 - cannot result from self-pollination.
- The typical angiosperm female gametophyte
 - is called a microspore.
 - has eight nuclei.
 - has eight cells.
 - is called a pollen grain.
 - is carried to the male gametophyte by wind or animals.
- Pollination in angiosperms
 - always requires wind.
 - never occurs within a single flower.
 - always requires help by animal pollinators.
 - is also called fertilization.
 - makes most angiosperms independent of external water for reproduction.
- Which statement about double fertilization is *not* true?
 - It is found in most angiosperms.
 - It takes place in the microsporangium.
 - One of its products is a triploid nucleus.
 - One sperm nucleus fuses with the egg nucleus.
 - One sperm nucleus fuses with two polar nuclei.
- The suspensor
 - gives rise to the embryo.
 - is heart-shaped in eudicots.
 - separates the two cotyledons of eudicots.
 - ceases to elongate early in embryonic development.
 - is larger than the embryo.
- Which statement about photoperiodism is *not* true?
 - It is related to the biological clock.
 - A phytochrome plays a role in the timing process.
 - It is based on measurement of the length of the night.
 - Some plants do not flower in response to photoperiod.
 - It is limited to plants.
- Florigen is
 - produced in the leaves and transported to the apical bud.
 - produced in the roots and transported to the shoots.
 - produced in the coleoptile tip and transported to the base.
 - the same as gibberellin.
 - activated by prolonged (more than a month) high temperature.
- Which statement about vernalization is *not* true?
 - It decreases the abundance of an inhibitor of flowering.
 - Vernalization involves exposure to cold temperatures.
 - It only occurs in crop plants such as cereals.
 - In the vernalized state, the synthesis of FLC protein is inhibited.
 - If winter wheat is not exposed to cold, it will not flower.
- Which of the following does *not* participate in asexual reproduction?
 - Stolon
 - Rhizome
 - Zygote
 - Tuber
 - Corm
- Apomixis involves
 - sexual reproduction.
 - complete meiosis.
 - fertilization.
 - a diploid embryo.
 - no production of a seed.

FOR DISCUSSION

1. Which method of reproduction might a farmer prefer for a crop plant that reproduces both sexually and asexually? Why?
2. Thompson Seedless grapes are produced by vines that are triploid. Think about the consequences of this chromosomal condition for meiosis in the flowers. Why are these grapes seedless? Describe the role played by the flower in fruit formation when no seeds are being formed. How do you suppose Thompson Seedless grapes are propagated?
3. Poinsettias are popular ornamental plants that typically bloom just before Christmas. Their flowering is photoperiodically controlled. Are they long-day or short-day plants? Explain.
4. You plan to induce the flowering of a crop of long-day plants in the field by using artificial light. Is it necessary to keep the lights on continuously from sundown until the point at which the critical day length is reached? Why or why not?

ADDITIONAL INVESTIGATION

The isolation of *dyad*, the *Arabidopsis* gene that controls apomixis, offers possibilities for crop plant breeding. How would you investigate the possibility of using the mutant allele of this gene

to produce hybrid corn plants that can be propagated and retain their hybrid nature?

Sharing plants' defensive strategies

The tropical rainforest of the eastern slopes of the Andes teems with plant life. This region of the Amazon Basin is host to about 40 species of *Cinchona*, a genus of trees that grow to a height of about 20 meters. In this moist environment, *Cinchona* trees grow rapidly and thrive, despite the many natural enemies that threaten their survival and growth.

Unlike animals, which can sometimes escape their enemies, plants must confront their enemies in place. Over evolutionary time, plants with the ability to fight off attackers have survived and passed on that ability to their offspring. In many instances, that ability comes in the form of defensive chemicals. In the case of *Cinchona*, one of those chemicals is quinine, a bitter molecule that is toxic to insects. It may be familiar to you as an ingredient in tonic water.

The Quechua, a group of people native to the Andes forests, have a long history of putting local plants to me-

dicinal use. In the tropics, malaria has long been, and still is, a common and lethal disease. Even today, about 400 million cases arise worldwide, and over 1.5 million people die from malaria each year. Centuries ago, the Quechua found that a tea made from the bark of *Cinchona* trees was highly effective in treating malaria. Legend has it that the tree got its name from the Peruvian countess of Cinchon, who was cured of malaria in 1638 when her physician got some bark from the Quechua. Use of the bark extract quickly spread around the world.

In 1820, the active ingredient of *Cinchona* bark, quinine, was isolated and became the mainstay of malaria treatment. Malaria is caused by an apicomplexan parasite that infects red blood cells. Quinine kills the parasite by interfering with its ability to break down hemoglobin. Unfortunately, mutations render some parasites resistant to quinine and its chemical derivatives. Over time, treatment of billions of people with quinine drugs has selected for

parasites with genes for quinine resistance. An urgent need for alternative treatments has led scientists to another plant and its defensive chemical.

Artemisia annua, or sweet wormwood, grows in forests all over the world. It synthesizes a molecule called artemisinin that helps defend the plant against insects. For over 3000 years, people in Asia have made a curative tea from sweet wormwood. In 1972 Japanese chemists isolated artemisinin and found that it works by reacting with iron in red blood cells to form free radicals, which damage lipids and DNA in the infecting par-

The Source of Quinine *Cinchona* trees from the Amazon rainforest synthesize a defensive chemical, quinine, that has been used to treat people with malaria.

A Substitute for Quinine Sweet wormwood (*Artemisia annua*) grows in forests throughout the world. It synthesizes a defensive chemical, called artemisinin, that is now being used to treat people with malaria whose infection is resistant to quinine drugs.

asite. Since this mechanism of action differs from that of quinine, it was thought that artemisinin might be effective in treating quinine-resistant malaria—and it is. Indeed, during the Vietnam War, drinking *Artemisia* tea helped Vietnamese soldiers cope with the quinine-resistant malaria that struck American soldiers. Since 2000, artemisinin has become a mainstay of malaria treatment. Millions of people take it every day.

Until recently, hundreds of such plant chemicals were contemplated only in the context of plant biochemistry. Today we view them as adaptations arising from a plant's interactions with its environment.

IN THIS CHAPTER we describe the biological (biotic) and nonbiological (abiotic) environmental challenges faced by plants and how plants deal with them. We begin by examining interactions between plants and plant pathogens, such as fungi, and then consider plant interactions with herbivores. The chapter concludes by considering plant adaptations to abiotic factors such as water, temperature, salinity, and heavy metals.

CHAPTER OUTLINE

- 39.1** How Do Plants Deal with Pathogens?
- 39.2** How Do Plants Deal with Herbivores?
- 39.3** How Do Plants Deal with Climatic Extremes?
- 39.4** How Do Plants Deal with Salt and Heavy Metals?

39.1 How Do Plants Deal with Pathogens?

Botanists know of dozens of diseases, with many different genetic strains, that can kill a wheat plant, each of them caused by a different pathogen. Plant pathogens—which include bacteria, fungi, protists, and viruses—are part of nature, and for that reason alone they merit our study in biology. Because we humans depend on plants for our food, however, the stakes in our effort to understand plant pathology are especially high. That is why, just as medical schools have departments of pathology, many universities in agricultural regions have departments of plant pathology.

Successful infection by a pathogen can have significant effects on a plant, reducing photosynthesis and causing massive cell and tissue death. Like the responses of the human immune system (see Chapter 42), the responses by which plants fight off disease are varied and fascinating. Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved mechanisms with which to attack plants, and plants have evolved mechanisms for defending themselves against those attacks. Each set of mechanisms uses information from the other. For example, the pathogen's enzymes may break down the plant's cell walls, and the breakdown products may signal to the plant that it is under attack. In turn, the plant's defenses alert the pathogen that it, too, is under attack.

An arms race of global importance is under way to combat wheat rust, a fungus that can devastate wheat crops (**Figure 39.1**). In 1999, a new genetic strain of the wheat rust fungus *Puccinia graminis* was identified in a wheat field in Uganda. Although many strains of wheat have natural resistance to other strains of rust, the new fungal strain, called Ug99, overcomes resistance in almost all of them. It has spread to the Middle East, and there is a good probability that it has already reached Asia. Over 90 percent of the wheat strains in its path are susceptible. Scientists are racing to discover wheat genes that confer resistance to Ug99 and to implement genetic crosses to get this resistance into the wheat strains under widespread cultivation. Failure in this arms race could have disastrous consequences for the global food supply.

What determines the outcome of a battle between a plant and a pathogen? The key to success for the plant is to respond to information from the pathogen quickly and massively. Plants use both mechanical and chemical defenses in this effort. These defenses can either be **constitutive**, always present in the plant, or **induced**, produced in reaction to damage or stress.

Mechanical defenses include physical barriers

A plant's first line of defense is its outer surfaces, which can prevent the entry of pathogens. As Section 34.3 describes, the or-

39.1 Wheat Rust A field of wheat infected with the wheat rust fungus (right) has a much reduced growth rate and has produced much less grain than an uninfected field of wheat that is resistant to the fungus (left). Inset: Wheat rust causes cell death in leaves.

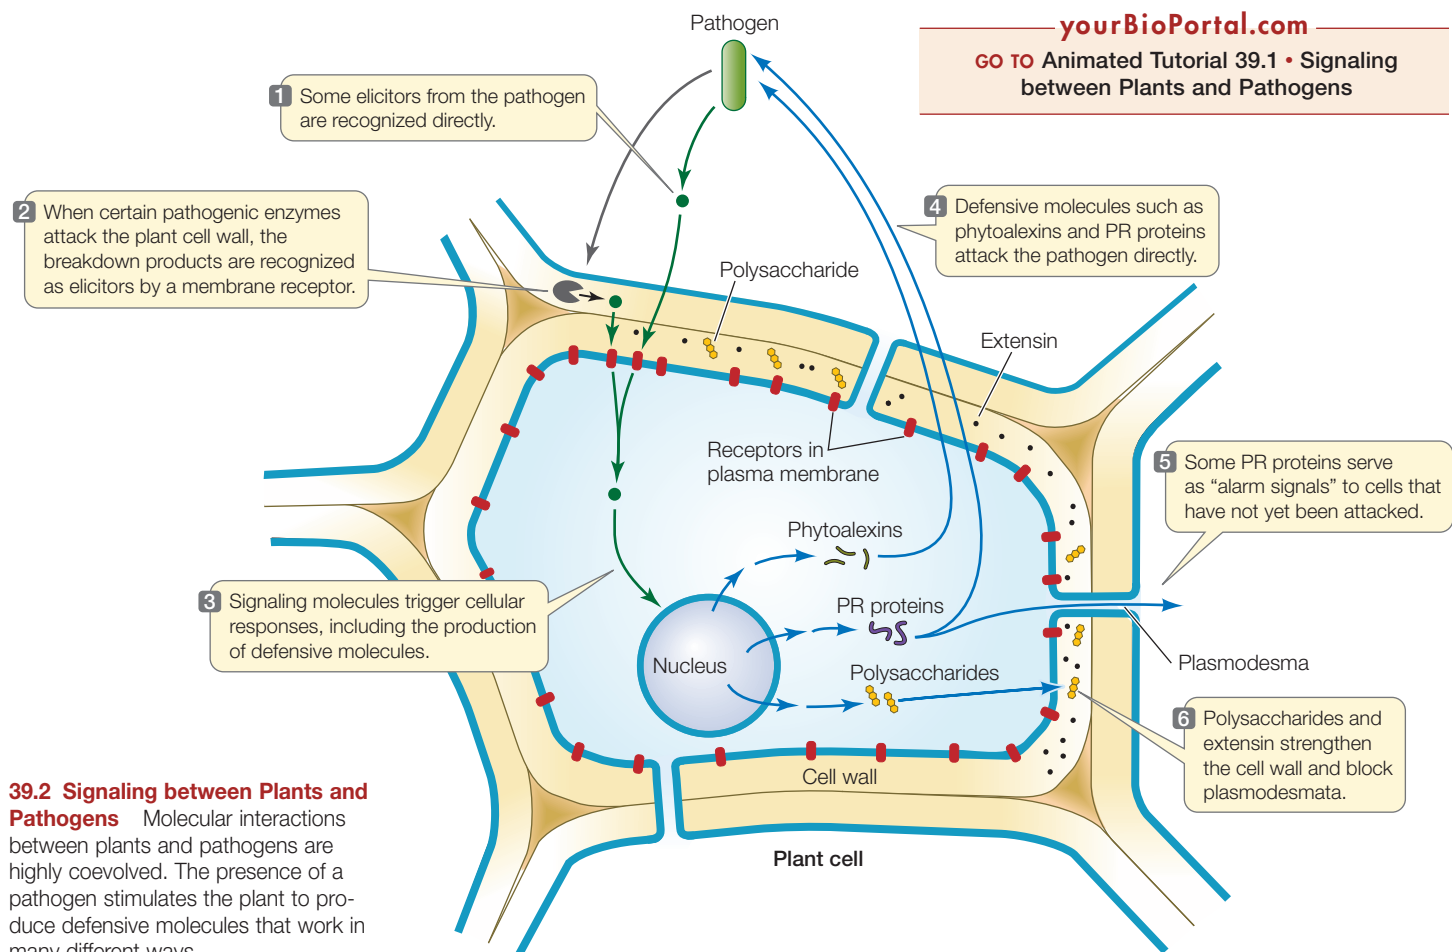

gans of a growing plant that are exposed to the outside environment are covered with cutin, suberin, and waxes. These substances not only prevent water loss by evaporation, but can also prevent fungal spores and bacteria from entering the underlying tissues. Some fungi get around this defense, however, by secreting enzymes that hydrolyze components of these substances, breaking them down to gain entry.

Much more important to the plant are the induced resistance mechanisms initiated when a pathogen lands on a plant. As we discuss these mechanisms, refer to the overview in **Figure 39.2**.

Plants can seal off infected parts to limit damage

While animals generally repair tissues that have been damaged by pathogens, plants do not. Instead, plants seal off and sacrifice damaged tissues so that the rest of the plant does not become infected. Plants have the option of discarding damaged tissues because most plants, unlike most animals, can replace damaged parts by growing new ones.

Before we look at the details of the defensive process, note that a key response by plant cells to invasion by pathogens is the rapid deposition of additional polysaccharides, as well as a cell wall protein called *extensin*, on the inside of the cell wall. These macromolecules not only reinforce the mechanical barrier formed by the cell wall, but also block the plasmodesmata,

39.2 Signaling between Plants and Pathogens Molecular interactions between plants and pathogens are highly coevolved. The presence of a pathogen stimulates the plant to produce defensive molecules that work in many different ways.

limiting the ability of viral pathogens to move from cell to cell. The polysaccharides also serve as a base on which lignin may be laid down. Lignin enhances the mechanical barrier, and the toxicity of lignin precursor chemicals makes the cell inhospitable to some pathogens. These lignin building blocks are only one example of the toxic substances that plants use as chemical defenses.

Plant responses to pathogens may be genetically determined

Plant pathogens cause the host plant to activate various chemical defense responses. Several distinctive molecules called *elicitors* have been identified that trigger these plant defenses. These molecules vary in character, from peptides made by bacteria to cell wall fragments from fungi. Elicitors can also be derived from fragments of plant cell wall components broken down by pathogens (see Figure 39.2, labels 1 and 2). Pathogen genes that code for elicitors are called **avirulence genes (*Avr*)**; there are hundreds of such genes. When an elicitor enters a plant cell, it may encounter a receptor protein in the cytoplasm. If the receptor binds to the elicitor, a signal transduction pathway is set in motion that leads to the plant's defensive response. If the plant has no receptor to bind to the elicitor, the plant does not defend itself.

Over 50 years ago, plant pathologist Harold Flor at North Dakota State University studied the susceptibility of various genetic strains of cereal grain plants to various strains of rust fungus. He proposed that susceptibility is determined by a genetic relationship between the pathogen and the plant (**Figure 39.3**). Today we know that plants have **resistance genes (*R*)**, and we know that these resistance genes code for receptors. We also know that pathogens have *Avr* genes that code for elicitors. If the *R* and *Avr* genes match, there is resistance: the molecules they encode will bind to each other and set off a response. Flor's idea, known as **gene-for-gene resistance**, has been borne out by molecular studies, and it has had a great influence on crop plant breeding for resistance to pathogens.

39.3 Gene-for-Gene Resistance If a gene in a pathogen that codes for an elicitor "matches" a gene in a plant that codes for a receptor, the receptor binds the elicitor, and a defensive response results.

The signal transduction pathway started by receptor-elicitor binding is mediated by the production of nitric oxide and the toxic peroxide H_2O_2 . Together, these substances initiate local defenses and, later, systemic defenses (defenses in parts of the plant distant from the attack site).

Receptor-elicitor binding evokes the hypersensitive response

When infected by certain fungi and bacteria, plants try to contain the infection locally by what is called the **hypersensitive response**. This three-pronged response involves the production of defensive compounds as well as physical isolation of the infection site (see Figure 39.2, labels 3 and 4).

PHYTOALEXINS **Phytoalexins** are antibiotics produced by infected plants that are toxic to many fungi and bacteria. Most are small molecules, and each is made by only a few plant species. They are produced by infected cells, and by their immediate neighbors, within hours of the onset of infection. Because their antimicrobial activity is nonspecific, phytoalexins can destroy many species of fungi and bacteria in addition to the one that originally triggered their production. Phytoalexins also kill the plant cells that produced them, thus sealing off the infection.

Phytoalexins are an example of an induced plant defense: they are not normally present in plants, but are synthesized rapidly when a bacterial or fungal infection occurs. Physical injuries and viral infections can also induce the production of phytoalexins.

Neither the mechanism of phytoalexin induction by pathogens, nor the specific effects of phytoalexins on invading organisms, is clear. Camalexin, a phytoalexin made by the model organism *Arabidopsis thaliana*, is being used to investigate these phenomena. It is synthesized by the plant from the amino acid tryptophan:

PATHOGENESIS-RELATED PROTEINS Plants produce several types of **pathogenesis-related proteins**, or **PR proteins**. Some are enzymes that break down the cell walls of pathogens. Chitinase, for example, is a PR protein that breaks down chitin, which is found in many fungal cell walls. In some cases, the breakdown

39.4 Sealing Off the Pathogen and the Damage These necrotic lesions on the leaves of a broad bean plant are a response to “chocolate spot” fungus, *Botrytis fabae*.

products of the pathogen’s cell walls serve as elicitors that trigger further defensive responses. Other PR proteins may serve as alarm signals to plant cells that have not yet been attacked (Figure 39.2, label 5). In general, PR proteins appear not to be rapid-response weapons; rather, they act more slowly, perhaps after other mechanisms have blunted the pathogen’s attack.

PHYSICAL ISOLATION A third component of the hypersensitive response seals off the damage and the pathogen from the rest of the plant. Cells around the site of infection undergo apoptosis, preventing the spread of the pathogen by depriving it of nutrients. Some of these cells produce phytoalexins and other chemicals before they die. The dead tissue, called a *necrotic lesion*, contains and isolates what is left of the infection (Figure 39.4). The rest of the plant remains free of the infecting pathogen.

Systemic acquired resistance is a form of long-term “immunity”

The hypersensitive response is not the only defensive response initiated by receptor–elicitor binding. **Systemic acquired resistance** is a general increase in the resistance of the entire plant to a wide range of pathogens. It is not limited to the pathogen that originally triggered it, or to the site of the original infection, and its effect may last as long as an entire growing season.

This defensive response is initiated by salicylic acid, a defensive chemical produced during the local hypersensitive response. Since ancient times, people in Asia, Europe, and the Americas have used willow (*Salix*) leaves and bark to relieve pain and fever. The active ingredient in willow is salicylic acid, the substance from which aspirin is derived. It now appears that all plants contain at least some salicylic acid.

Systemic acquired resistance is accompanied by the synthesis of PR proteins. Treatment of plants with salicylic acid or aspirin leads to the production of PR proteins and to resistance to pathogens. It provides substantial protection, for example,

against tobacco mosaic virus (a well-studied plant pathogen) and some other viruses. In some cases salicylic acid inhibits virus replication, and in others it interferes with the movement of viruses out of the infected area.

Salicylic acid also acts as a hormone. In some cases, infection in one part of a plant leads to the export of salicylic acid to other parts, where it triggers the production of PR proteins before the infection can spread. Infected plant parts also produce the closely related compound methyl salicylate (also known as oil of wintergreen). This volatile substance travels to other plant parts through the air and may trigger the production of PR proteins in neighboring plants that have not yet been infected.

Plants develop specific immunity to RNA viruses

Before we leave the topic of plant defenses against pathogens, let’s consider a recently discovered defense mechanism directed against a specific pathogen type: RNA viruses (viruses that have RNA instead of DNA as their hereditary material). The plant uses its own enzymes to convert some of the single-stranded RNA of the invading virus into *double-stranded RNA* (dsRNA) and to chop that dsRNA into small pieces called *small interfering RNAs* (siRNAs). Some of the viral RNA is transcribed, forming mRNAs that advance the infection. However, the siRNAs interact with another cellular component to degrade those mRNAs, blocking viral replication. This phenomenon is an example of *RNA interference* (RNAi) (see Section 18.4).

The immunity conferred by RNAi spreads quickly throughout the entire plant through plasmodesmata. However, the establishment of immunity depends on the extent of the original infection and the speed of the plant’s response. Plant viruses are continuing their side of the arms race: most have evolved mechanisms to confound RNA interference.

39.1 RECAP

In the hypersensitive response to infection by pathogens, plants produce two types of chemical defenses and seal off infected areas. Systemic acquired resistance, providing a longer-lasting, more general immunity, may follow.

- Name two types of defensive compounds produced by plant cells when they are infected by bacteria or fungi. **See p. 817 and Figure 39.2**
- How do *R* and *Avr* genes determine which pathogens a plant can resist? **See p. 817 and Figure 39.3**
- How do infected plant cells signal infection to other parts of the plant, or other plants? **See p. 818**

Not all biological threats to plants come from pathogens. Another threat comes from the many animals, from inchworms to elephants, that eat plants.

39.2 How Do Plants Deal with Herbivores?

Herbivores—animals that eat plants—depend on plants for energy and nutrients. Their foraging activities cause physical damage to plants, and they often spread disease among plants as well. While the majority of herbivores are insects (**Figure 39.5**), every major class of vertebrates includes at least a few herbivores (see also Section 56.2, which discusses herbivory in the ecological context of species interactions). Plants cannot evade their consumers by running away, but they have many other ways of protecting themselves against herbivory.

While in most cases, the physical damage caused by herbivores is severe, sometimes limited herbivory may be harmless or even beneficial. Before turning to the ways that plants resist herbivory, let's examine those few cases in which herbivory enhances plant growth.

Herbivory increases the growth of some plants

How detrimental is herbivory to plants? How well have plants adapted to their place in the food web? Like plants and pathogens, plants and herbivores have evolved together, each acting as an agent of natural selection on the other. This coevolution

has led to arms races in some cases, but it has favored increased photosynthetic production in some plant species subjected to herbivory.

Removal of some leaves from a plant usually increases the rate of photosynthesis in the remaining leaves for several reasons:

- Nitrogen obtained from the soil by the roots no longer needs to be divided among as many leaves.
- The export of sugars and other photosynthetic products from the leaves may be enhanced because the demand for those products in the roots is undiminished, while the sources for those products—leaves—have been decreased.
- The removal of older or dead leaves makes more light available to the younger, more active leaves or leaf parts.

Grasses are especially tolerant of herbivory because, unlike most other plants, which grow from shoot apical meristems, grasses grow from the base of the shoot and leaf, so their growth is not cut short by grazing.

In western North America, mule deer and elk graze many plants, including a wildflower called scarlet gilia (*Ipomopsis aggregata*). Although grazing removes about 95 percent of the aboveground plant, the scarlet gilia quickly regrows not one, but up to four replacement stems (Figure 39.6). Grazed individuals produce three times as many fruits by the end of the growing season as do ungrazed plants.

Mechanical defenses against herbivores are widespread

All parts of the plant body offer some resistance against herbivores. In addition, plants have a number of constitutive anatom-

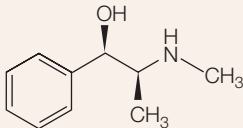

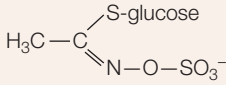

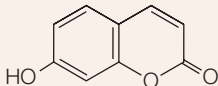

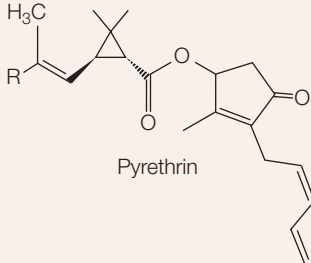

39.5 Insect Herbivores The great majority of herbivores are insects. (A) Some herbivores, such as this locust, are generalists that will attack nearly any plant. (B) Others are specialists, like this tobacco hornworm, which feeds only on tobacco plants.

39.6 Overcompensation for Being Eaten Experiments confirm that herbivory increases the growth of some plants.

TABLE 39.1
Secondary Metabolites Used in Defense

CLASS	TYPE	ROLE	EXAMPLE
Nitrogen-containing  Ephedrine (an alkaloid)	Alkaloids Glycosides Nonprotein amino acids	Neurotoxin Inhibit electron transport Disrupt protein structure	Nicotine in tobacco Dhurrin in sorghum Canavanine in jack bean
Nitrogen-sulfur-containing  Methylglucosinolide	Glucosinolates	Inhibit respiration	Methylglucosinolate in cabbage
Phenolics  Umbelliferone	Coumarins Flavonoids Tannins	Block cell division Phytoalexins Inhibit enzymes	Umbelliferone in carrots Capsidol in peppers Gallotannin in oak trees
Terpenes  Pyrethrin	Monoterpenes Diterpenes Triterpenes Sterols Polyterpenes	Neurotoxins Disrupt reproduction and muscle function Inhibit ion transport Block animal hormones Deter feeding	Pyrethrin in chrysanthemums Gossypol in cotton Digitalis in foxglove Spinasterol in spinach Latex in <i>Euphorbia</i>

ical features, such as trichomes, thorns, spines, or hairs, that are specialized for defense. An example of an induced mechanical defense is the production of latex. When they are injured by an herbivore attack, some plants, such as *Euphorbia* species, produce a thick, white aqueous suspension of cellular debris, oils, and resins called *latex*. Insects trapped by this sticky substance starve to death.

Plants produce chemical defenses against herbivores

Many plants attract, resist, and inhibit other organisms with special chemicals known as secondary metabolites. You learned about two of these chemicals, quinine and artemisinin, in the opening of this chapter.

Primary metabolites are substances—such as proteins, nucleic acids, carbohydrates, lipids, and their building blocks—that are produced and used by all living organisms, including plants. They and their metabolic products are used in basic cellular processes such as photosynthesis, respiration, and nutrient uptake. **Secondary metabolites** are substances that are not used for basic cellular processes. Each is found in only certain plants or plant groups.

The more than 10,000 known secondary metabolites range in molecular mass from about 70 to more than 390,000 daltons, but most have a low molecular mass (Table 39.1). Some are produced by only a single plant species, while others are characteristic of entire genera or even families. The effects of defensive secondary metabolites on animals are diverse. Some act on the nervous systems of herbivorous insects, mollusks, or mammals. Others mimic the natural hormones of insects, causing some larvae to fail to develop into adults. Still others damage the digestive tracts of herbivores. Some secondary metabolites are toxic to fungal pests. As we saw at the opening of this chapter, humans make use of many secondary metabolites as pharmaceuticals and pesticides.

The secondary metabolite nicotine was one of the first insecticides to be used by farmers and gardeners. This molecule kills insects by acting as an inhibitor of nervous system function. Yet commercial varieties of tobacco and related plants that produce nicotine are still attacked, with moderate damage, by pests such as the tobacco hornworm (see Figure 39.5B). Given that observation, does nicotine really deter herbivores? Biologists answered this question conclusively with a study that used tobacco plants in which an enzyme involved in nicotine biosynthesis had

INVESTIGATING LIFE

39.7 Nicotine Is a Defense against Herbivores

The secondary metabolite nicotine, made by tobacco plants, is an insecticide, yet most commercial varieties of tobacco are susceptible to insect attack. Ian Baldwin demonstrated that a tobacco strain with a reduced nicotine concentration was more susceptible to insect damage.

HYPOTHESIS Nicotine helps protect tobacco plants against insects.

METHOD

RESULTS

The low-nicotine plants suffered more than twice as much leaf damage as did the wild-type controls.

CONCLUSION Nicotine provides tobacco plants with at least some protection against insects.

FURTHER INVESTIGATION: Treatment of tobacco plants with jasmonate (a hormone) elicits the production of nicotine and other compounds. How would you modify this experiment to determine whether nicotine is the only insecticidal compound produced by tobacco?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

been silenced, lowering the nicotine concentration in the plants by more than 95 percent. These low-nicotine plants suffered much more damage from insect herbivory than normal plants did (Figure 39.7).

Some secondary metabolites play multiple roles

Canavanine is a secondary metabolite that has two important roles in the plants that produce it. The first is as a nitrogen-storing compound in seeds. The second role is defensive, and is based on its chemical structure. Canavanine is an amino acid that is not found in proteins, but is very similar to the amino acid arginine, which is found in almost all proteins:

When an insect larva consumes canavanine-containing plant tissue, the canavanine is incorporated into the insect's proteins in some of the places where the mRNA codes for arginine, because the enzyme that charges the tRNA specific for arginine fails to discriminate accurately between the two amino acids (see Section 14.5). The structure of canavanine, however, is different enough from that of arginine that some of the resulting proteins end up with a modified tertiary structure, and hence reduced biological activity. These defects in protein structure and function lead to developmental abnormalities that kill the insect.

In plants that produce them, canavanine and other secondary metabolites are constitutive defenses—that is, they are present regardless of whether the plant is under attack. Other chemical defenses come into play only when an herbivore strikes.

Plants respond to herbivory with induced defenses

The first step in a plant's response to herbivory is to somehow sense the event. Two mechanisms for plant perception of herbivore damage have been described: *membrane signaling* and *chemical signaling*.

MEMBRANE SIGNALING The plasma membrane is the part of the plant cell that is in contact with the environment. Within the first minute after an herbivore strikes, changes

in the electrical potential of the plasma membrane occur in the damaged area. As you will see later when you study the animal nervous system (see Section 45.2), such changes can be rapidly transmitted as a signal along the plasma membrane. In the case of plants responding to herbivory, the continuity of the symplast (see Figure 35.6) ensures that the signal travels over much of the plant within 10 minutes.

CHEMICAL SIGNALING When an insect chews on a plant, substances in the insect's saliva combine with fatty acids derived from the consumed plant tissue. The resulting compounds act as elicitors (see Section 39.1) to trigger both local and systemic responses to the herbivore. In corn, the herbivore-produced elicitor has been named volicitin for its ability to induce production of volatile signals that can travel to other plant parts—and to neighboring corn plants—and simulate their defense responses.

SIGNAL TRANSDUCTION PATHWAY The perception of damage from herbivory initiates a signal transduction pathway in the plant that involves the plant hormone *jasmonic acid* (*jasmonate*) (Figure 39.8):

When the plant senses an herbivore-produced elicitor, it makes jasmonate, which triggers many plant defenses, including the synthesis of a protease inhibitor. The inhibitor, once in an insect's gut, interferes with the digestion of proteins and thus stunts the insect's growth. Jasmonates also "call for help" by triggering the formation of volatile compounds that attract insects that prey on the herbivores attacking it.

Why don't plants poison themselves?

Why don't the chemicals that are so toxic to herbivores and pathogens kill the plants that produce them? Plants that produce toxic defensive chemicals generally use one of the following measures to protect themselves:

- The toxic substance is isolated in a special compartment within the cell.
- The toxic substance is produced only after the plant's cells have already been damaged.
- The plant uses modified enzymes or modified receptors that do not react with the toxic substance.

Isolation of the toxic substance is the most common means of avoiding exposure. Plants store their toxins in vacuoles if the toxins are water-soluble. If they are hydrophobic, the toxins may be dissolved in latex and stored in specialized tubes called

39.8 A Signal Transduction Pathway for Induced Defenses The chain of events initiated by herbivory that leads to the production of a defensive chemical can consist of many steps. These steps may include the synthesis of one or two hormones, binding of receptors, gene activation, and, finally, synthesis of defensive compounds.

laticifers, or dissolved in waxes on the epidermal surface. Such compartmentalized storage keeps the toxins away from the mitochondria, chloroplasts, and other parts of the plant's metabolic machinery.

Some plants store the precursors of toxic substances in one type of tissue, such as the epidermis, and store the enzymes that convert those precursors into the active toxin in another type, such as the mesophyll. When an herbivore chews part of the plant, cells are ruptured, the enzymes come into contact with the precursors, and the toxin is produced. The only part of the plant that is damaged by the toxin is that which was already damaged by the herbivore. Plants such as sorghum and some legumes, which respond to herbivory by producing cyanide—an inhibitor of cellular respiration—are among those that use this type of protective measure.

The third protective measure is used by the canavanine-producing plants described earlier. In these plants, unlike most other plants, the enzyme that charges the arginine tRNA discriminates correctly between arginine and canavanine, so canavanine is not incorporated into their proteins. Some herbivores, however, can evade canavanine poisoning in a similar manner, demonstrating that no plant defense is perfect. Like plants and pathogens, plants and herbivores evolve together in a continuing arms race, which the plants don't always win.

The plant doesn't always win the arms race

Milkweeds such as *Asclepias syriaca* store their defensive chemicals in laticifers. When damaged, a milkweed releases copious amounts of toxic latex from its laticifers, which run alongside the veins in its leaves. Field studies have shown that most insects that feed on neighboring plants of other species do not attack laticiferous plants, but there are exceptions. One population of beetles that feeds on *A. syriaca* exhibits a remarkable pre-feeding behavior: these beetles cut a few veins in the leaves before settling down to dine (**Figure 39.9**). Cutting the veins, with their adjacent laticifers, causes massive latex leakage and

39.9 Disarming a Plant's Defenses This beetle is inactivating a milkweed's defense system by cutting its laticifer supply lines.

interrupts the latex supply to a downstream portion of the leaf. The beetles then move to the relatively latex-free portion and eat their fill.

Does this behavior of the beetles negate the adaptive value of latex protection? Not entirely. Great numbers of potential insect pests are still effectively deterred by the latex. And evolution proceeds. Over time, milkweed plants producing higher concentrations of toxins may be selected by virtue of their ability to kill even the beetles that cut their laticifers.

39.2 RECAP

Many plants use secondary metabolites as defenses against herbivory. Other defenses are induced by herbivory through a signal transduction pathway involving the hormone jasmonate.

- Describe one example of a secondary metabolite and how it affects herbivores. **See pp. 820–821**
- What role does jasmonate play in plant defense? **See p. 822 and Figure 39.8**
- What are three ways in which a plant avoids being poisoned by its own defensive chemicals? **See pp. 822–823**

A plant's survival depends not only on successful defenses against pathogens and herbivores, but also on coping with a sometimes hostile physical environment. In the next section we consider how plants deal with climate-imposed stresses.

39.3 How Do Plants Deal with Climatic Extremes?

Plants are threatened by many aspects of the physical environment, such as drought, waterlogged soils, and extreme temperatures. How do plants survive these environmental challenges? Plants cope with environmental stresses through adaptation or acclimation.

- **Adaptation** is genetically encoded resistance to stress. A plant may have structures or biochemical properties that aid in its survival in the face of environmental challenges.
- **Acclimation** is increased tolerance for environmental extremes because of prior exposure to them. An individual plant previously exposed to extreme cold, for example, may be more likely to survive the subsequent winter.

Let's begin by describing some adaptations of plants to extremes of water availability and temperature.

Desert plants have special adaptations to dry conditions

Many plants, especially those living in deserts, must cope with extremely limited water supplies. Some desert plants have no spe-

39.10 Desert Annuals Avoid Drought The seeds of many desert annuals lie dormant for long periods awaiting conditions appropriate for germination. When they do receive enough moisture to germinate, they grow and reproduce rapidly before the short wet season ends. During the long dry spells, only dormant seeds remain alive.

cial structural adaptations for water conservation. Instead, these desert annuals, called *drought avoiders*, simply evade periods of drought. Drought avoiders carry out their entire life cycle—from seed to seed—during a brief period in which rainfall has made the surrounding desert soil sufficiently moist (**Figure 39.10**). Deciduous plants, particularly in Africa and South America, shed their leaves in response to drought as a way to conserve water.

39.11 Stomatal Crypts Stomata in the leaves of some xerophytes are located in sunken cavities called stomatal crypts. The hairs covering these crypts trap moist air.

39.12 Succulence The *Aloe* plant stores water in its fleshy leaves.

LEAF STRUCTURES Most desert plants grow in their dry environment year-round. Plants adapted to dry environments are called **xerophytes** (from the Greek *xeros*, “dry”). Three structural adaptations are found in the leaves of many xerophytes:

- Specialized leaf anatomy that reduces water loss
- A thick cuticle and a profusion of trichomes over the leaf epidermis, which retard water loss
- Diffraction and reflection of sunlight by trichomes, which decrease the intensity of the light impinging on the leaves, thus decreasing the risk of damage to the photosynthetic apparatus by excess light

In some species the stomata are strategically located in sunken cavities below the leaf surface (known as **stomatal crypts**), where they are sheltered from the drying effects of air currents (**Figure 39.11**). Hairs surrounding the stomata slow air currents as well.

Cacti and similar plants have spines rather than typical leaves, and photosynthesis is confined to the fleshy stems. The spines may help plants cope with desert conditions by reflecting incident radiation, or by dissipating heat.

WATER-STORING STRUCTURES **Succulence**—the possession of fleshy, water-storing leaves or stems—is an adaptation to dry environments (**Figure 39.12**). Other adaptations of succulents include a reduced number of stomata and CAM photosynthesis, which separates the light-requiring and CO_2 -assimilating reactions of photosynthesis to conserve water (see Section 10.4).

39.13 Mining Water with Deep Taproots In Death Valley, California, the root of this mesquite tree must reach far beneath the dunes for its water supply.

ROOT SYSTEMS THAT MAXIMIZE WATER UPTAKE Roots may also be adapted to dry environments. Cacti have shallow but extensive fibrous root systems that effectively intercept water at the soil surface following even light rains. Mesquite trees (*Prosopis*; **Figure 39.13**) obtain water through taproots that grow to great depths, reaching water supplies far underground, as well as from condensation on their leaves. The Atacama Desert in northern Chile often goes several years without measurable rainfall, but the landscape there has many surprisingly large mesquite trees.

One of the most successful desert plants of the southwestern United States, creosote bush (*Larrea tridentata*), displays a range of xerophytic features. It has a deep taproot, a shallow and ex-

tensive root system that can absorb water quickly after rare rain events, and small wax-covered leaves. The plant owes its name to its ability to produce noxious resins that smell like the wood preservative creosote. These natural resins not only help to seal in water, but also render the leaves virtually indigestible to browsing mammals—another adaptation to the stresses of desert life.

CHANGES IN WATER POTENTIAL Xerophytes and other plants that must cope with inadequate water supplies

may accumulate high concentrations of the amino acid proline or of secondary metabolites in their vacuoles. These accumulations lower the water potential in the plant's cells below that in the soil, which results in the uptake of water by the cells via osmosis (see Section 35.1). Plants living in salty environments share this and several other adaptations with xerophytes, as we will see shortly.

In water-saturated soils, oxygen is scarce

For some plants, the environmental challenge is the opposite of that faced by xerophytes: too much water. Some plants live in environments so wet that the diffusion of oxygen to their roots is severely limited. Since most plant roots require oxygen to support respiration and ATP production, most plants cannot tolerate saturated soil conditions for long.

Some species, however, are adapted to life in a water-saturated habitat. Their roots grow slowly and hence do not penetrate deeply. Because the oxygen concentration in saturated soil is too low to support aerobic respiration, their roots carry on alcoholic fermentation (an anaerobic process; see Section 9.4), which provides ATP for the activities of the root system. This adaptation explains why their growth is slow: fermentation is much less efficient in producing ATP than aerobic respiration.

The root systems of some plants adapted to swampy environments, such as cypresses and some mangroves, have **pneumatophores**, which are extensions that grow out of the water and up into the air (**Figure 39.14**). Pneumatophores have lenticels that allow oxygen to diffuse through them, aerating the submerged parts of the root system.

Pneumatophores are root extensions that grow out of the water, under which the rest of the roots are submerged.

39.14 Coming Up for Air The roots of these mangroves obtain oxygen through pneumatophores.

Large air spaces are found in the leaf parenchyma and in the petioles of many submerged or partly submerged aquatic plants. Tissue containing such air spaces is called **aerenchyma** (Figure 39.15). Aerenchyma stores oxygen produced by photosynthesis and permits its ready diffusion to parts of the plant where it is needed for cellular respiration. Aerenchyma also imparts buoyancy. Furthermore, because it contains far fewer cells than most other plant tissues, metabolism in aerenchyma proceeds at a lower rate, so the need for oxygen is much reduced.

Many plants, rather than facing continual water deficits or excesses, live in fluctuating environments with unpredictable rainfall. We now turn to the mechanisms plants use to respond to those challenges.

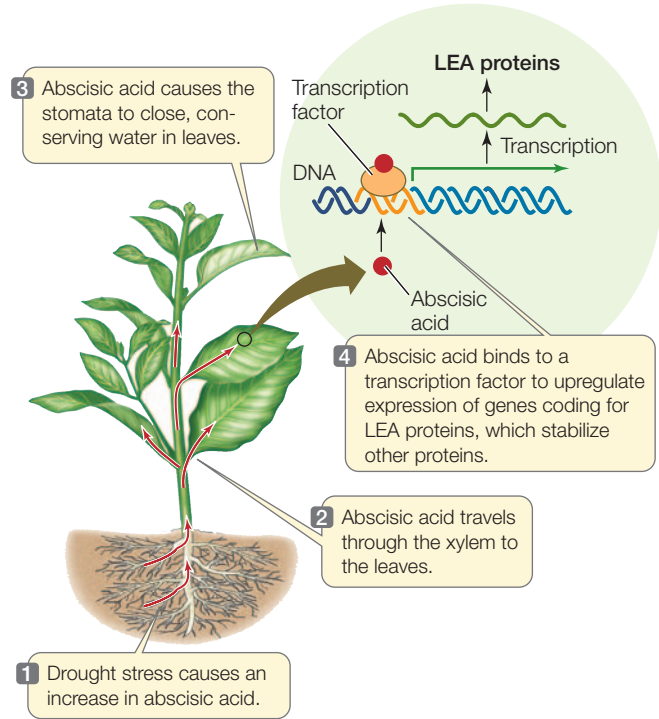

Plants can acclimate to drought stress

When the weather is abnormally dry, the water content of the soil is reduced, and less water is available to plants. Water deficits in plant cells have two major effects: a reduction in membrane integrity as the polar–nonpolar forces that orient the lipid bilayer proteins are reduced, and changes in the three-dimensional structures of proteins. Plant growth is reduced when the structure of plant cells is compromised in these ways. Indeed, inadequate water supply is the single most important factor that limits production of our most important food crops.

Plants can, however, acclimate to drought stress to maintain their structure and function. How do they do it? When plants sense a water deficit in their roots, a signal transduction pathway is set in motion that initiates several measures to conserve water and maintain cellular integrity. This signal transduction pathway begins with the production of a hormone, abscisic acid, in the roots. This hormone travels from the roots to the shoot, where it causes stomatal closure and initiates gene transcrip-

39.15 Aerenchyma Lets Oxygen Reach Submerged Tissues This scanning electron micrograph of a cross section of a petiole of the yellow water lily shows the structure of the air-filled channels that make up aerenchyma tissue.

39.16 A Signal Transduction Pathway in Response to Drought Stress Acclimation to drought stress begins in the root with the production of the hormone abscisic acid.

tion that leads to other physiological events that conserve water and cellular integrity (Figure 39.16).

Plant genes whose expression is altered by drought stress have been identified, largely through research using DNA microarrays (see Figure 18.9), proteomics (see Figure 17.17), and other molecular approaches. One group of proteins whose production is upregulated during drought stress is the *late embryogenesis abundant* (LEA; pronounced “lee-yuh”) proteins. These hydrophobic proteins accumulate in maturing seeds as they dry out. The LEA proteins bind to membranes and other cellular proteins to stabilize them, preventing their aggregation during desiccation. The importance of LEA proteins in coping with drought stress was demonstrated by Ray Wu and his colleagues at Cornell University, who showed that transgenic rice plants expressing a high level of a LEA protein in their leaves and roots grew better than normal plants under drought conditions (Figure 39.17). Genes that code for LEA proteins are widely distributed among plants, bacteria, and invertebrates; in all these organisms, high-level expression results in drought tolerance. As described at the opening of Chapter 35, which discusses the discovery of *HARDY*, another gene that promotes water use efficiency in plants, genetic research holds the promise of solutions to many agricultural problems, including those that may be presented by global climate change.

Plants have ways of coping with temperature extremes

Temperatures that are too high or too low can stress plants and even kill them. Plants differ in their sensitivity to heat and cold, but all plants have their limits. Any temperature extreme can damage cellular membranes.

INVESTIGATING LIFE

39.17 A Molecular Response to Drought Stress

Understanding the responses of plants to drought conditions is vital for agriculture. Ray Wu and colleagues transformed rice cells with a gene that codes for a LEA protein that is expressed in seeds as they mature and dry out. The investigators then measured the response of the transgenic rice plants to 28 days of drought.

HYPOTHESIS LEA proteins protect plants from the effects of drought stress.

METHOD

RESULTS

CONCLUSION Plants with higher concentrations of a LEA protein grow better under drought conditions.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

- High temperatures destabilize membranes and denature many proteins, especially some of the enzymes of photosynthesis.
- Low temperatures cause membranes to lose their fluidity and alter their permeabilities to solutes.
- Freezing temperatures may cause ice crystals to form, damaging membranes.

Therefore, it is not surprising that many plants living in hot environments have adaptations similar to those of xerophytes. These adaptations include hairs and spines that dissipate heat, leaf forms that intercept less direct sunlight, and CAM photosynthesis, which allows plants to perform some metabolic processes in the cool of night (see Section 10.4).

The plant response to heat stress is similar to the response to drought stress in that new proteins are made, often under the direction of an abscisic acid-mediated signal transduction pathway. Within minutes of experimental exposure to raised temperatures (typically a 5°C–10°C increase), plants synthesize several kinds of **heat shock proteins**. Among these proteins are chaperonins (see Figure 3.12), which help other proteins maintain their structures and avoid denaturation. Threshold temperatures for the production of heat shock proteins vary, but 39°C is sufficient to induce them in most plants.

Low temperatures above the freezing point can cause *chilling injury* in many plants, including crops such as rice, corn, and cotton, as well as tropical plants such as bananas. Many plant species can acclimate to cooler temperatures through a process called **cold-hardening**, which requires repeated exposure to cool, but not injurious, temperatures over many days. A key change during the hardening process is an increase in the proportion of unsaturated fatty acids in membranes, which allows them to retain their fluidity and function normally at cooler temperatures. Plants have a greater ability to modify the degree of saturation of their membrane lipids than animals do. In addition, low temperatures induce the formation of proteins similar to heat shock proteins, which protect against chilling injury.

If ice crystals form within plant cells, they can kill the cells by puncturing organelles and plasma membranes. Furthermore, the growth of ice crystals outside the cells can draw water from the cells and dehydrate them. Freeze-tolerant plants have a variety of adaptations to cope with these problems, including the production of *antifreeze proteins* that slow the growth of ice crystals.

39.3 RECAP

Plants that live in continually dry or water-saturated environments have structural adaptations to cope with those conditions. Mechanisms that protect plants from drought stress are initiated by a signal transduction pathway involving abscisic acid. Heat shock proteins help plants acclimate to high and low temperatures.

- Describe two structural adaptations for growth in water saturated soils. **See pp. 825–826**
- What is the role of abscisic acid in acclimation to drought stress? **See p. 826 and Figure 39.16**
- What environmental conditions induce the formation of heat shock proteins, and what functions do those proteins serve? **See p. 827**

Just as climatic extremes can limit plant growth, the presence of certain substances, such as salt and heavy metals, can make an environment inhospitable to plant growth.

39.4 How Do Plants Deal with Salt and Heavy Metals?

A number of toxic solutes are found in soils, but worldwide, no toxic substance restricts angiosperm growth more than salt (sodium chloride). Saline—salty—habitats support, at best, limited types of vegetation. Saline habitats are found in diverse locales, from hot, dry, deserts to moist, cool coastal marshes. Along the seashore, saline environments are created by ocean spray. The ocean itself is a saline environment, as are estuaries, where fresh and salt water meet and mingle. Salinization of agricultural land is an increasing global problem. Even where crops are irrigated with fresh water, sodium ions from the water accumulate in the soil to ever greater concentrations as the water evaporates.

Saline environments pose an osmotic challenge for plants. Because of its high salt concentration, a saline environment has an unusually negative water potential. To obtain water from such an environment, a plant must have an even more negative water potential; otherwise, water will diffuse out of its cells, and the plant will wilt and die. Plants in saline environments are also challenged by the potential toxicity of sodium, which inhibits enzymes and protein synthesis.

Most halophytes accumulate salt

Halophytes—plants adapted to saline habitats—are found in a wide variety of flowering plant groups. Most halophytes share one adaptation: they take up sodium and, usually, chloride ions and transport those ions to their leaves. The accumulated ions are stored in the central vacuoles of leaf cells, away from more sensitive parts of the cells. Nonhalophytes accumulate relatively little sodium, even when placed in a saline environment; of the sodium that is absorbed by their roots, very little is transported to the shoot. The increased salt concentration in the tissues of halophytes lowers their water potential and allows them to take up water from their saline environment.

Some halophytes have other adaptations to life in saline environments. Some, for example, have **salt glands** in their leaves. These glands excrete salt, which collects on the leaf surface until it is removed by rain or wind (**Figure 39.18**). This adaptation, which reduces the danger of poisoning by accumulated salt, is found in some desert plants, such as *Frankenia palmeri*, and in some mangroves growing in seawater.

Salt glands can play multiple roles, as in the desert shrub *Atriplex halimus*. This shrub has glands that secrete salt into small bladders on the leaves. By lowering the water potential of the leaves, this salt not only helps them obtain water from the roots, but also reduces their transpirational loss of water to the atmosphere.

The adaptations we have just discussed are specific to halophytes. Several other adaptations are shared by halophytes and

39.18 Excreting Salt This saltwater mangrove plant has special salt glands that excrete salt, which appears here as crystals on the leaves.

xerophytes, including thick cuticles, succulence, and CAM photosynthesis.

Some plants can tolerate heavy metals

Salt is not the only toxic solute found in soils. High concentrations of some heavy metal ions, such as chromium, mercury, lead, and cadmium, are toxic to most plants; many of these ions are more toxic than sodium at equivalent concentrations.

Some geographic sites are naturally rich in heavy metals as a result of normal geological processes. In other places, acid rain leads to the release of toxic aluminum ions in the soil. Human activities, notably the mining of metallic ores, leave localized areas—known as tailings—with high concentrations of heavy metals and low concentrations of nutrients. Such sites are hostile to most plants, and seeds falling on them generally do not produce adult plants.

Most mine tailings rich in heavy metals, however, are not completely barren. They may support healthy plant populations that differ genetically from populations of the same species on the surrounding normal soils. How do these plants survive?

Initially, botanists believed that some plants were able to tolerate heavy metals by excluding them: that by not taking up the metal ions, the plants avoided being poisoned. Further investigations have shown, however, that tolerant plants growing on mine tailings do take up heavy metals, accumulating concentrations that would kill most plants. Over 200 plant species have been identified as **hyperaccumulators** that store large quantities of metals such as arsenic (As), cadmium (Cd), nickel (Ni), aluminum (Al), and zinc (Zn).

Perhaps the best-studied hyperaccumulator is alpine pennycress (*Thlaspi caerulescens*). Before the advent of chemical analysis, miners used to use the presence of this plant as an indicator of mineral-rich deposits. A *Thlaspi* plant may accumulate as much as 30,000 ppm Zn (most plants contain 100 ppm) and 1,500 ppm Cd (most plants contain 1 ppm). Studies of *Thlaspi*

and other hyperaccumulators have revealed the presence of several common mechanisms:

- Increased ion transport into the roots
- Increased rates of translocation of ions to the leaves
- Accumulation of ions in vacuoles in the shoot
- Resistance to the ions' toxicity

Knowledge of these hyperaccumulation mechanisms and the genes underlying them has led to the emergence of **phyto-remediation**, a form of bioremediation (see Section 18.6) that uses plants to clean up environmental pollution. Some phytoremediation projects use natural hyperaccumulators, while others use genes from hyperaccumulators to create transgenic plants that grow more rapidly and are better adapted to a particular polluted environment. In either case, the plants are

39.19 Phytoremediation Plants that accumulate heavy metals can be used to clean up contaminated soils. Here, poplars are being used to remove contaminants from an air base.

grown in the contaminated soil, where they act as natural “vacuum cleaners” by taking up the contaminants (**Figure 39.19**). The plants are then harvested and disposed of to remove the contaminants. Perhaps the most dramatic use of phytoremediation occurred after an accident at the nuclear power plant at Chernobyl, Ukraine (then part of the Soviet Union), in 1986, when sunflower plants were used to remove uranium from the nearby soil. Phytoremediation is now widely used in cleaning up land after strip mining.

After finding plants that accumulate valuable metals such as Ni, cobalt (Co), and silver (Ag), some scientists have proposed using those plants for *phytomining*. As in phytoremediation, the plants would be used to take up metals from the soil, but the metals would be extracted from the plants after they are harvested.

39.4 RECAP

Halophytes have a number of adaptations to saline habitats, most of which involve mechanisms that lower their water potential. Some plants can tolerate heavy-metal-rich soils that are toxic to most other plants.

- What are some of the roles of salt glands in halophyte leaves? **See p. 828**
- How are plants used for phytoremediation? **See p. 829**

CHAPTER SUMMARY

39.1 How Do Plants Deal with Pathogens?

- Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved mechanisms for attacking plants, and plants have evolved mechanisms for defending themselves against those attacks. **Review Figure 39.2, ANIMATED TUTORIAL 39.1**
- Plants strengthen their cell walls and block plasmodesmata when attacked, limiting the ability of viral pathogens to move from cell to cell.
- **Gene-for-gene resistance** depends on a match between a plant's **resistance (R) genes** and a pathogen's **avirulence (Avr) genes**. **Review Figure 39.3**
- In the **hypersensitive response** to infection by bacteria or fungi, cells produce two kinds of defensive molecules: **phytoalexins** and **PR proteins**. Some cells around the infected area die, sealing off the pathogens and the damage they have caused.

- The hypersensitive response is often followed by **systemic acquired resistance**, in which salicylic acid activates further synthesis of defensive compounds.
- Plants use RNA interference to develop specific immunity to invading RNA viruses.

39.2 How Do Plants Deal with Herbivores?

- Herbivory increases the productivity of some plants. **Review Figure 39.6**
- Some plants produce **secondary metabolites** as defenses against herbivores. **Review Table 39.1, Figure 39.7**
- Hormones, including **jasmonates**, participate in signal transduction pathways leading to the production of defensive compounds. **Review Figure 39.8**
- Plants protect themselves against their own toxic defensive chemicals by isolating them in specialized compartments, by producing them only after the plant has already been damaged, or by using modified enzymes or receptors that are not affected by the toxic substance.

39.3 How Do Plants Deal with Climatic Extremes?

- Plants cope with environmental stresses by **adaptation** (genetically encoded resistance) or **acclimation** (increased tolerance).
- Xerophytes** are plants that are adapted to dry environments.
- Some xerophytic adaptations are structural, including thickened cuticles, specialized trichomes, **stomatal crypts**, **succulence**, and long taproots.
- Some plants accumulate solutes, making their water potential lower so they can tolerate drought.
- Adaptations to water-saturated habitats include **pneumatophores**, extensions of roots allow oxygen uptake from the air, and **aerenchyma**, in which oxygen can be stored and diffuse throughout the plant.
- A signal transduction pathway involving abscisic acid initiates a plant's response to drought stress. **Review Figures 39.16 and 39.17**

- Membranes and proteins can be damaged by extremely high or low temperatures. Plants respond to extreme temperatures by producing **heat shock proteins**.
- Some plants undergo **cold-hardening**, an acclimation process that includes changes in membrane lipids and production of heat shock proteins.
- Some plants resist freezing by producing antifreeze proteins.

39.4 How Do Plants Deal with Salt and Heavy Metals?

- Most **halophytes** accumulate salt. Some have **salt glands** that excrete salt to the leaf surface.
- Some plants living in soils that are rich in heavy metals are **hyperaccumulators** that take up large amounts of those metals into their tissues.
- Phytoremediation** is the use of hyperaccumulating plants or their genes to clean up environmental pollution.

SEE WEB ACTIVITY 39.1 for a concept review of this chapter.

SELF-QUIZ

- Which of the following is *not* a common defense against bacteria and fungi?
 - Lignin formation
 - Phytoalexins
 - A waxy covering
 - The hypersensitive response
 - Mycorrhizae
- Plants sometimes protect themselves from their own toxic secondary metabolites by
 - producing special enzymes that destroy the toxin.
 - storing precursors of the toxic substances in one compartment and the enzymes that convert those precursors to toxic products in another compartment.
 - storing the toxic substances in mitochondria or chloroplasts.
 - distributing the toxic substances to all cells of the plant.
 - performing crassulacean acid metabolism.
- Herbivory
 - is an attack by plants on animals.
 - always reduces plant growth.
 - usually increases the rate of photosynthesis in the remaining leaves.
 - reduces the rate of transport of photosynthetic products from the remaining leaves.
 - is always lethal to the grazed plant.
- Which statement about secondary metabolites is *not* true?
 - They may be used in defense against fungi.
 - Some are poisonous to herbivores.
 - Some are amino acids that are normally part of proteins.
 - Water soluble molecules are stored in vacuoles.
 - Some mimic the hormones of animals.
- Which statement about latex is *not* true?
 - It is sometimes contained in laticifers.
 - It is typically white.
 - It is often toxic to insects.
 - It is a rubbery solid.
 - Milkweeds produce it.
- Which of the following is *not* an adaptation to dry environments?
 - Increased solute concentration in the vacuoles
 - Hairy leaves
 - A heavier cuticle over the leaf epidermis
 - Sunken stomata
 - A root system that grows each rainy season and dies back when it is dry
- Some plants adapted to swampy environments meet the oxygen needs of their roots by means of a specialized tissue called
 - parenchyma.
 - aerenchyma.
 - collenchyma.
 - sclerenchyma.
 - chlorenchyma.
- Halophytes
 - may accumulate abscisic acid in their vacuoles.
 - may have water potentials that are lower than those of other plants.
 - only accumulate sodium.
 - have low root-to-shoot ratios.
 - rarely accumulate sodium.
- Which of the following is *not* involved in the response to drought stress?
 - Abscisic acid
 - Closing of aquaporins
 - LEA gene expression
 - Closing of stomata
 - Jasmonate
- Plants that tolerate heavy metals commonly
 - differ genetically from other members of their species.
 - do not take up the heavy metals.
 - are tolerant to all heavy metals.
 - are slow to colonize an area rich in heavy metals.
 - weigh more than plants that are sensitive to heavy metals.

FOR DISCUSSION

1. How might plant adaptations affect the evolution of herbivores? How might the adaptations of herbivores affect plant evolution?
2. The stomata of the common oleander (*Nerium oleander*) are located in sunken crypts in its leaves. Whether or not you know what an oleander is, you should be able to describe an important feature of its natural habitat. What is that feature?
3. In the coming decades, climate change may have significant effects on the growth and productivity of plants, in particular the crop plants on which we depend for our food. Discuss the physiological effects, and possible genetic responses in terms of plant breeding, of the following:
 - a. In Pakistan, reduced rainfall causes a reduction in wheat yields.
 - b. In the Mekong Delta of Vietnam, rising sea level inundates rice fields, causing a drastic reduction in yields.
 - c. Increased temperature and humidity in western Canada causes an increase in wheat rust.

ADDITIONAL INVESTIGATION

The tobacco hornworm (*Manduca sexta*) is adapted to feeding on nicotine-producing plants. Using the genetically modified tobacco plants described in Figure 39.7, how might you test the

hypothesis that dietary nicotine protects the tobacco hornworm against its parasite *Cotesia congregata*?

WORKING WITH DATA (GO TO yourBioPortal.com)

Nicotine Is a Defense against Herbivores To test the hypothesis that nicotine is a plant defense chemical, Baldwin and colleagues generated transgenic plants that expressed a low

amount of nicotine (Figure 39.7). In this exercise, you will analyze data from the original research paper, which included the effects of the hormone jasmonic acid.

40

Physiology, Homeostasis,
and Temperature Regulation

Cool it!

"A new world record!" These words convey the thrill of world-class athletic competition. But as records are broken by mere centimeters or by fractions of a second, are we reaching absolute limits to human performance? We can assess many physiological limits to extreme performance—maximum breathing rate, for example, or the maximum rate at which the heart can supply blood to the muscles. A less obvious physiological limit is temperature.

The 2008 New York City Marathon took place on a cold, clear, windy day in November. For the third time, the first-place woman in this 41-km race was world record holder Paula Radcliffe. Radcliffe had also been expected to win

the women's marathon back in the 2004 Olympics. But that race took place on a hot, humid day in Athens. Overcome by heat stress, Radcliffe collapsed 6 km from the finish line. The critical difference in the two races was probably temperature.

Thermal stress can have more serious consequences than losing a race. Every year some athletes die of heat stroke, which can occur when internal body temperature exceeds 41°C. This elevated internal temperature results in the failure of major organs and, in more than 20 percent of cases, death. Soldiers in the desert are at extreme risk of heat stroke, as are firefighters. Agricultural, industrial, and construction workers are also subject to the adverse affects of heat. Biologists at Stanford University developed a technology to cool individuals in such situations, and in the process discovered a way to enhance athletic performance.

Working muscles produce heat, which is carried by the blood to skin surfaces, where it is lost to the environment. Not all skin surfaces are equally good at dissipating heat, however. Because fur impedes heat loss, mammals evolved efficient bare-skin heat-loss portals such as the nose, tongue, footpads, and parts of the face. These areas have specialized blood vessels that can act like radiators to disperse heat or close down to conserve heat. Humans are not furred, but we retain these ancestral blood vessels in our hands, feet, and face (which is why we blush). The Stanford team designed a device to amplify heat extraction from these areas.

The heat extractor is a chamber that encases the hand and is sealed at the wrist. The hand is in contact with a

Limits to Performance Paula Radcliffe, photographed here during her winning performance at the 2008 New York City Marathon, collapsed from heat stress during the 2004 Olympic marathon. When the body's internal temperature is subjected to extreme heat, its homeostatic mechanisms may fail.

A Cooling Glove The heat extractor increases heat loss and allows the body to perform at a higher level in severe conditions.

cooled surface. A mild vacuum in the chamber pulls more blood into the hand, enabling the cool surface to extract more heat. With this device, an active individual's body temperature rises more slowly, and cools more rapidly during rest. An unexpected benefit is that cooling reduces fatigue and greatly increases exercise capacity. In one study, college freshmen improved their push-up performance at a rate of 5 push-ups a day without cooling, but 9 push-ups a day with cooling. Some men and women in the study achieved more than 800 push-ups in a workout session.

Human beings survive in environments that are extremely hot or extremely cold because we have the physiological and behavioral means of regulating our internal body temperature—an example of *homeostasis*, the maintenance of a “steady state” in our internal environment.

IN THIS CHAPTER we will explore the internal environment that serves the needs of all of the body's cells. We will survey the cell and tissue types that make up physiological systems and discuss how these systems maintain the internal environment within certain physiological limits, a condition called homeostasis. Homeostasis will be described using one important example, the regulation of body temperature.

CHAPTER OUTLINE

- 40.1** How Do Multicellular Animals Supply the Needs of Their Cells?
- 40.2** How Does Temperature Affect Living Systems?
- 40.3** How Do Animals Alter Their Heat Exchange with the Environment?
- 40.4** How Do Mammals Regulate Their Body Temperatures?

40.1 How Do Multicellular Animals Supply the Needs of Their Cells?

All animal cells need nutrients and oxygen from the environment and must eliminate carbon dioxide and other waste products of metabolism to the environment. The cells of very small or very thin aquatic animals meet these needs by direct exchanges with the external environment. In such animals, no cell is far from direct contact with the water it lives in; the water contains nutrients, absorbs waste, and provides a relatively unchanging physical environment. Most cells of larger animals do not have direct contact with the external environment, and their needs must be served by an environment that is wholly internal to the animal.

An internal environment makes complex multicellular animals possible

The cells of multicellular animals exist within an **internal environment** of extracellular fluid (ECF). A human, for example, is about 60 percent water. Two-thirds of that water is contained within cells, and one-third makes up the ECF that is our internal environment. About 20 percent of that extracellular fluid, or 3 liters, is the blood plasma that circulates in our blood vessels. The rest—about 11 liters—is the **interstitial fluid** that bathes every cell of the body (**Figure 40.1**). Individual cells get their nutrients from this interstitial fluid and dump their waste products into it. As long as conditions in this internal environment are held within certain limits, the cells are protected from changes or harsh conditions in the external environment. A stable internal environment makes it possible for an animal to occupy habitats that would kill its cells if they were exposed to it directly. How is the internal environment kept constant?

As multicellular organisms evolved, cells became specialized for maintaining specific aspects of the internal environment. In turn, the internal environment enabled these specializations, since each cell did not have to provide for all of its own needs. Some cells evolved to be the interface between the internal and the external environments and to provide the necessary transport functions to get nutrients in and move wastes out. Other cells became specialized to provide internal functions such as circulation of the extracellular fluids, energy storage, movement, and information processing. The evolution of physiological systems to maintain the internal environment made it possible for multicellular animals to become larger, thicker, and more complex, and to occupy many different habitats.

40.1 The Internal Environment The “internal environment” is the extracellular fluid, or ECF. ECF, which accounts for about one-third of total body water, is made of the blood plasma and the interstitial fluid. The physiological composition of the ECF must remain stable within narrow limits, and maintaining that stability is the job of the body’s organ systems.

The composition of the internal environment is constantly being challenged by the external environment and by the metabolic activity of the cells of the body. The maintenance of stable conditions (within a narrow range) in the internal environment is called **homeostasis**. If a physiological system fails to function properly, homeostasis is compromised and cells are damaged and can die. To avoid the loss of homeostasis, physiological systems must be controlled and regulated in response to changes in both the external and internal environments.

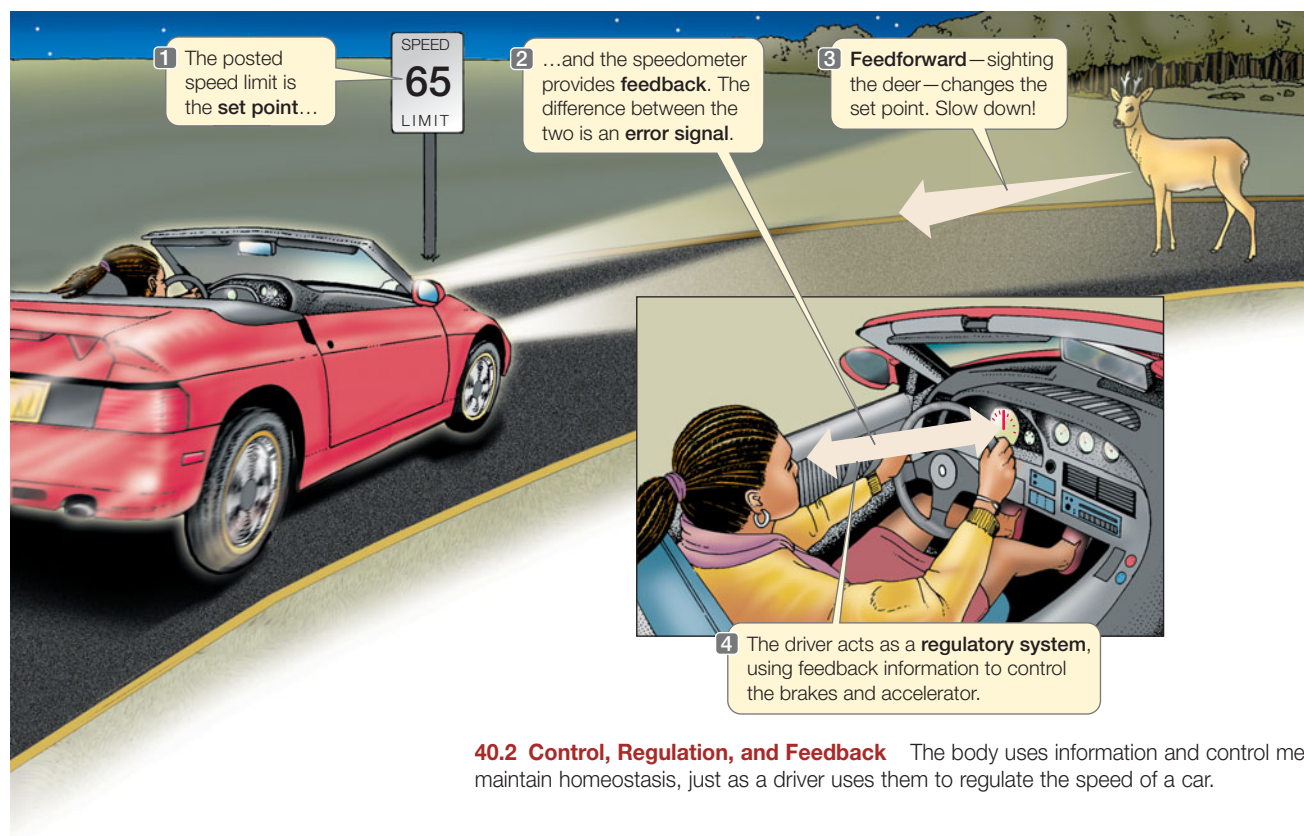

Physiological systems maintain homeostasis

The activities of all physiological systems are controlled—speeded up or slowed down—by actions of the nervous and endocrine systems. But to *regulate* the internal environment, information is required. As an analogy, think of driving a car (**Figure 40.2**). To regulate the speed of your car, you have to know both how fast you are going and how fast you want to go. The desired speed is a **set point**, or reference point; the reading on your speedometer is **feedback information**. Any difference between the set point and the feedback information is an **error signal**. Error signals suggest corrective actions, such as stepping on the accelerator or brake.

Some components of physiological systems are called **effectors** because they *effect* changes in the internal environment. Effectors are **controlled systems** because their activities are controlled by commands from regulatory systems. **Regulatory systems**, in contrast, obtain, process, and integrate information, then issue commands to controlled systems.

Important components of any regulatory system are the **sensors** that provide the feedback information to be compared with the internal set point. How is information from the sensors used?

Negative feedback is the most common use of sensory information in regulatory systems. Negative feedback information is used to counteract the influence that created an error signal. Whatever force is pushing the system away from its set point must be “negated.” In our car analogy, the recognition that you are going too fast is negative feedback that causes you to release the accelerator and press the brake.

40.2 Control, Regulation, and Feedback The body uses information and control mechanisms to maintain homeostasis, just as a driver uses them to regulate the speed of a car.

Although not as common as negative feedback, **positive feedback** is also seen in physiological systems. Rather than returning a system to a set point, positive feedback amplifies a response (i.e., it *increases* the deviation from the set point). Examples of regulatory systems that use positive feedback are the responses that empty body cavities, such as urination and defecation. Another example is sexual behavior, in which a little stimulation causes more behavior, which causes more stimulation, and so on. Positive feedback responses tend to reach a limit and terminate rapidly. The birth process is a good example. Contractions of the uterus stretch the birth canal, which stimulates more and stronger contractions until the baby is delivered, at which time contractions cease.

Feedforward information is another feature of regulatory systems. The function of feedforward information is to change the set point. Seeing a deer in the road when you are driving is an example of feedforward information; this information takes precedence over the posted speed limit, and you slow down. Before the start of a race, hearing the command “on your mark” is feedforward information that raises your heart rate before you begin to run. Feedforward information predicts a change in the internal environment before that change occurs.

These principles of control and regulation help organize our thinking about physiological systems. Once we understand how a system works, we can then ask how it is regulated. The example we will explore in this chapter is the regulation of body temperature. But first we need to become acquainted with the important structural features that all physiological systems have in common.

Cells, tissues, organs, and systems are specialized to serve homeostatic needs

Each physiological system is composed of discrete organs, such as the liver, heart, lungs, and kidneys. These organs are made

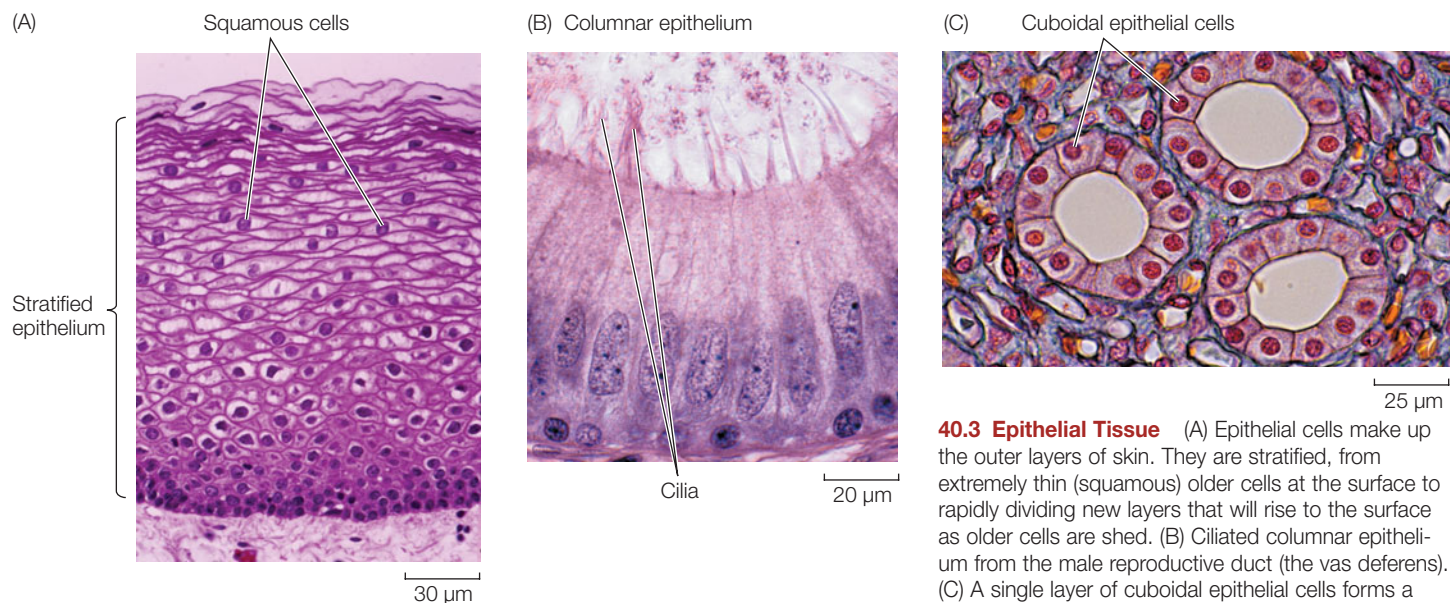

up of assemblages of cells known as **tissues**. Although there are many specialized cell types, there are only four kinds of tissues: *epithelial*, *muscle*, *connective*, and *nervous*.

The word “tissue” is often used in a general way to refer to a piece of an organ, such as “lung tissue” or “kidney tissue.” As we will see, an organ always consists of more than one of the four kinds of tissues.

EPITHELIAL TISSUES **Epithelial tissues** are sheets of densely packed, tightly connected *epithelial cells* (Figure 40.3). Epithelial cells create boundaries between the inside and the outside of the body and between body compartments; they line the blood vessels and make up various ducts and tubules.

Filtration and transport are important functions of epithelial cells; they both act as barriers and provide transport across those barriers. They control what molecules and ions can move between the blood and the interstitial fluid. They can selectively transport ions and molecules from one side of an epithelial membrane to the other. Examples are the absorption of nutrient molecules from your gut and the secretion of acid into your stomach. Some epithelial cells, like those in the lungs or at the skin’s surface, are extremely thin (*squamous*) to facilitate movement of substances across them.

The skin is epithelial tissue that receives much wear and tear. Accordingly, epithelial cells in the deepest layer of the skin have a high rate of cell division, producing new cells that move progressively to the skin surface, die, and are shed. A cross section of the skin reveals the layering of cells, from the newly formed ones on the innermost germinal layer to the dead ones on the surface. Because of this appearance, the skin is called a stratified epithelium (see Figure 40.3A). In contrast, gut epithelium consists of a single layer of tall, closely packed cells called a simple columnar epithelium. The epithelial cells of your gut are replaced about every 5 days; those in your skin are renewed every 1 to 2 months.

40.3 Epithelial Tissue (A) Epithelial cells make up the outer layers of skin. They are stratified, from extremely thin (squamous) older cells at the surface to rapidly dividing new layers that will rise to the surface as older cells are shed. (B) Ciliated columnar epithelium from the male reproductive duct (the vas deferens). (C) A single layer of cuboidal epithelial cells forms a tubule in the kidney. These cells have many molecular transport functions.

Epithelial cells have many other roles. Some secrete hormones, milk, mucus, digestive enzymes, or sweat. Others have cilia that move substances over surfaces or through tubes (see Figure 40.3B). Epithelial cells can also provide information to the nervous system. Smell and taste receptors, for example, are epithelial cells that detect specific chemicals.

MUSCLE TISSUES Muscle tissues consist of elongated cells that contract to generate forces and cause movement. Muscle tissues are the most abundant tissues in the body, and they use most of the energy produced in the body. All muscle cells contain long protein polymers called actin and myosin which interact to cause muscle cells to contract and exert force. There are three types of muscle tissues (Figure 40.4).

- **Skeletal muscles** (so named because they mostly attach to bones) are responsible for locomotion and other body movements such as facial expressions, shivering, and breathing.
- **Cardiac muscle** makes up the heart and is responsible for the beating of the heart and the pumping of blood. Individual cardiac muscle cells are branched, and the interweaving of these branches gives heart muscle structural strength.
- **Smooth muscle** is responsible for involuntary generation of forces in many hollow internal organs such as the gut, bladder, and blood vessels.

Skeletal muscles are under both voluntary and involuntary control, as will be described in detail in Section 48.1. Cardiac and smooth muscles are under involuntary control; they are controlled by physiological regulatory systems.

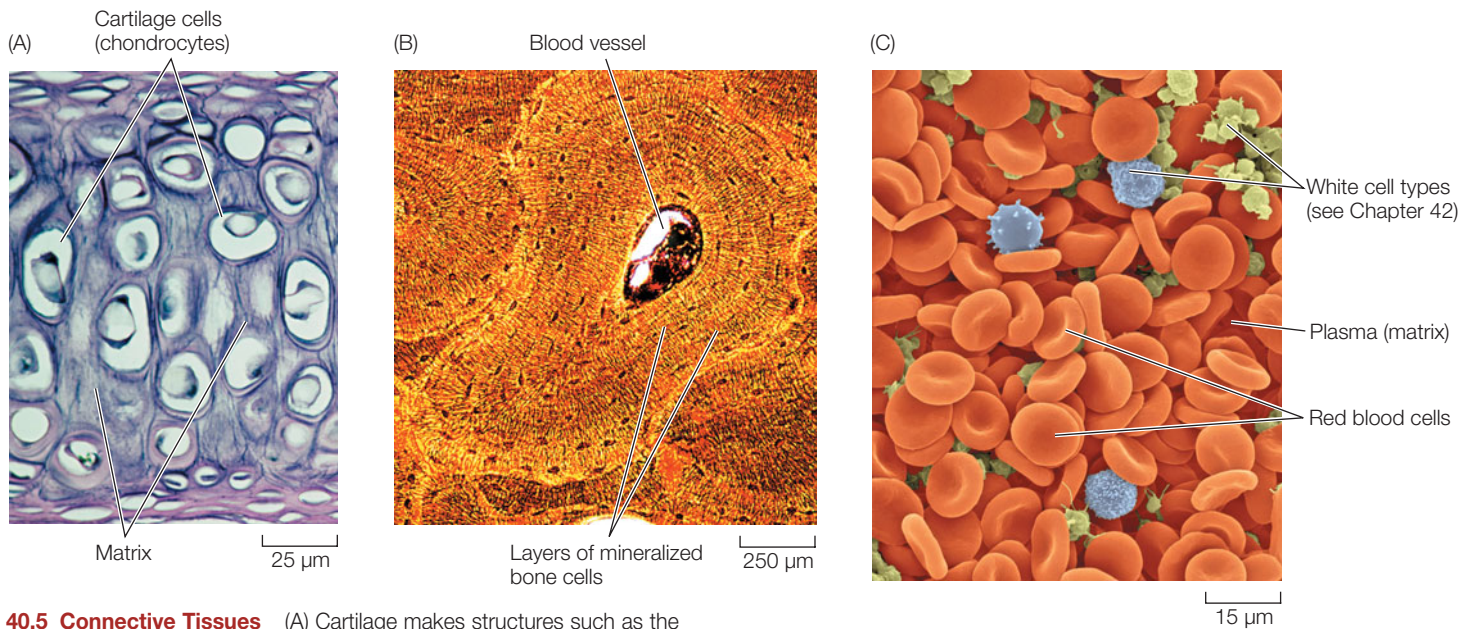

CONNECTIVE TISSUES In contrast to densely packed epithelial and muscle tissues, **connective tissues** are generally dispersed populations of cells embedded in an *extracellular matrix* that they secrete (Figure 40.5). The composition and properties of the matrix differ among types of connective tissues.

Protein fibers are an important component of the extracellular matrix of connective tissue cells. The dominant protein in the extracellular matrix is *collagen* (see Figure 5.25), which makes up about 25 percent of total body protein. Collagen fibers are strong and resistant to stretch, giving strength to the skin and to the connections between bones and between bones and muscles. The fibers provide a netlike framework for organs, giving them shape and structural strength.

Elastin is another type of protein fiber in the extracellular matrix of connective tissues. It is so named because it can be stretched to several times its resting length and then recoil. Fibers composed of elastin are most abundant in tissues that are regularly stretched, such as the walls of the lungs and the large arteries.

Cartilage and bone are connective tissues that provide rigid structural support. In *cartilage*, a network of collagen fibers is embedded in a flexible matrix consisting of a protein-carbohydrate complex, along with a specific type of cell called a *chondrocyte*. Cartilage, which lines the joints of vertebrates, is resistant to compressive forces. Since it is flexible, it provides structural support for flexible structures such as external ears and noses. The extracellular matrix in *bone* also contains many collagen fibers, but it is hardened by the deposition of the mineral calcium phosphate. We discuss cartilage and bone in greater detail in Section 48.3.

40.4 Muscle Cells Contain Protein Filaments The filaments of two specific proteins—actin and myosin—interact to cause contraction and generate force in muscle tissue. (A) The regular arrangement of actin and myosin filaments results in the striated (striped) appearance of skeletal muscle. (B) The individual cells of cardiac muscle are branched and form a strong structural meshwork. (C) The actin and myosin filaments of smooth muscle are not regularly arranged and thus it does not have a striated appearance.

40.5 Connective Tissues (A) Cartilage makes structures such as the ear stiff but flexible. Cartilage cells, or chondrocytes, secrete an extracellular matrix rich in collagen and elastin fibers. In this micrograph, the elastin fibers are stained dark blue. (B) Bone is the mineral-rich connective tissue of the vertebrate skeleton. (C) Blood is unique among the connective tissues, consisting of blood cells floating in an extracellular matrix of plasma.

Adipose cells form loose connective tissue that stores lipids. Adipose tissue, or “fat,” is a major source of stored energy. It also cushions organs, and layers of adipose tissue under the skin can provide a barrier to heat loss.

Blood is a connective tissue consisting of cells dispersed in an extensive liquid extracellular matrix, the blood *plasma*. We present many of the proteins and cellular elements of blood in Section 42.1, and we will discuss blood again in Section 50.4.

NERVOUS TISSUES The two basic cell types in **nervous tissues** are *neurons* and *glial cells* (Figure 40.6). Neurons come in many shapes and sizes, and all neurons encode information as electrical signals. These signals can travel over long extensions called *axons* to communicate with other neurons, muscle cells, or secretory cells through the release of chemicals called *neurotransmitters*. Neurons control the activities of most organ systems. Glial cells do not generate or conduct electrical signals, but they provide a variety of supporting functions for neurons. There are more glial cells than neurons in the nervous system.

Chapters 45, 46, and 47 detail the many fascinating properties of nervous tissues.

Organs consist of multiple tissues

Organs include more than one kind of tissue, and most organs include all four (Figure 40.7). The wall of the gut is a good example. Its inner surface is lined with a sheet of columnar epithelial cells. Different epithelial cells secrete mucus, enzymes, or stomach acid. Beneath the epithelial lining is connective tissue. Within this connective tissue are blood vessels, neurons, and glands (clusters of secretory epithelial

40.6 Nervous Tissue Includes Neurons and Glial Cells (A) This human neuron consists of a cell body, a number of processes that receive input from other neurons, and one long axon that sends information to other cells. (B) A section through human brain tissue shows astrocytes, a type of glial cell. Glial cells provide support and protection for neurons, including creating a barrier that protects the brain from many chemicals circulating in the blood.

40.7 Tissues Form Organs Most organs contain more than one of the four tissue types. The organs of the human digestive system, such as the stomach and small intestine, are made up of all four.

cells). Concentric layers of smooth muscle tissue enable the gut to contract to mix food with digestive juices. A network of neurons between the muscle layers controls these movements.

An individual organ is usually part of an **organ system**—a group of organs that work together to carry out certain functions. The stomach and small intestine, for example, are part of the digestive system. The digestive system is the subject of Chapter 51.

40.1 RECAP

The internal environment provides for the needs of all the cells that make up a complex animal. Organs and organ systems control the composition of the internal environment. The activities of organs and organ systems are regulated to maintain homeostasis of the internal environment.

- Explain the difference between negative and positive feedback control mechanisms. **See pp. 834–835 and Figure 40.2**
- Describe a key function of each of the four kinds of tissue found in animals. **See pp. 835–837 and Figures 40.3–40.7**

Subsequent chapters will describe each of the organ systems mentioned above in much greater detail. The remainder of this chapter focuses on the mechanisms of homeostasis, using one important variable of the internal environment—its temperature—as our example.

40.2 How Does Temperature Affect Living Systems?

Temperatures vary enormously over the face of Earth, from the boiling hot springs of Yellowstone National Park to the interior of Antarctica, where the temperature can fall below -80°C . Cells, however, can function over only a narrow range of temperatures. If cells cool below 0°C , ice crystals form and damage cell structures. Some animals have adaptations, such as antifreeze molecules in their blood, that help them resist freezing; others can survive freezing. Generally, however, cells must remain above 0°C to stay alive.

The upper temperature limit for survival in most cells is about 45°C (although some specialized algae can grow in hot springs at 70°C , and some archaea live at near 100°C). In general, proteins begin to denature and lose their function as temperatures rise above 40°C . Therefore, most cellular functions are limited to the range between 0°C and 40°C , which approximates the thermal limits for life. Each particular species, however, usually has much narrower limits. To stay within those limits in spite of environmental conditions, animals have evolved thermoregulatory adaptations that give them certain thermal tolerances that determine their distribution ranges. When environments change rapidly, as may be happening with global climate warming, animals may find themselves in situations that exceed their thermal tolerances.

Q_{10} is a measure of temperature sensitivity

Even between 0°C and 40°C , changes in tissue temperature create problems for animals. Most physiological processes, like the biochemical reactions that constitute them, are temperature-sensitive, going faster at higher temperatures (see Figure 8.21). The temperature sensitivity of a reaction or process is described in terms of Q_{10} , a factor calculated by dividing the rate of a process or reaction at a certain temperature, R_T , by that rate at a temperature 10°C lower, R_{T-10} :

$$Q_{10} = \frac{R_T}{R_{T-10}}$$

Q_{10} can be measured for a simple enzymatic reaction or for a complex physiological process, such as rate of oxygen consumption. If a reaction or process is not temperature-sensitive, it has a Q_{10} of 1. Most biological Q_{10} values are between 2 and 3. A Q_{10} of 2 means that the reaction rate doubles as temperature increases by 10°C , and a Q_{10} of 3 indicates a tripling of the rate over a 10° temperature range (**Figure 40.8**).

Changes in body temperature can disrupt an animal's physiology because not all of the biochemical reactions that constitute the metabolism of an animal have the same Q_{10} . These biochemical reactions are linked together in complex networks. The products of one reaction are the reactants for other reactions.

Because different reactions have different Q_{10} 's, changes in tissue temperature will shift the rates of some reactions more than others, disrupting the overall network. To maintain homeostasis, organisms must be able to compensate for or prevent changes in body temperature.

Animals acclimatize to seasonal temperatures

The body temperature of some animals (especially aquatic animals) is coupled to environmental temperature. The body temperature of a fish in a pond, for example, will be the same as the water temperature, which might range from 4°C in winter to 24°C in summer. If we bring that fish into the laboratory in the summer and measure its metabolism at different temperatures, we will demonstrate a Q_{10} relationship and can predict what the fish's metabolic rate will be in its pond in the winter. However, if we bring that fish back into the laboratory in the winter and measure its metabolic rate at winter pond temperature, we will find the rate to be much higher than we predicted. The fish's biochemistry and physiology have *acclimatized* to the seasonal change in water temperature so that the fish can remain active at winter temperatures. For example, it may express isozymes with different temperature optima. The ability to acclimatize means that metabolic functions are less sensitive to long-term changes in temperature than to short-term changes.

40.2 RECAP

Cells can survive only within a narrow range of temperatures, but even changes within that range can be disruptive because different physiological processes have different temperature sensitivities.

- Plot a $Q_{10} = 2.5$ curve for a physiological process. **See p. 838 and Figure 40.8**
- Explain how a change in body temperature can disrupt physiological processes. **See pp. 838–839**

40.8 Q_{10} and Reaction Rate The larger the Q_{10} of a reaction or process, the faster its rate rises in response to an increase in temperature.

We have seen how animals are affected by the temperature of their environment. Now let's take a look at the adaptations that allow animals to control and regulate their body temperatures.

40.3 How Do Animals Alter Their Heat Exchange with the Environment?

Many of us learned to think of animals as being either “cold-blooded” or “warm-blooded,” which implies a comparison with our own body temperature and sets mammals and birds apart from other animals. This simple classification breaks down when we realize that mammals that hibernate become cold, and that many reptiles and insects can be quite warm when they are active. Physiologists sometimes classify animals according to whether they have a constant body temperature (homeotherms) or a variable body temperature (poikilotherms). But a deep-sea fish has a constant body temperature. Should it be classified with mammals?

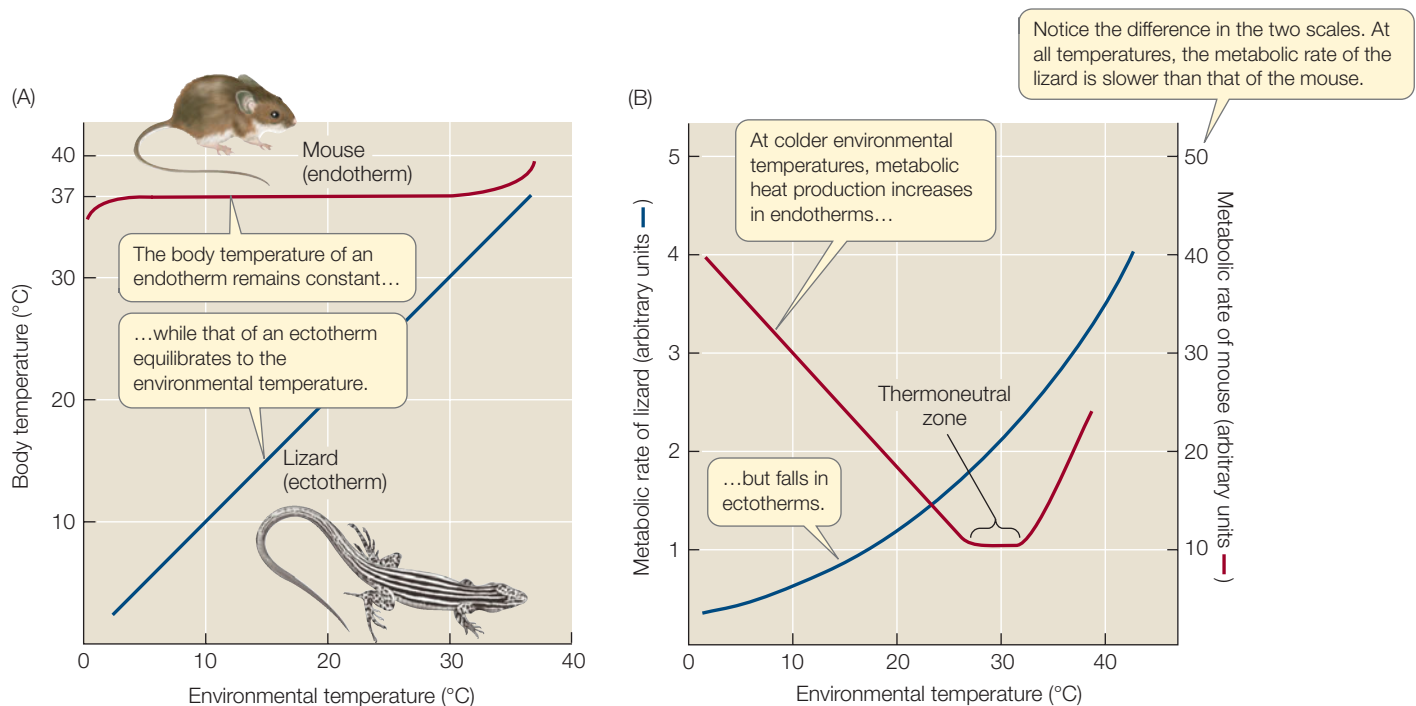

A thermal classification system that avoids such irrational results is one based on the source of heat that predominantly determines the temperature of the animal. **Ectotherms** are animals whose body temperatures are determined primarily by external sources of heat. **Endotherms** regulate their body temperatures by producing heat metabolically or by using active mechanisms of heat loss.

Mammals and birds are endotherms most of the time; other animals are ectotherms most of the time. Like the homeotherm/poikilotherm classification, the endotherm/ectotherm scheme is not perfect. Therefore we have a third category; a **heterotherm** is an animal that behaves sometimes as an endotherm and other times as an ectotherm. For example, a mammal that hibernates is a perfect endotherm over the summer, but during the winter it has bouts of hibernation during which its internal heat production falls and it behaves much like an ectotherm. At times some ectotherms can produce internal heat and act like endotherms.

Endotherms produce heat metabolically

Section 8.1 described how transfers of energy in biological systems are always inefficient. With every transfer of energy—from food molecules to ATP, from ATP to biological work—some of the energy is lost as heat. This is true for both ectotherms and endotherms, so why do endotherms produce more heat? The answer is that the cells of endotherms are less efficient at using energy than are the cells of ectotherms.

In a resting endotherm, most of the energy expended goes into pumping ions across membranes. K^+ is the dominant positive ion inside cells, and Na^+ is the dominant positive ion outside cells. To the extent that cell membranes permit, these ions diffuse down their concentration gradients. To maintain their proper concentrations inside and outside cells, the ions must be transported back “uphill,” which requires expending energy.

While this is true for both ectotherms and endotherms, the cells of endotherms tend to be more “leaky” to ions than are those of ectotherms. Thus endotherms must expend more energy (and thus release more heat) than do ectotherms to maintain ion concentration gradients. This is akin to running on a treadmill: the faster the treadmill goes (analogous to leaking ions), the faster you have to run (analogous to pumping ions) to remain in the same position.

We can speculate that a mutation allowing seemingly faulty or leaky ion channels may have led to the evolution of endothermy. Such a mutation in a small ectotherm may have promoted sufficient heat production to allow this ectotherm to remain active for a longer time after the sun went down. Thus, for the first endotherms an entirely new nocturnal world of ecological opportunities opened, one in which there was less competition from similar-sized ectotherms. Major differences between endotherms and ectotherms are their resting metabolic rates—the sum total of all energy expenditures in their bodies when at rest—and their responses to changes in environmental temperature.

Ectotherms and endotherms respond differently to changes in temperature

Let’s compare how two similar-sized animals, a lizard (an ectotherm) and a mouse (an endotherm) respond to changes in temperature. We put each animal in a closed chamber and measure its body temperature and metabolic rate as we change the temperature of the chamber from 37°C to 0°C.

The body temperature of the lizard equilibrates with that of the chamber, whereas the body temperature of the mouse remains stable (Figure 40.9A). The metabolic rate of the lizard (already much lower than that of the mouse) decreases as the temperature is lowered (Figure 40.9B). In contrast, the mouse’s

40.9 Ectotherms and Endotherms React Differently to Environmental Temperatures

(A) At the same environmental temperature, an ectotherm and an endotherm of approximately the same body size (here, a lizard and a mouse) have different body temperatures. (B) The metabolic rates of the lizard and mouse react in opposite manners to cooler temperatures. (The mouse’s metabolic rate rises again at higher temperatures because, after a certain point, it takes metabolic energy to dissipate heat by sweating or panting.)

metabolic rate increases as the chamber temperature falls below 25°C. The increase in the mouse’s metabolism produces enough heat to prevent its body temperature from falling. In other words, the mouse can regulate its body temperature by increasing its metabolic rate; the lizard cannot.

This experiment might lead us to conclude that the ectotherm cannot regulate its body temperature, but observations of the lizard in nature do not support this conclusion. In nature, unlike in the laboratory, the lizard’s body temperature is sometimes considerably different than the environmental temperature. The desert habitat where the lizard lives can fluctuate by 40°C in a few hours. During its daily activities, however, the lizard maintains a fairly stable body temperature by using behavior to alter its heat exchange with the environment (Figure 40.10A). Its behavioral strategies include spending time in a burrow, basking in the sun, seeking shade, climbing vegetation, and changing its orientation with respect to the sun. While the lizard can regulate its body temperature quite well, it does so by behavioral mechanisms rather than by altering its internal metabolic heat production.

Behavioral thermoregulation is not the exclusive domain of ectotherms (Figure 40.10B). Endotherms usually select the most comfortable thermal environment possible. They may change posture, orient to the sun, move between sun and shade, and move between still air and moving air, the same as the ectotherm in our field experiment. Examples of more complex

(B) *Loxodonta africana*(C) *Maccaca fuscata*

40.10 Using Behavior to Regulate Body Temperature (A) The body temperature of a lizard (an ectotherm) depends on environmental heat, but the lizard can regulate its temperature by moving from place to place within its environment. (B) When air temperatures on the African savanna soar, an elephant (an endotherm) may thermoregulate by showering itself with water. (C) Japanese macaques are social primates and will huddle together for warmth.

thermoregulatory behaviors include nest construction and social behaviors such as huddling. Humans put on or remove clothing and burn fossil fuels to generate the energy to heat or cool buildings.

Energy budgets reflect adaptations for regulating body temperature

Both ectotherms and endotherms can influence their body temperatures by altering four avenues of heat exchange between their bodies and the environment (**Figure 40.11**):

- **Radiation:** Heat transfers from warmer objects to cooler ones via the exchange of infrared radiation (what you feel when you stand in front of a fire).
- **Convection:** Heat transfers to a surrounding medium such as air or water as that medium flows over a surface (the wind-chill factor).
- **Conduction:** Heat transfers directly when objects of two different temperatures come into contact (think of putting an icepack on a sprained ankle).
- **Evaporation:** Heat transfers away from a surface when water evaporates on that surface (the effect of sweating).

40.11 Animals Exchange Heat with the Environment An animal's body temperature is determined by the balance between internal heat production and four avenues of heat exchange with the environment: radiation, convection, conduction, and evaporation.

The total balance of heat production and heat exchange can be expressed as an **energy budget**, based on the simple fact that if the body temperature of an animal is to remain constant, the heat entering the animal must equal the heat leaving it. The heat coming in usually comes from metabolism and solar radiation (R_{abs} for radiation absorbed). Heat leaves the body via the four mechanisms listed above: radiation emitted (R_{out}), convection, conduction, and evaporation. The energy budget takes the following form:

$$\underbrace{\text{heat}_{\text{in}}}_{\text{metabolism} + R_{\text{abs}}} = \underbrace{\text{heat}_{\text{out}}}_{R_{\text{out}} + \text{convection} + \text{conduction} + \text{evaporation}}$$

Anyone who has experienced a very hot environment knows that heat can also *enter* the body through convection (e.g., the hot desert wind) and conduction (e.g., a hot car seat). In that case, the values of those factors become negative in the energy budget equation.

The energy budget is a useful concept because any adaptation that influences the ability of an animal to deal with its thermal environment must affect one or more components of the budget. So the energy budget gives us the ability to quantify and compare the thermal adaptations of animals. One interesting observation is that all of the components on the right side of the energy budget equation—that is, the heat-loss side—depend on the surface temperature of the animal. One way surface temperature can be controlled is by altering the flow of blood to the skin.

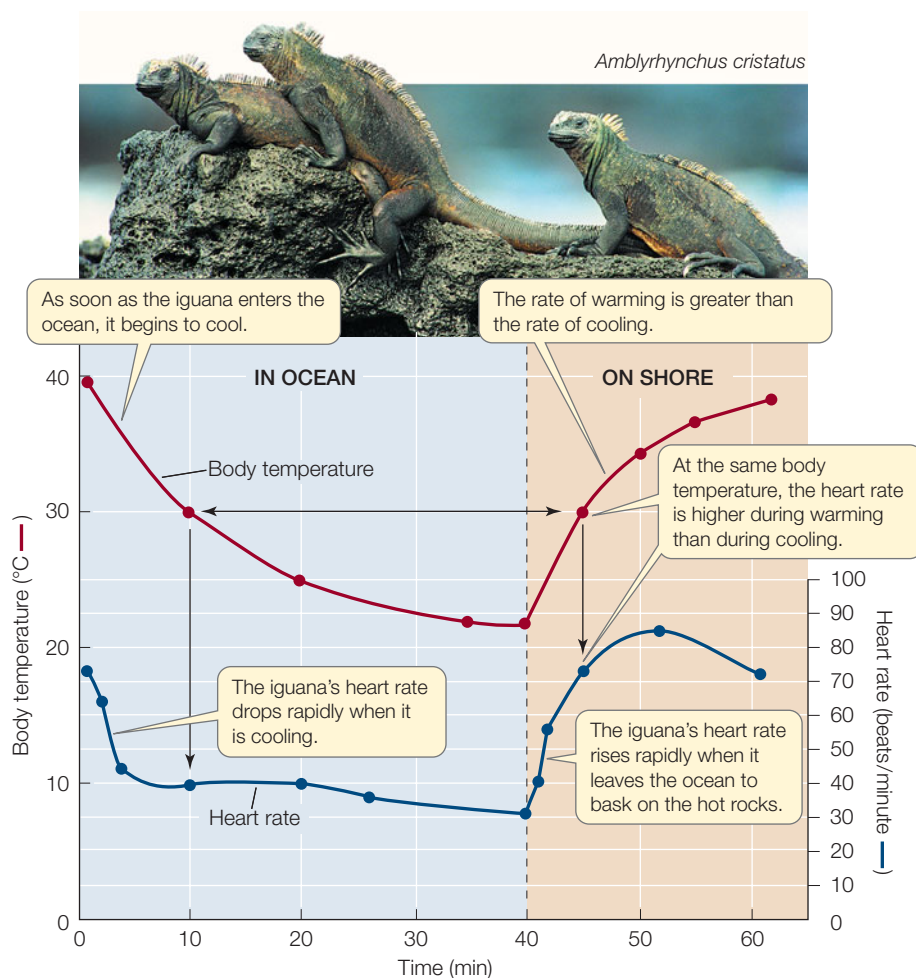

Both ectotherms and endotherms control blood flow to the skin

Heat exchange between the internal environment and the skin occurs largely through blood flow. As described at the beginning of this chapter, when body temperature rises because of exercise, blood flow to the skin increases, and the skin surface becomes warm. The heat that the blood brings from the body core to the skin is lost to the environment through the four avenues listed above, which helps bring the body temperature back to normal. In contrast, when body temperature is too low or the environment is too cold, the blood vessels supplying the skin constrict, reducing heat loss to the environment.

The control of blood flow to the skin can be an important adaptation for an ectotherm such as the marine iguana (a reptile) of the Galápagos archipelago (**Figure 40.12**). The Galápagos are volcanic islands that lie on the equator but are bathed by cold ocean currents. The iguanas bask on hot black lava rocks on the shore, then en-

ter the cold ocean water to feed on seaweed. When the iguanas are feeding, they cool to the temperature of the sea. This cooling lowers their metabolism, making them slower, more vulnerable to predators, and incapable of efficient digestion. They therefore alternate between feeding in the cold sea and basking on the hot rocks. It is advantageous for iguanas to retain body heat as long as possible while swimming and to warm up as fast as possible when basking. They can accomplish these changes in heat transfer rates by changing their heart rate and the rate of blood flow to their skin.

What about furred mammals? Fur acts as *insulation* to keep body heat in, making it possible for mammals to live in very cold climates. When they are active, however, mammals still must get rid of excess heat, and it does little good to transport that heat to the skin under the fur. Thus, as mentioned at the beginning of this chapter, mammals have special blood vessels for transporting heat to their hairless skin surfaces. Heat loss from these areas of skin is tightly controlled by the opening and closing of these special blood vessels. When you are cold, the blood flow to your hands and feet decreases and they can feel very cold, but when you exercise, these same surfaces can get very hot quickly.

40.12 Some Ectotherms Regulate Blood Flow to the Skin Galápagos marine iguanas control blood flow to the skin to alter their heating and cooling rates.

(A) “Cold” fish

(B) “Hot” fish

40.13 “Cold” and “Hot” Fishes (A) Most fish species are “cold” fish. Their circulatory systems conduct cool, oxygenated blood from the gills through a large dorsal aorta to the rest of the body. (B) The anatomy of “hot” fish species includes a mechanism—the countercurrent heat exchanger—that allows heat to pass into cold arterial blood from venous blood that has been warmed by the metabolism of the muscles.

Some fishes elevate body temperature by conserving metabolic heat

Active fishes can produce substantial amounts of metabolic heat, but they have difficulty retaining any of that heat. Blood pumped from the heart goes directly to the gills, where it comes very close to the surrounding water to exchange respiratory gases. So any heat that the blood picks up from metabolically active muscles is lost to the surrounding water as it flows through the gills. It is thus surprising that some large, rapidly swimming fishes, such as bluefin tuna and great white sharks, can maintain temperature differences as great as 10° to 15°C between their bodies and the surrounding water. The heat comes from their powerful swimming muscles, and the ability of these “hot” fishes to conserve that heat is based on the remarkable arrangements of their blood vessels.

In the usual (“cold”) fish circulatory system, oxygenated blood from the gills collects in a large dorsal vessel, the aorta, which travels through the center of the fish, distributing blood to all organs and muscles (**Figure 40.13A**). “Hot” fishes have a smaller central dorsal aorta, and most of their oxygenated blood is transported in large vessels just under the skin (**Figure 40.13B**). The cold blood from the gills is thus kept close to the surface of the fish. Smaller vessels transporting this cold blood into the muscle mass run parallel to vessels transporting warm blood from the muscle mass back toward the heart. Since the vessels carrying the cold blood into the muscle are in close contact with the vessels carrying warm blood away, heat flows from the warm to the cold blood by conduction and is therefore retained in the muscle mass.

Because heat is exchanged between blood vessels carrying blood in opposite directions, this adaptation is called a **countercurrent heat exchanger**. It keeps the heat within the muscle

mass, enabling these fishes to have an internal body temperature considerably higher than the water temperature. Why is it advantageous for the fish to be warm? Each 10°C rise in muscle temperature increases the fish’s sustainable power output almost threefold, giving it a faster foraging capability!

Some ectotherms regulate heat production

Some ectotherms raise their body temperature by producing heat. For example, the powerful flight muscles of many insects must reach 35° to 40°C before the insects can fly, and they must maintain these high temperatures during flight. Such insects produce the required heat by contracting their flight muscles in a manner analogous to shivering in mammals. The heat-producing ability of insects can be quite remarkable. Probably the most impressive case is a species of scarab beetle that lives mostly underground in mountains north of Los Angeles, California. To mate, these beetles come aboveground, and males fly in search of females. They undertake this mating ritual at night, in winter, and only during snowstorms.

Honey bees regulate temperature as a group. They live in large colonies consisting mostly of female worker bees that maintain the hive and rear the larval offspring of the single queen bee. During winter, worker bees cluster around the brood of larvae. They adjust their individual metabolic heat production and density of clustering so that the brood temperature remains remarkably constant, at about 34°C, even as the outside air temperature drops below freezing (**Figure 40.14**).

40.14 Bees Keep Warm in Winter Honey bee colonies survive winter cold because workers generate metabolic heat. In this infrared photograph of the center of an overwintering hive, individual bees are discernible by the heat their bodies produce as they cluster around their queen.

40.3 RECAP

Animals that metabolically produce their own heat are called **endotherms**. Those that depend on environmental sources of heat are called **ectotherms**. Heat exchange between an animal and its environment occurs via radiation, convection, conduction, and evaporation.

In terms of the energy budget relationship, why is the control of blood flow to the skin so important for thermoregulation? **See p. 842**

Explain how countercurrent heat exchange makes it possible for some fishes to have a body temperature higher than that of the surrounding water. **See p. 843 and Figure 40.13**

Endotherms must keep their body temperatures within a critical physiological range. Let's look more closely at the evolutionary adaptations that enable endothermic mammals to maintain this optimal temperature range.

40.4 How Do Mammals Regulate Their Body Temperatures?

As we saw in Figure 40.9, endotherms can respond to changes in environmental temperature by changing their metabolic rate. Physiologists determine metabolic rate by measuring the rate at which an animal consumes O_2 and produces CO_2 . Within a narrow range of environmental temperatures, called the **ther-**

moneutral zone (see Figure 40.9B), the metabolic rate of endotherms is low and independent of temperature. The metabolic rate of a resting animal at a temperature within the thermoneutral zone is known as the **basal metabolic rate**, or **BMR**. It is usually measured in animals that are quiet but awake and not using energy for digestion, reproduction, or growth. Thus the BMR is the rate at which a resting animal is consuming just enough energy to carry out its minimal body functions.

Basal metabolic rates are correlated with body size and environmental temperature

As you might expect, the BMR of an elephant is greater than that of a mouse. After all, the elephant is more than 100,000 times larger than the mouse. However, the BMR of the elephant is only about 7,000 times greater than that of the mouse. That means that a gram of mouse tissue uses energy at a rate 15 times greater than a gram of elephant tissue (**Figure 40.15**). Across all of the endotherms, BMR per gram of tissue increases as animals get smaller.

Why should this disproportionate difference exist? We don't know for sure. As animals get bigger, they have a smaller ratio of surface area to volume (see Figure 5.2). Since heat production is related to the volume, or mass, of the animal, but its capacity to dissipate heat is related to its surface area, it was once reasoned that larger animals evolved lower metabolic rates to avoid overheating. This explanation is insufficient because the relationship between body mass and metabolic rate holds for even very small organisms and for ectotherms, in which overheating is not a problem. Other hypotheses have also been advanced. For example, a larger animal has a greater proportion of support tissue (skin, bone), which is not as metabolically active. The real answer is probably a mixture of different causative factors.

In an endotherm, the metabolic rate versus environmental temperature curve represents the integrated response of all of the animal's thermoregulatory adaptations (**Figure 40.16**). The

40.15 The Mouse-to-Elephant Curve On a weight-specific basis, the metabolic rate of small endotherms is much greater than that of larger endotherms. This graph plots O_2 consumption per kilogram of body mass (a measure of metabolic rate) against a logarithmic plot of body mass.

40.16 Environmental Temperature and Mammalian Metabolic Rates

Outside the thermoneutral zone, maintaining a constant body temperature requires expending energy. Outside extreme limits (0°C and 40°C in this instance), the animal cannot maintain its body temperature and dies.

thermoneutral zone is bounded by a *lower* and an *upper critical temperature*. Within its thermoneutral zone, an endotherm's thermoregulatory adaptations do not require much energy and could be considered passive; such adaptations include changing posture, fluffing fur, and controlling blood flow to the skin. Outside its thermoneutral zone, however, an endotherm's thermoregulatory responses are active and require considerable metabolic energy, as shown on the left side of Figure 40.16.

—yourBioPortal.com—

GO TO Web Activity 40.1 • Thermoregulation in an Endotherm

Endotherms respond to cold by producing heat and adapt to cold by reducing heat loss

When environmental temperatures fall below the lower critical temperature, endotherms must produce heat to compensate for the heat they lose to the environment. Mammals can accomplish this in two ways: shivering and nonshivering heat production. Birds use only shivering heat production.

Shivering uses the contractile machinery of skeletal muscles to consume ATP without causing large movements. Shivering muscles pull against each other so that little movement other than a tremor results. The energy from the conversion of ATP to ADP in this process is released as heat. "Shivering heat production" is perhaps too narrow a term, however; increased mus-

40.17 Brown Fat In many mammals, specialized brown fat tissue produces heat. When looking through a microscope at similar magnifications, we see that white fat cells (left) contain large droplets of lipid but have few organelles and limited blood supply, whereas brown fat cells (right) are packed with mitochondria and richly supplied with blood.

cle tone and increased body movements also contribute to increased heat production in cold environments.

Most *nonshivering heat production* occurs in a specialized adipose tissue called **brown fat** (Figure 40.17). This tissue looks brown because of its abundant mitochondria and rich blood supply. In brown fat cells, a protein called *thermogenin* uncouples proton movement from ATP production, allowing protons to leak across the inner mitochondrial membrane rather than having to pass through the ATP synthase and generate ATP (review the discussion of the chemiosmotic mechanism and Figure 9.9). As a result, metabolic fuels are consumed without producing ATP, but heat is still released. Brown fat is abundant in newborns of many mammalian species (including humans), in some adult mammals that are small and acclimatized to cold, and in mammals that hibernate.

In spite of their ability to produce heat, endotherms in cold climates have evolved adaptations to reduce their heat loss and therefore remain within their thermoneutral zones as much as possible. Heat is lost from the body surface, and cold-climate species have anatomical adaptations that give them smaller surface-to-volume ratios than their warm-climate relatives. These adaptations include rounder body shapes and shorter appendages (Figure 40.18).

The most significant means of decreasing heat loss is to increase thermal insulation. Animals adapted to cold climates have much thicker layers of fur, feathers, or fat than do their warm-climate relatives. Fur and feathers are good insulators because they trap a layer of still, warm air close to the skin surface. If that air is displaced by water, insulation is drastically reduced. In many species, oil secretions spread through fur or

(A) *Lepus alleni*

40.18 Adaptations to Hot and Cold Climates (A) The antelope jackrabbit is found in the Sonoran Desert of Arizona. Its large ears serve as heat exchangers, passing heat from the animal's blood to the surrounding air. (B) The thick fur of the Arctic hare provides insulation in the frigid winter. This species' ears and extremities are smaller than those of the jackrabbit.

(B) *Lepus arcticus*

feathers by grooming are critical for resisting wetting and maintaining a high level of insulation.

Decreasing blood flow to the skin is an important thermoregulatory adaptation in the cold. Constriction of blood vessels in the skin, and especially in the appendages, greatly improves an animal's ability to conserve heat. Countercurrent heat exchange like we saw in the "hot" fishes is also an important adaptation in the appendages of endotherms. Blood flowing out to the paw of a wolf, the hoof of a caribou, or the foot of a bird parallels the flow of the blood returning. Heat is transferred from the outgoing to the returning blood, thus retaining heat in the animal's core.

Evaporation of water can dissipate heat, but at a cost

As environmental temperature rises within an endotherm's thermoneutral zone, the animal dissipates more of its metabolic heat by increasing blood flow to the skin. When the temperature exceeds the upper critical temperature, however, overheating becomes a problem. For an exercising animal, overheating can occur even at low environmental temperatures. Large mammals, especially those in hot habitats such as elephants, rhinoceroses, and water buffaloes, have little or no insulating fur and seek out water to wallow in when the air temperature is high (see Figure 40.10B). Having water in contact with the skin greatly increases heat loss because the heat-absorbing capacity of water is much greater than that of air.

Evaporation from external or internal body surfaces through sweating or panting can also cool an endotherm. A gram of water absorbs about 580 calories of heat when it evaporates. If this evaporation occurs on the skin, most of that heat is absorbed

from the skin and the underlying blood. Sweat and saliva that fall off of the body, however, provide no cooling. Thus when the need for heat loss is greatest, water from the internal environment can be squandered with no cooling benefit. Water is heavy, so animals do not carry an excess supply of it, and many hot environments are also arid. In habitats that are both hot and dry, sweating and panting are cooling adaptations of last resort.

Sweating and panting are *active* processes that require expending metabolic energy. That is why the metabolic rate increases when the upper critical temperature is exceeded (see Figure 40.16). A sweating or panting animal is generating heat in the process of dissipating heat, which can be a losing battle.

The mammalian thermostat uses feedback information

The thermoregulatory mechanisms and adaptations we have just discussed work through a regulatory system that integrates information from environmental and physiological sources and then issues commands that control body temperature. Such a regulatory system is based on feedback information, and can be thought of as a thermostat like the one in your home.

The major thermoregulatory integrative center of mammals is at the bottom of the brain in a structure called the **hypothalamus**. If you slide your tongue back as far as possible along the roof of your mouth, it will be just a few centimeters below your hypothalamus. The hypothalamus is a key part of many regulatory systems, including thermoregulation in all vertebrates.

In many vertebrates and all mammals, the temperature of the hypothalamus itself is the major negative feedback signal, and damage to the hypothalamus can disrupt thermoregulation. The hypothalamus generates a set point like a setting on a home thermostat. When the temperature of the hypothalamus exceeds or drops below that set point, thermoregulatory responses (the controlled system) are activated to reverse the direction of temperature change.

In mammals, experiments show that directly cooling the hypothalamus increases metabolic heat production and stimulates constriction of the blood vessels that supply the skin, thus causing body temperature to rise. Conversely, mild warming of the hypothalamus stimulates dilation of the blood vessels, while stronger hypothalamic heating stimulates sweating or panting. Consequently, heating the hypothalamus causes the overall body temperature to fall (Figure 40.19).

The mammalian thermoregulatory system has adjustable set points and integrates sources of information in addition to hypothalamic temperature. For example, temperature sensors in the skin register environmental temperature; change in skin tem-

INVESTIGATING LIFE

40.19 The Hypothalamus Regulates Body Temperature

In this laboratory experiment, a mammal's hypothalamus was subjected directly to temperature manipulation. The body's responses to the experimenters' manipulations were as expected if the hypothalamus is indeed the mammalian "thermostat."

HYPOTHESIS Heating or cooling the mammalian hypothalamus results in corresponding and predictable changes in body temperature.

METHOD 1. Implant a probe that directly heats or cools the hypothalamus.

2. Manipulate the hypothalamic temperature.

3. Measure the animal's metabolic rate and body temperature throughout the period of hypothalamic manipulation.

RESULTS

1 When the hypothalamus was cooled, metabolic heat production increased...

3 When the hypothalamus was heated, the squirrel's metabolic rate fell...

2 ...and the animal's body temperature rose.

4 ...as did its body temperature.

CONCLUSION The ground squirrel's hypothalamus acts as a thermostat. When cooled it activates metabolic heat production; when warmed, it suppresses metabolic heat production and favors heat loss.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

perature is feedforward information that shifts the hypothalamic set point for thermoregulatory responses. The set point for metabolic heat production is higher when skin is cold and lower when skin is warm.

Hypothalamic set points are higher during wakefulness than during sleep, and they are higher during the active part of the daily cycle than during the inactive part, even if the animal is awake at both times. Even when an endotherm is kept under constant environmental conditions, its body temperature displays a daily cycle of changes in set point. This kind of cycle is controlled by an internal *circadian rhythm*; we discuss these endogenous bodily rhythms in Chapter 54.

Fever helps the body fight infections

Fever is an adaptive response that helps the body fight pathogens. A fever is a rise in body temperature in response to molecules called **pyrogens**. *Exogenous pyrogens* come from foreign substances such as bacteria or viruses that invade the body. *Endogenous pyrogens* are produced by cells of the immune system in response to infection.

The presence of a pyrogen in the body causes a rise in the hypothalamic set point for the metabolic heat production response. As a result, you shiver, put on a sweater, or crawl under a blanket, and your body temperature rises until it matches the new set point. At the higher body temperature you no longer feel cold, and you may not feel hot, but someone touching your forehead will say that you are "burning up." Taking aspirin lowers your set point to normal. Now you feel hot, take off clothes, and even sweat until your elevated body temperature returns to normal. Although modest fevers help the body fight infections, extreme fevers can be dangerous and must be controlled, usually with fever-reducing drugs.

Turning down the thermostat

Hypothermia is a below-normal body temperature. It can result from starvation (lack of metabolic fuel), exposure to extreme cold, serious illness, or anesthesia. In each of these cases, the drop in body temperature is unregulated. However, many birds and mammals undergo regulated drops in body temperature to survive periods of cold and food scarcity, an adaptation known as *regulated hypothermia*.

Hummingbirds, for example, are very small endotherms with a high metabolic rate. Just getting through a single day without food could exhaust their metabolic reserves. Hummingbirds and other small endotherms can extend the pe-

40.20 Repeated Bouts of Hibernation At the beginning of each bout of its winter hibernation, the ground squirrel's metabolic rate and body temperature fall. Its body temperature may come into equilibrium with the temperature of its nest and stay at that level for days. The bout is ended by a rise in metabolic heat production that returns body temperature to a normal level.

riod over which they can survive without food by dropping their body temperature during the portion of day or night when they are normally inactive. This adaptive hypothermia is called **daily torpor**. Body temperature can drop 10° to 20°C during daily torpor, lowering metabolic rate and saving energy.

Regulated hypothermia that lasts for days or even weeks, with body temperature falling close to the ambient temperature, is called **hibernation** (Figure 40.20). Many species of mammals, including bats, bears, and ground squirrels, hibernate, but only one species of bird (the poorwill) has been shown to hibernate. The metabolic rate needed to sustain a hibernating animal may be only one-fiftieth its basal metabolic rate, and many animals maintain body temperatures close to the freezing point. Arousal from hibernation occurs when the hypothalamic set point returns to the normal level for a mammal.

The ability of hibernators to reduce their thermoregulatory set point so dramatically probably evolved as an extension of the set point decrease that accompanies sleep even in nonhibernating species of mammals and birds.

40.4 RECAP

Within the thermoneutral zone, an endotherm controls its body temperature by altering insulation and blood flow to the skin. When the temperature drops below the thermoneutral zone, the animal increases metabolic heat production. Above this zone, it dissipates heat by panting or sweating.

- Describe how endotherms produce heat. How does heat production change with body size? **See p. 844 and Figure 40.15**
- Why is dependence on evaporative water loss a dangerous strategy for dealing with hot environments? **See p. 846**
- What is the nature of negative feedback information and feedforward information used by the mammalian thermostat? **See pp. 847–848 and Figure 40.19**

CHAPTER SUMMARY

40.1 How Do Multicellular Animals Supply the Needs of Their Cells?

- Multicellular animals provide for the needs of all their cells by maintaining a stable **internal environment**, which consists of the two types of extracellular fluid: the interstitial fluid, and the plasma of blood. **Review Figure 40.1**
- The regulation of physiological systems is mostly through **negative feedback**. **Feedforward information** functions to change **set points**. **Review Figure 40.2**
- The four types of **tissues** are assemblages of cells. **Epithelial tissues** provide barriers and have secretory and transport func-

tions. The three types of **muscle tissue** (skeletal, cardiac, and smooth muscle) are able to contract and are the source both voluntary and involuntary movement. **Connective tissues**, including cartilage, bone, adipose tissue, and blood, are supportive tissues made up of cells embedded in an extracellular matrix. **Nervous tissues** process and communicate information; they contain two cell types, neurons and glial cells.

Organs are made up of tissues, and most organs contain all four kinds of tissue. Organs are grouped into **organ systems**. **Review Figure 40.7**

40.2 How Does Temperature Affect Living Systems?

- Life is sustained within a narrow range of environmental temperatures. Q_{10} is a measure of the sensitivity of a life process to temperature. A Q_{10} of 2 means that the reaction rate doubles as temperature increases by 10°C. **Review Figure 40.8**
- Animals can acclimatize to seasonal changes in temperature through biochemical and physiological adaptations.

40.3 How Do Animals Alter Their Heat Exchange with the Environment?

- **Endotherms** can produce considerable metabolic heat to compensate for heat loss to the environment. **Ectotherms** generally do not. **Review Figure 40.9**
- **Energy budgets** describe all pathways for heat exchange between an organism and its environment. The four avenues of

heat exchange are **radiation, convection, conduction, and evaporation**. **Review Figure 40.11**

- Skin temperature is an important variable, and it can be influenced by blood flow. Circulatory system adaptations such as **countercurrent heat exchange** can conserve metabolic heat. **Review Figures 40.12 and 40.13**

40.4 How Do Mammals Regulate Their Body Temperatures?

- Within the **thermoneutral zone**, mammals have a **basal metabolic rate** (BMR) that scales with body size. **Review Figures 40.15 and 40.16, WEB ACTIVITY 40.1**
- In mammals, control of thermoregulatory effectors relies on commands from a regulatory center in the **hypothalamus**. This thermostat uses its own temperature as a major negative feedback signal, and skin temperature as a feedforward signal. **Review Figure 40.19, ANIMATED TUTORIAL 40.1**

SELF-QUIZ

- Which of the following characterizes the protein elastin?
 - It functions predominantly in muscle tissue to resist excess stretching.
 - It is found predominantly in epithelial tissue.
 - It is found in the extracellular matrix of connective tissue.
 - It is the most abundant protein in the body.
 - It is responsible for the elasticity of the long extensions of neurons.
- If the Q_{10} of the metabolic rate of an animal is 2, then
 - the animal is better acclimatized to a cold environment than if its Q_{10} is 3.
 - the animal is an ectotherm.
 - the animal consumes half as much oxygen per hour at 20°C as it does at 30°C.
 - the animal's metabolic rate is not at basal levels.
 - the animal produces twice as much heat at 20°C as it does at 30°C.
- Which statement about brown fat is true?
 - It produces heat without producing ATP.
 - It insulates animals acclimatized to cold.
 - It is a major source of heat production for birds.
 - It is found only in hibernators.
 - It provides fuel for muscle cells.
- Which of the following is the most important and most general characteristic of endotherms adapted to cold climates compared with those adapted to warm climates?
 - Higher basal metabolic rates
 - Higher Q_{10} values
 - Brown fat
 - Greater insulation
 - Ability to hibernate
- Which of the following would cause a decrease in the hypothalamic temperature set point for metabolic heat production?
 - Entering a cold environment
 - Taking an aspirin when you have a fever
 - Arousing from hibernation
 - Getting an infection that causes a fever
 - Cooling the hypothalamus
- Mammalian hibernation
 - occurs when animals run out of metabolic fuel.
 - is a regulated decrease in body temperature.
 - is less common than hibernation in birds.
 - can occur at any time of year.
 - lasts for several months, during which body temperature remains close to the environmental temperature.
- Which of the following is an important difference between an ectotherm and an endotherm of similar body size?
 - An ectotherm has higher Q_{10} values.
 - Only an ectotherm uses behavioral thermoregulation.
 - Only an endotherm can constrict and dilate the blood vessels to the skin to alter heat flow.
 - Only an endotherm can have a fever.
 - At a body temperature of 37°C, an ectotherm has a lower metabolic rate than an endotherm.
- How would you describe the role of skin temperature in the human thermoregulatory system?
 - It provides feedforward information.
 - It acts as a set point for metabolic heat production.
 - It provides positive feedback information.
 - It provides an error signal.
 - It provides negative feedback information.
- What is the biggest difference between a "cold" fish such as a trout and a "hot" fish such as a tuna?
 - The temperature of the blood leaving the heart
 - The temperature of the blood entering the gills
 - The arrangement of blood vessels in the gills
 - The temperature of the brain
 - The volume of blood flowing in arteries just under the skin
- Which of the following statements about the thermoneutral zone is true?
 - Metabolic heat production is variable.
 - Skin blood flow is variable.
 - The environmental temperature equals body temperature.
 - The lower boundary (lower critical temperature) is lower for small than for large endotherms.
 - It is the range of hypothalamic temperatures that do not alter metabolic heat production.

FOR DISCUSSION

1. What is the advantage of feedforward information for homeostasis? Can you suggest what some sources of feedforward information could be for regulation of breathing, blood pressure, secretion of digestive juices, and elimination of wastes?
2. In some epithelial tissues there are “tight junctions” between the individual cells that prevent anything from passing between them (see Figure 6.7); in other cases the junctions between epithelial cells are quite loose. What are the possible advantages in different organs of loose versus tight junctions between epithelial cells? Give some examples in which these differences would be important.
3. Newton’s law of cooling describes how a physical object comes into thermal equilibrium with its environment. The law is expressed

$$HL = K(T_o - T_a)$$

HL is the rate of heat loss, *K* is the thermal conductance constant (how easily an object loses heat), *T_o* is the temper-

ature of the object, and *T_a* is the ambient temperature. Compare this expression with the metabolic rate/temperature curve for endotherms. In Newton’s law of cooling, *K* is a constant reflecting the properties of the object. What would *K* represent for an endotherm? Using a version of Newton’s law that replaces *T_o* with *T_b* (body temperature), explain why the metabolic rate curve projects to zero at an ambient temperature that equals body temperature.

4. The range of temperatures compatible with life is about 0°C to 40°C. Endotherms have regulated body temperatures much closer to the upper limit of this range than to the lower. What are the advantages of living so close to the upper limit?
5. Discuss what it means when we say that the metabolic rate of mammals scales to the $\frac{3}{4}$ power of body mass. In contrast, heart size of mammals scales according to the first power of body mass. What does this difference imply for the functions of the hearts of mammals of different sizes?

ADDITIONAL INVESTIGATION

1. The text described the drop in body temperature of a hibernator as regulated hypothermia—a turning down of the thermostat. Yet we also saw that if we put an ectotherm in a cold environment, its body temperature will fall. What experiment could you do to prove that the mammalian hibernator did not just simply turn off or inactivate its thermoregulatory system in order to behave like an ectotherm in the cold?
2. The observations on the Galápagos marine iguana showed that its body temperature rose faster in air than it fell in water. The inference was that the iguana was influencing its gain or loss of heat by altering the blood flow to its skin. However, the thermal properties of air and water are different, and in the case described in the text, the animal was breathing when in air but not when diving in the water. What experiment could you do to strengthen the argument that the iguana was actively altering the flow of heat across its skin?

WORKING WITH DATA (GO TO yourBioPortal.com)

A Hibernator’s Thermostat In this exercise based on the experiments outlined in Figure 40.19, you will plot data gathered from hibernating and non-hibernating ground squirrels to graph the relationship between hypothalamic temperature

and metabolic rate. You will then analyze these data and draw conclusions about the role of the hypothalamus in mammalian hibernation.

41

Animal Hormones

Juiced

The use of performance-enhancing drugs—particularly *anabolic steroids*—has become a scandal in athletics. Olympic champions have lost medals, professional athletes have been suspended, coaches have lost their jobs, and exceptional performances have been expunged from the record books. The recent history of baseball in the United States has been termed “the steroid era” because of the huge impact the extensive use of performance-enhancement drugs has had on the game and the controversy this has created. Gains in performance and new records raise the question of whether an aspiring athlete can succeed without using performance-enhancing drugs. The U.S. Congress has passed laws against non-

medical use of steroids, and Major League Baseball has instituted penalties for players who break the law. To date, over 100 Major League players have admitted to or been implicated in the use of steroids, and many have been suspended for up to 80 games.

You have probably heard of one anabolic steroid: testosterone, the male sex hormone. Shortly before puberty, the male reproductive system increases its production of this important chemical signal. Testosterone enters cells, where it binds to receptors and alters gene expression. Cells that have these receptors are those involved in the development of male secondary sexual characteristics, such as a deep voice, facial and body hair, and increased muscle and bone mass. Anabolic steroids are used therapeutically to treat conditions such as delayed puberty, erectile dysfunction, and the loss of muscle mass that occurs with certain diseases.

When a muscle is exercised, an interaction between the exercise and the steroids results in growth of that muscle. Body builders who abuse anabolic steroids typically use them in doses 10 to 100 times greater than normal levels or therapeutic doses. The resulting extreme growth of skeletal muscle mass occurs in women as well as men. Both sexes have receptors for testosterone, but women normally have much lower concentrations of testosterone in their blood than men do. When female body builders use these hormones, they develop male muscle patterns. They also develop deep voices and body and facial hair, and because these steroids generate negative feedback

How Baseball Got Big Jose Canseco was the American League Rookie of the Year in 1986. In 1988, he became the first major league player to hit 40 home runs and steal 40 bases in a season and was named the American League’s Most Valuable Player. In 2005 he wrote a book called *Juiced: Wild Times, Rampant ‘Roids, Smash Hits, and How Baseball Got Big* in which he admitted to using anabolic steroids and implicated many other players.

Anabolic Steroids Build Big Muscles Anabolic steroids greatly enhance the development of skeletal muscle in response to exercise. Steroids have this effect on women as well as men.

information that controls female reproductive physiology, their breast tissue diminishes, they stop menstruating, and they become infertile. Similar negative feedback in males causes infertility. Behavioral changes—“roid rage”—are also common. The most serious side effects, for both men and women, are greatly increased risks of cancer and of heart, liver, and kidney diseases.

Despite the risks, athletes seeking an advantage have frequently turned to anabolic steroids. Athletic governing organizations administer blood and urine tests to detect their use; in their turn, illicit drug makers constantly seek to design new forms of anabolic steroids that produce the desired physical results but are not detectable.

IN THIS CHAPTER we will examine how hormones control and regulate anatomical, developmental, physiological, and behavioral changes in animals. First we examine hormonal control of invertebrate life cycles. Next we discuss the general characteristics of hormones and their receptors. Then we describe the functions, control, and mechanisms of action of mammalian hormones.

CHAPTER OUTLINE

- 41.1** What Are Hormones and How Do They Work?
- 41.2** How Do the Nervous and Endocrine Systems Interact?
- 41.3** What Are the Major Mammalian Endocrine Glands and Hormones?
- 41.4** How Do We Study Mechanisms of Hormone Action?

41.1 What Are Hormones and How Do They Work?

In multicellular animals, physiological control and regulation require information and cell-to-cell communication. Most intercellular communication is by means of chemical signals that bind to receptors, as described in Chapter 7. **Hormones** are chemical signals that are released by certain types of cells and that influence the activities of other cells at a distance. In this and subsequent chapters you will learn about hormones and other examples of chemical signals, including growth factors, morphogens, cytokines, and neurotransmitters. These general names come from the context in which the chemical signal operates—endocrine system, growth and development, immune system, or nervous system—but the principles of their function are the same: one cell releases a chemical signal that travels to and binds to a receptor, causing a cellular response.

The information that animals use to develop, grow, and function comes from four major sources: the genome, the endocrine system, the immune system, and the nervous system. In each of these systems, information is encoded in the specificity of chemical signals and their receptors. In earlier chapters we learned a lot about genetic information. In this and following chapters we discuss the endocrine, immune, and nervous systems. Lest you think that all signaling is chemical, however, keep in mind that there are also receptors in the nervous system that encode physical sources of information, such as temperature, pressure, and light. And the nervous system uses electrical signals called action potentials to get information from place to place in the body. Regardless of the system, the processing of information depends on which cells have receptors for the signals and how those cells respond and interact with other cells.

Some analogies might help distinguish how the immune, endocrine, and nervous informational systems operate. The immune system (the topic of Chapter 42) operates like an army of private security guards. The various cellular agents make their rounds of the body, and when they detect a security breach, they sound their alarms—cytokines—which activate the body’s defenses. The nervous system (see Chapters 45–47) operates like a telephone system with a central integration and command center that sends signals along specific wires to specific receivers. The endocrine system is more like a radio or TV network that broadcasts signals that can be picked up by anyone who has an appropriate receiver that is turned on and tuned in.

In this chapter we focus on the **endocrine system**, which includes a variety of cells that produce and release hormonal chemical signals into the extracellular fluid.

Chemical signals can act locally or at a distance

Endocrine cells secrete chemical signals; **target cells** have receptors for those signals. Chemicals secreted into the extracellular fluid diffuse locally and may diffuse into the blood. Endocrine signals that enter the blood are called **hormones**, and they can activate target cells far from their site of release (**Figure 41.1A**). Testosterone is an example of a **hormone**.

Some endocrine signals are released in such tiny quantities, or are so rapidly inactivated by enzymes, or are taken up so efficiently by local cells that they never diffuse into the blood in sufficient amounts to act on distant cells. Because these signals affect only target cells near their release site, they are called **paracrine**s (*para*, “near”; **Figure 41.1B**). An example of a paracrine is histamine, one of the mediators of inflammation. The most local action an endocrine signal can have is when it binds to receptors on or in the same cell that secreted it. When a chemical signal influences the cell that secreted it, it has **autocrine** function (**Figure 41.1C**). Hormones and paracrine can have autocrine functions as a means of providing negative feedback to control their rates of secretion.

Some endocrine cells exist as single cells within a tissue. Hormones of the digestive tract, for example, are secreted by isolated endocrine cells in the walls of the stomach and small intestine. Many hormones, however, are secreted by aggregations of endocrine cells forming secretory organs called **endocrine glands**. The name “endocrine” reflects the fact that these glands secrete their products directly into the extracellular fluid, which they pass into the blood. In contrast, **exocrine glands**, such as

sweat glands or salivary glands, have ducts that carry their products to the surface of the skin or into a body cavity such as the gut. A single endocrine gland may secrete multiple hormones.

To complete our overview of intercellular chemical communication, we must mention neurotransmitters, which we discuss in detail in Chapters 45–47, and pheromones, which we discuss in Chapter 54. Neurons, the cells of the nervous system, conduct information over long distances as electrical signals, but where a neuron communicates that information to another cell, be it another neuron, a muscle cell, or a secretory cell, it does so by releasing chemical signals called **neurotransmitters**. Most neurotransmitters act very locally and frequently act on the neuron that released them. Some neurotransmitters, however, diffuse into the blood and are therefore referred to as **neurohormones**. **Pheromones** are chemical signals that an animal releases into the environment to communicate information to other individuals of the same species.

Hormonal communication has a long evolutionary history

Intercellular chemical signaling was critical for the evolution of multicellularity. A protist, the slime mold *Dictyostelium*, uses a chemical signal (cAMP) to coordinate the aggregation of individual cells to form a multicellular fruiting structure (see Figure 27.32). The most primitive of the multicellular animals—the sponges—do not have nervous systems, but they do have intercellular chemical communication. And as discussed in Chapter 37, plant growth is regulated by a variety of hormones.

Studying the evolution of hormonal signaling reveals an interesting generalization: the signal molecules themselves are highly conserved. We find the same chemical compounds over broad groups of organisms, but their functions differ. As organisms have evolved to occupy different environments and have different lifestyles, hormone–receptor systems have evolved to serve different functions—for example, the hormone prolactin (**Figure 41.2**). Another important example is the hormonal control of molting and metamorphosis—critical events in the lives of arthropods, the most diverse animal group on Earth (see Chapter 32). The hormones involved represent an ancient system of hormonal communication that is genetically related to the anabolic steroid system discussed at the opening of this chapter.

HORMONAL CONTROL OF MOLTING IN ARTHROPODS
Insects, like all arthropods, have a rigid exoskeleton. Therefore, their growth is episodic, punctu-

41.1 Chemical Signaling Systems Hormones (A) are distributed throughout the body by the blood. Paracrine and autocrine do not enter the bloodstream; paracrine (B) simply diffuse to nearby cells, while autocrine (C) influence the cells that release them.

Fish

Required for osmoregulation in freshwater species. In saltwater species that return to fresh water to spawn (e.g., salmon), prolactin production in adults may play a role in generating the drive to return to natal streams.

**Amphibians**

Alters the osmoregulatory properties of the skin for animals that enter fresh water. In some species, creates a “water drive” that returns adults to breeding locations. Stimulates oviduct development and production of egg jelly in females. In some species, controls development of sexual characteristics.

The structure of prolactin is similar in all vertebrate groups.

**Birds**

In some species, stimulates nesting activity, incubation behavior, and parental care in both sexes. Stimulates the epithelial cells of the upper GI tract to proliferate and slough off to form “crop milk” to nourish the young.

**Mammals**

In females, stimulates growth of the mammary glands and milk production. In humans, it is responsible for the sensation of sexual gratification as well as the male refractory period following sexual intercourse.

41.2 Prolactin's Structure Is Conserved, but Its Functions Have Evolved

The hormone prolactin is found in all vertebrate groups and has a long evolutionary history. Its probable function in early vertebrates was in regulating the body's salt and water balance (osmoregulation). It maintains this function in some species, and has evolved in others to control a number of physiological processes, most of which are associated with reproduction.

nius looks like a miniature adult but lacks certain adult features. The juvenile bug molts five times before developing into a mature adult; a blood meal triggers each episode of molting and growth.

Rhodnius is an amazingly hardy experimental animal—it survives for quite a long time even after its head is cut off. Wigglesworth's studies revealed that, if decapitated within an hour after a blood meal, *Rhodnius* can survive for up to a year, but it never molts. If decapitated a week after its blood meal, however, it does molt. Wigglesworth hypothesized that the time lag meant that the substance that triggers molting diffuses slowly from the head. He tested this hypothesis with the experiment described in **Figure 41.3**.

We now know that two hormones working in sequence regulate molting in arthropods: *prothoracicotropic hormone* (PTTH) and *ecdysone*. Cells in the brain produce PTTH, which is why it has also been called “brain hormone.” PTTH is transported to and stored in paired structures called the *corpora cardiaca* attached to the brain. After appropriate stimulation (which for *Rhodnius* is a blood meal), PTTH is released and diffuses through the extracellular fluid to an endocrine gland, the prothoracic gland. PTTH stimulates the prothoracic gland to release the hormone ecdysone. Ecdysone diffuses to target tissues and stimulates molting.

Ecdysone is a lipid-soluble steroid that readily passes through the plasma membrane of its target cells (mostly cells of the epidermis). In the target cells, ecdysone binds to a receptor that is probably related to the vertebrate testosterone receptor. The hormone–receptor complex acts as a transcription factor that induces expression of the genes encoding enzymes involved in digesting the old cuticle and secreting a new one. The related testosterone receptor, when bound to testos-

ated with *molts* (shedding of the exoskeleton). Each growth stage between two molts is called an *instar*.

The British physiologist Sir Vincent Wigglesworth was a pioneer in the study of the hormonal control of growth and development in insects. Wigglesworth conducted a series of experiments on the bloodsucking bug *Rhodnius prolixus*. Upon hatching, *Rhod-*

INVESTIGATING LIFE

41.3 A Diffusible Substance Triggers Molting

The bloodsucking bug *Rhodnius prolixus* develops from hatchling to adult in a series of five molts (instars) that are triggered by ingesting blood. Sir Vincent Wigglesworth's experiments demonstrated that a blood meal stimulates production of some molt-inducing substance in the insect's head.

HYPOTHESIS The substance that controls molting in *R. prolixus* is produced in the head segment and diffuses slowly through the body.

OBSERVATION

METHOD

1. Decapitate third-instar juveniles at different times after blood meal.

RESULTS

CONCLUSION A blood meal stimulates production of some substance within the insect's head that then diffuses slowly through the body, triggering a molt.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

The control of molting by PTTH and ecdysone is a general arthropod hormonal control mechanism, and it exemplifies how the endocrine system works with the nervous system to integrate diverse information and induce long-term effects. The nervous system of an arthropod receives various types of information about the animal's environment (such as day length, temperature, social cues, and nutrition) that help determine the optimal timing for the stages of growth and development. When conditions are right, the brain (part of the nervous system) signals the prothoracic gland (part of the endocrine system), which produces the hormone (ecdysone) that orchestrates the physiological processes involved in development and molting. Later in this chapter we will see similar links between the nervous system and endocrine glands in vertebrates.

HORMONAL CONTROL OF MATURATION IN ARTHROPODS

Wigglesworth's experiments with *Rhodnius* yielded another curious result: regardless of the instar used, decapitated bugs that molted always molted directly into an adult. Additional experiments by Wigglesworth demonstrated that another hormone determines whether a bug molts into another juvenile instar or into an adult.

Because the head of *Rhodnius* is long, it is possible to remove just the front part of it, which contains the brain, while leaving the rear part intact. When fourth-instar bugs that had had a blood meal a week earlier were partly decapitated in this way, they molted into fifth-instar juveniles, not into adults.

This experiment was followed by more experiments using glass tubes to connect individual bugs. When an unfed, completely decapitated fifth-instar bug was connected to a fed, partly decapitated fourth-instar bug (with only the front part of its head removed), both bugs molted into juvenile forms. A substance from the rear part of the head of the fourth-instar bug prevented both bugs from molting into adults.

The substance responsible for preventing maturation is **juvenile hormone**, which is released continuously from the *corpora allata* (structures that are attached to the *corpora cardiaca*, which release PTTH). As long as juvenile hormone is present, *Rhodnius* molts into another juvenile instar. Normally *Rhodnius* stops producing juvenile hormone during the fifth instar, then molts into an adult.

The control of development by juvenile hormone is more complex in insects, such as butterflies, that undergo complete metamorphosis. These animals undergo dramatic developmental changes in their life cycles. The fertilized egg hatches into a *larva*, which feeds and molts several times, becoming bigger each time. After a fixed number of molts, it enters an inactive stage called *pupation*. The pupa undergoes major body reorganization and finally emerges as an adult.

An excellent example of complete metamorphosis is provided by the silkworm moth *Hyalophora cecropia*.

terone, also plays important roles in development and growth, illustrating the evolutionary conservatism of both the chemical signal and its general domain of function.

(Figure 41.4). As long as juvenile hormone is present in high concentrations, larvae molt into larger larvae. When the level of juvenile hormone falls, larvae spin cocoons and molt into pupae. Because no juvenile hormone is produced in pupae, they molt into adults.

The existence and function of insect hormones were experimentally demonstrated many years before the hormones were

41.4 Hormonal Control of Metamorphosis Three hormones control molting and metamorphosis in the silkworm moth *Hyalophora cecropia*.

yourBioPortal.com

GO TO Animated Tutorial 41.1 • Complete Metamorphosis

identified chemically. That is not surprising when you consider the tiny amounts of certain hormones that exist in an organism. In one of the earliest studies of ecdysone, biochemists produced only 250 milligrams of pure ecdysone (about one-fourth the weight of an apple seed) from 4 tons of silkworms!

Hormones can be divided into three chemical groups

Now that we have seen examples of the roles hormones can play in long-term physiological and developmental processes, we can step back and ask some general questions about them. What kinds of hormones exist? What is their chemical nature, and what is their mode of action? There is enormous diversity in the chemical structure of hormones, but most of them can be classified into three groups:

- The majority of hormones are *peptides* or *proteins*. These hormones (insulin is an example) are water-soluble and thus are easily transported in the blood without carrier molecules. Peptide and protein hormones are packaged in vesicles within the cells that make them; they are released by exocytosis. Their receptors are on cell surfaces.
- *Steroid hormones* (such as testosterone) are synthesized from the steroid cholesterol, are lipid-soluble, and easily pass through cell membranes. Steroid hormones diffuse out of the cells that make them and are usually bound to carrier molecules in the blood. Their receptors are mostly intracellular.
- *Amine hormones* are mostly synthesized from the amino acid tyrosine (thyroxine is one example). Some amine hormones are water-soluble and others are lipid-soluble; their modes of release differ accordingly.

Hormone receptors can be membrane-bound or intracellular

Water-soluble hormones cannot pass readily through plasma membranes, so their receptors are located on the surfaces of target cells. These receptors are large transmembrane glycoprotein complexes with three domains: a *binding domain* that projects outside the plasma membrane, a *transmembrane domain* that anchors the receptor in the membrane, and a *cytoplasmic domain* that extends into the cytoplasm of the cell. When a hormone binds to the binding domain, the cytoplasmic domain initiates the target cell's response through a second messenger-activated cascade, eventually activating protein kinases or protein phosphatases (see Figures 7.7 and 7.8). In most cases these protein kinases and phosphatases activate

41.5 The Fight-or-Flight Response When a person is suddenly faced with a threatening situation, the brain sends a signal to the adrenal glands, which almost instantaneously release the hormone epinephrine. Epinephrine circulates around the body and induces the various components of the fight-or-flight response in different tissues.

or inactivate enzymes in the cytoplasm, which leads to the cell's response, but the signaling cascade initiated by the receptor can also generate signals that enter the nucleus and alter gene expression (see Figure 7.12).

Lipid-soluble hormones can diffuse through plasma membranes, and therefore their receptors are usually inside cells, in either the cytoplasm or the nucleus (although some membrane-bound receptors for lipid-soluble hormones have recently been described). In most cases, the complex formed by the lipid-soluble hormone and its receptor acts by altering gene expression in the cell's nucleus (see Figure 7.9).

Hormone action depends on the nature of the target cell and its receptors

Wherever a hormone encounters a cell with a receptor to which it can bind, it binds to that receptor and triggers a response. The nature of the response depends on the responding cell and its receptors. Thus the same hormone can cause different responses in different types of cells.

Consider the amine hormone *epinephrine*. Suppose you are walking in the forest and almost trip over a rattlesnake. You jump back. Your heart starts to thump, and an entire set of protective actions are set in motion. The jump and the initial heart thumping are driven by your nervous system, which reacts very quickly. Simultaneously with these muscular responses, however, your nervous system stimulates endocrine cells in the adrenal glands just above your kidneys to secrete epinephrine. Within seconds, epinephrine is diffusing into your blood and circulating around your body to activate the many components of the **fight-or-flight response** (Figure 41.5).

Epinephrine binds to receptors in your heart, causing a faster and stronger heartbeat. Your heart is now pumping more blood. Epinephrine also binds to receptors in certain blood vessels. By causing constriction of blood vessels supplying your skin, kidneys, and digestive tract (digesting lunch can wait!), the hormone diverts more blood to the muscles needed for your escape from danger.

Epinephrine also binds to cells in the liver and to receptors on fat cells. In the liver, epinephrine stimulates the breakdown of glycogen into glucose for a quick energy supply (see Figure 7.20). In fatty tissue, it stimulates the breakdown of fats to yield fatty acids—another source of energy. These are just some of the many actions that are triggered by one hormone; they all contribute to increasing your chances of surviving a dangerous situation. In each case the cellular response depends on the cell's receptors and associated intracellular signaling cascade.

41.1 RECAP

Hormones are chemical signals released by endocrine cells into the extracellular fluid, where they diffuse into the blood and travel to distant target cells. The receptors for water-soluble hormones are on the surfaces of target cells; receptors for most lipid-soluble hormones are inside the target cells.

- What is the role of juvenile hormone in metamorphosis? **See pp. 855–856 and Figures 41.3 and 41.4**
- Describe the different methods by which water-soluble and lipid-soluble hormones reach their receptors. **See p. 856**
- Do you understand why a single hormone can have diverse effects in the body?

Since the nervous system and the endocrine system are the two major information systems of the body, it is not surprising that their activities are coordinated. Let's look next at how this coordination works.

41.2 How Do the Nervous and Endocrine Systems Interact?

The list of hormones known to exist is long and growing longer. To make the subject manageable, we will focus primarily on the endocrine system of humans and other mammals (**Figure 41.6**). We will begin our survey by considering the hormones involved in the integration of nervous system and endocrine system functions.

The pituitary connects the nervous and endocrine systems

The **pituitary gland** sits in a depression at the bottom of the skull, just over the back of the roof of the mouth (**Figure 41.7A**). It is attached by a stalk to a part of the brain called the **hypothalamus**, which is involved in many physiological regulatory systems. Through its close connection with the hypothalamus, the pituitary serves as the interface between the nervous system and the endocrine system and is involved in the hormonal control of many physiological processes.

Other organs include cells that produce and secrete hormones

Organ	Hormone
Adipose tissue	Leptin
Heart	Atrial natriuretic peptide
Kidney	Erythropoietin
Stomach	Gastrin
Intestine	Secretin, cholecystokinin
Skin	Vitamin D (cholecalciferol)
Liver	Somatomedins, insulin-like growth factors

41.6 The Endocrine System of Humans Cells that produce and secrete hormones may be organized into discrete endocrine glands, or they may be embedded in the tissues of other organs, such as the digestive tract or kidneys. The hypothalamus is part of the brain, but it includes cells that secrete neurohormones into the extracellular fluid.

GO TO Web Activity 41.1 • The Human Endocrine Glands

The pituitary has two parts with different developmental origins. The *anterior pituitary* originates as an outpocketing of the roof of the embryonic mouth cavity, whereas the *posterior pituitary* originates as an outpocketing of the floor of the developing brain. Thus the anterior pituitary originates from gut epithelial tissue and the posterior pituitary from neural tissue. Both parts interact with the nervous system but in different ways. The anterior pituitary contains endocrine cells controlled

—yourBioPortal.com—

GO TO Animated Tutorial 41.2 • The Hypothalamic–Pituitary–Endocrine Axis

by neurohormones secreted by the hypothalamus. The posterior pituitary contains axons from hypothalamic neurons.

THE POSTERIOR PITUITARY Long axons extend into the **posterior pituitary** from neurons in the hypothalamus. The ends (*terminals*) of those axons release two hormones produced by the neurons, antidiuretic hormone and oxytocin (**Figure 41.7B**). These neurohormones are packaged in vesicles that are transported down the axons. The vesicles are stored until an action potential stimulates their release.

The main action of **antidiuretic hormone (ADH)** in mammals and birds is to increase the amount of water conserved by the kidneys. When ADH secretion is high, the kidneys produce only a small volume of highly concentrated urine. When ADH secretion is low, the kidneys produce a large volume of dilute urine. The posterior pituitary increases its release of ADH when blood pressure falls or the blood becomes too salty. ADH is also known as *vasopressin* because at high concentrations it causes the constriction of peripheral blood vessels as a means of elevating blood pressure.

When a woman is about to give birth, her posterior pituitary releases **oxytocin**, which stimulates the uterine contractions that deliver the baby (see Figure 44.16). Oxytocin also brings about the flow of milk from the mother's breasts. The baby's suckling stimulates neurons in the mother's brain that cause the secretion of oxytocin. Even the sight and sound of a baby can cause a nursing mother to secrete oxytocin and release breast milk. This is a good example of how the nervous system integrates information and contributes to the control of hormonally mediated processes.

Hormones, in turn, can influence the nervous system. Oxytocin, for example, promotes bonding (see the story that opens Chapter 7). If oxytocin release is experimentally blocked, mammalian mothers, from rats to sheep, will reject their newborn offspring, but if a virgin rat is given a dose of oxytocin, she will adopt strange pups as if they were her own. Oxytocin promotes pair bonding and trust in a variety of animals. In humans, its secretion rises with intimate sexual contact. Not surprisingly, oxytocin has been nicknamed the "cuddle hormone."

THE ANTERIOR PITUITARY The **anterior pituitary** releases four peptide and protein hormones that act as **tropic hormones**, meaning they control the activities of other endocrine glands

41.7 The Posterior Pituitary Releases Neurohormones

Neurons in the hypothalamus produce two peptide neurohormones, which are stored and released by the posterior pituitary.

(Figure 41.8). These four hormones are *thyrotropin*, *luteinizing hormone*, *follicle-stimulating hormone*, and *corticotropin*. Each tropic hormone is produced by a different type of pituitary cell. We will say more about the tropic hormones when we describe their target glands (thyroid, testes, ovaries, and adrenal cortex) later in this chapter and in Chapter 43.

Other peptide and protein hormones produced by the anterior pituitary are *growth hormone*, *prolactin* (see Figure 41.2) *melanocyte-stimulating hormone*, *enkephalins*, and *endorphins*.

Growth hormone (GH) acts on a wide variety of tissues to promote growth. One of its important effects is to stimulate cells to take up amino acids. Growth hormone also promotes growth by stimulating the liver to produce chemical signals called *somatomedins* or *insulin-like growth factors (IGFs)*, which stimulate the growth of bone and cartilage. Thus growth hormone can be considered a tropic hormone because it stimulates endocrine cells in the liver.

Overproduction of growth hormone in children causes *gigantism*, in which affected individuals may grow to nearly 8 feet tall. Underproduction causes *pituitary dwarfism*, in which individuals fail to reach normal adult height. Beginning in the late 1950s, children with serious growth hormone deficiencies were treated with growth hormone extracted from pituitaries of human cadavers. The treatment was successful in stimulating substantial growth, but a year's supply of the hormone for one individual required up to 50 cadaver pituitaries. In the 1980s,

41.8 The Anterior Pituitary Is Controlled by the Hypothalamus

Cells of the anterior pituitary produce four tropic hormones that control other endocrine glands, as well as several other peptide and protein hormones. These cells are controlled by neurohormones produced in the hypothalamus and delivered through portal blood vessels that run between the hypothalamus and the anterior pituitary through the pituitary stalk.

scientists using recombinant DNA technology isolated the gene for human growth hormone and introduced it into bacteria that could be grown in large quantities, making it possible to purify enough of the hormone to make it widely available.

Endorphins and enkephalins are the body's natural painkillers. In the brain, these molecules act as neurotransmitters in pathways that control pain. Their production in the anterior pituitary is normally quite small and probably has no significant effect. They are a by-product of the production of two other anterior pituitary hormones. One gene encodes a large parent molecule called *pro-opiomelanocortin*, or POMC, which is cleaved to produce several peptides. Corticotropin, melanocyte-stimulating hormone, endorphins, and enkephalins all result from the cleavage of POMC.

The anterior pituitary is controlled by hypothalamic neurohormones

In contrast to the posterior pituitary, the anterior pituitary makes and secretes its own hormones, but its secretion of hormones is under the control of neurohormones from the hypothalamus. The hypothalamus senses and receives information about conditions in the body and in the external environment, and it communicates that information to the anterior pituitary by releasing neurohormones. If the connection between the hypothalamus and the pituitary is experimentally cut, the release of pituitary hormones no longer changes when conditions in the internal or external environment change. In experiments in which pituitary cells were maintained in culture, adding extracts of hypothalamic tissue stimulated some of those cells to release their hormones into the culture medium. Therefore, scientists hypothesized that secretions from hypothalamic cells control the activities of anterior pituitary cells.

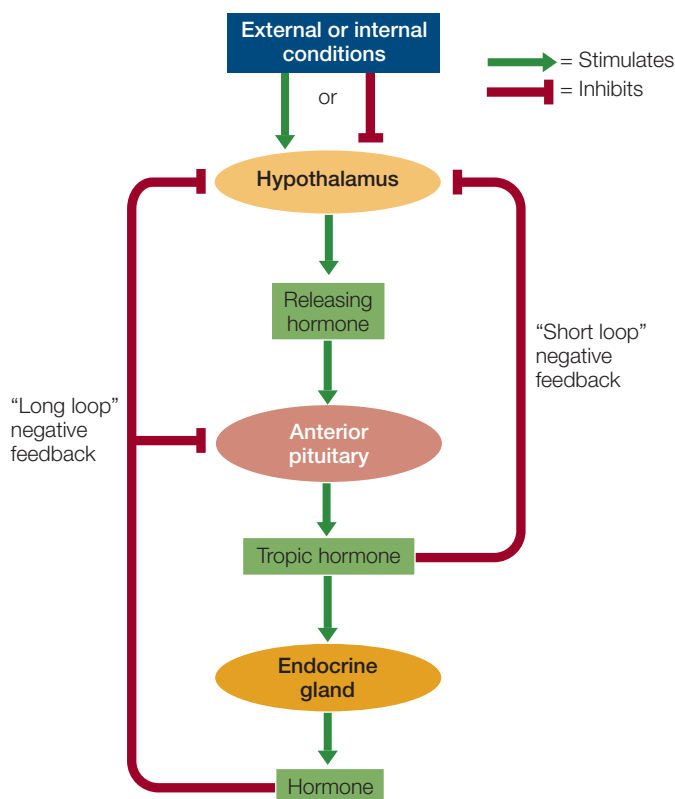

Hypothalamic neurons do not extend into the anterior pituitary as they do into the posterior pituitary. Remember that the posterior pituitary develops from neural tissue whereas the anterior pituitary develops from gut tissue. A special set of **portal blood vessels** bridges the gap between the hypothalamus and the anterior pituitary (see Figure 41.8). It was thus proposed that secretions from neurons in the hypothalamus enter the blood and are conducted down the portal vessels to the anterior pituitary, where they stimulate the release of anterior pituitary hormones.

In the 1960s, two large teams of scientists, led by Roger Guillemin and Andrew Schally, initiated the search for these hypothalamic secretions. Because the amounts of such neurohor-

mones in any individual mammal would be tiny, massive numbers of hypothalami from pigs and sheep were collected from slaughterhouses and shipped to laboratories in refrigerated trucks. One extraction effort began with the hypothalami from 270,000 sheep and yielded only 1 milligram of purified **thyrotropin-releasing hormone (TRH)**. TRH was the first hypothalamic *releasing hormone* (that is, release-stimulating hormone) to be isolated and characterized. It turned out to be a simple tripeptide consisting of glutamine, histidine, and proline. It causes certain anterior pituitary cells to release the tropic hormone thyrotropin, which in turn stimulates the activity of the thyroid gland.

Soon after discovering TRH, Guillemin's and Schally's teams identified **gonadotropin-releasing hormone (GnRH)**, which stimulates certain anterior pituitary cells to release the tropic hormones that control the activity of the gonads (the ovaries and the testes). For these discoveries, Guillemin and Schally received the 1977 Nobel Prize in Medicine. Many other hypothalamic neurohormones, including both releasing hormones and release-inhibiting hormones, are now known. The major hypothalamic neurohormones that control anterior pituitary function are:

- Thyrotropin-releasing hormone
- Gonadotropin-releasing hormone
- Prolactin-releasing and release-inhibiting hormones
- Growth hormone-releasing hormone

41.9 Multiple Feedback Loops Control Hormone Secretion

Multiple negative feedback loops regulate the chain of command from hypothalamus to anterior pituitary to endocrine glands.

- Growth hormone release-inhibiting hormone (somatostatin)
- Corticotropin-releasing hormone

Negative feedback loops regulate hormone secretion

As well as being controlled by hypothalamic releasing and release-inhibiting hormones, the endocrine cells of the anterior pituitary are also under direct and indirect negative feedback control by the hormones of the target glands they stimulate (**Figure 41.9**). For example, the hormone cortisol, produced by the adrenal gland in response to corticotropin secreted by the anterior pituitary, reaches the pituitary in the circulating blood and inhibits further release of that tropic hormone. Cortisol also acts as a negative feedback signal to the hypothalamus, inhibiting the release of corticotropin-releasing hormone. In some cases, a tropic hormone also exerts negative feedback control on the hypothalamic cells that produce the corresponding releasing hormone.

41.2 RECAP

The pituitary is the interface between the nervous system and the endocrine system. The posterior pituitary releases two neurohormones. The anterior pituitary, under the control of other neurohormones from the hypothalamus, releases hormones that control other endocrine glands.

- Describe the anatomical and functional relationships between the brain and the two parts of the pituitary.
- What are the tropic hormones of the anterior pituitary, and how do they influence the endocrine system?
See pp. 859–860 and Figure 41.8

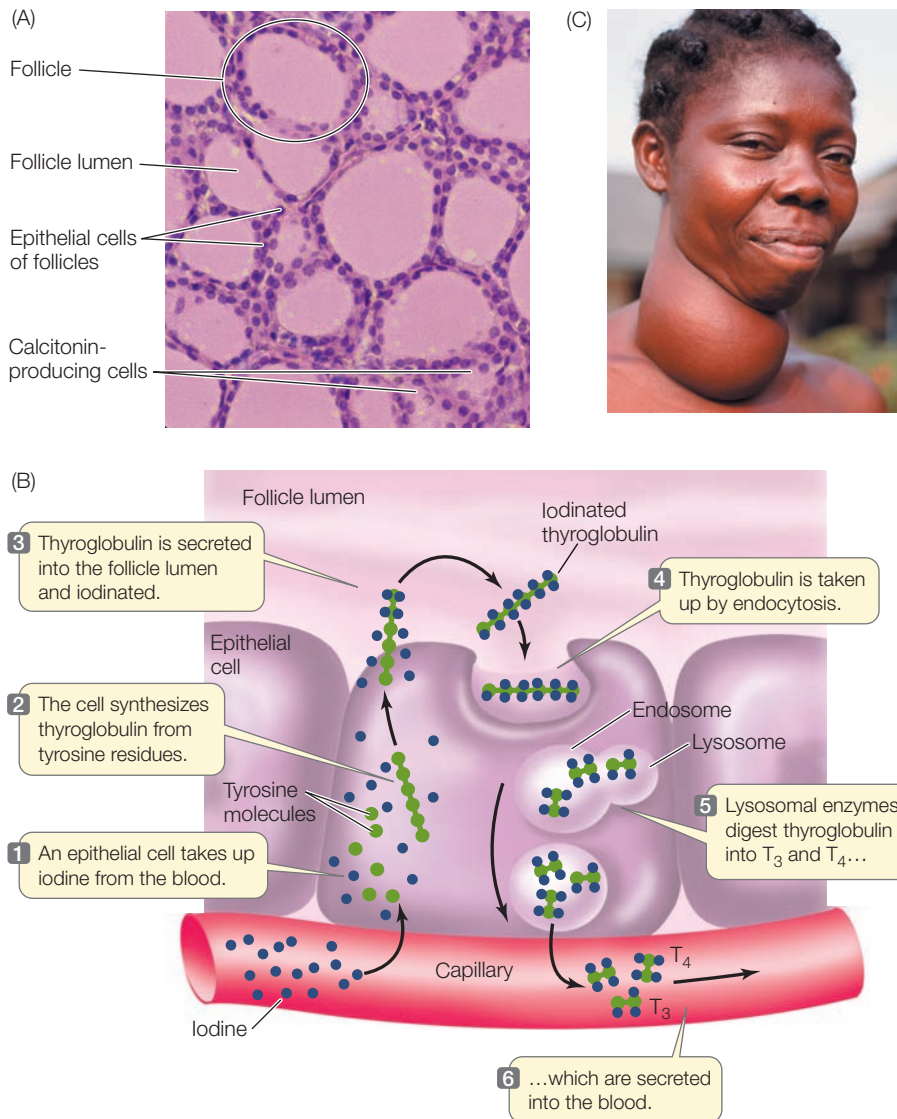

Now that we know some of the mechanisms by which endocrine systems are controlled, we will take a more detailed look at the functions of the major endocrine glands of the mammalian body.

41.3 What Are the Major Mammalian Endocrine Glands and Hormones?

Hormones help regulate functions in all mammalian physiological systems. In this section we will examine a few major examples of hormonal action in physiological processes. We will see many more in the chapters that follow.

The thyroid gland secretes thyroxine

The **thyroid gland** wraps around the front of the windpipe (*trachea*) and expands into a lobe on either side (see Figure 41.6). There are two cell types in the thyroid gland, each of which produces a specific hormone. Thyroxine is produced, stored, and released by epithelial cells that make up round, colloid-contain-

41.10 The Thyroid Gland Consists of Many Follicles

(A) Cross section through a thyroid gland, showing numerous follicles bounded by epithelial cells. Calcitonin-secreting cells are located in the spaces between the follicles. (B) The epithelial cells of the follicle synthesize thyroglobulin and secrete it into the lumen of the follicle, where it is iodinated and stored until it is processed by the epithelial cells to generate T_3 and T_4 . (C) Iodine deficiency can result in hypothyroid goiter. In this condition, a lack of functional thyroxine results in oversynthesis of thyroglobulin and subsequent enlarged follicles.

and if they are iodinated at only three sites, they are triiodothyronine, or T_3 :

The thyroid usually releases about four times as much T_4 as T_3 ; however, T_3 is the more active hormone in the cells of the body. Circulating T_4 can be converted to T_3 by an enzyme within target cells. Therefore, each target cell can set its own sensitivity to thyroid hormones by controlling the conversion of T_4 to the more active T_3 . When you read about thyroxine, keep in mind that the actions discussed are primarily those of T_3 .

THYROXINE REGULATES CELL METABOLISM

Thyroxine in mammals plays many roles in regulating cell metabolism. Thyroxine is lipid-soluble, so it enters cells readily and binds to receptors in the nucleus. The recep-

ing structures called *follicles* (Figure 41.10A and B). Calcitonin is produced in cells in spaces between the follicles.

Thyroxine begins as the glycoprotein **thyroglobulin**, which the follicle cells synthesize as long chains consisting largely of tyrosine residues. As these thyroglobulin molecules are exported into the follicle for storage, the tyrosine residues are iodinated with one or two atoms of iodine. When the thyroid gland is stimulated to release thyroxine, the follicle cells take up thyroglobulin from the follicle by endocytosis. These bits of thyroglobulin are then cleaved to form smaller molecules consisting of only two tyrosine residues, and these molecules leave the follicle cells. If these molecules are iodinated at the maximum of four sites on the tyrosine residues, the hormone is tetraiodothyronine, or T_4 ;

tor is found in most cells of the body, and when combined with thyroxine, it acts as a transcription factor that stimulates the transcription of numerous genes whose products are enzymes involved in energy metabolic pathways, transport proteins, and structural proteins. As a result, thyroxine elevates the metabolic rates of most cells and tissues. Exposure to cold for several days leads to an increased release of thyroxine, an increased conversion of T_4 to T_3 , and therefore an increased basal metabolic rate (see Section 40.4). Thyroxine is especially crucial during development and growth, as it promotes amino acid uptake and protein synthesis. Insufficient thyroxine in a human fetus or growing child greatly retards physical and mental development, resulting in a condition known as *cretinism*.

The tropic hormone **thyrotropin**, or **thyroid-stimulating hormone (TSH)**, produced by the anterior pituitary, activates the thyroxine-producing follicle cells in the thyroid. Thyrotropin-releasing hormone (TRH), produced in the hypothalamus and transported to the anterior pituitary through the portal blood vessels, activates the TSH-producing pituitary cells. The hypothalamus uses environmental information, such as temperature or

day length, to determine whether to increase or decrease its secretion of TRH. This sequence of steps is regulated by a negative feedback loop like the one described earlier for cortisol (see Figure 41.9). Circulating thyroxine inhibits the response of pituitary cells to TRH, so less TSH is released when thyroxine levels are high, and more TSH is released when thyroxine levels are low. Circulating thyroxine also exerts negative feedback on the production and release of TRH by the hypothalamus.

A **goiter** is an enlarged thyroid gland (**Figure 41.10C**) that can be associated with either **hyperthyroidism** (excess production of thyroxine) or **hypothyroidism** (thyroxine deficiency). The negative feedback loop whereby thyroxine controls TSH release helps explain how two very different conditions can result in the same symptom.

The most common cause of *hyperthyroid* goiter is an autoimmune disease involving an antibody to the TSH receptor. This antibody binds to and activates the TSH receptors on the follicle cells, causing uncontrolled production and release of thyroxine. Blood levels of TSH are quite low because of the negative feedback from high levels of thyroxine, but the thyroid remains maximally stimulated and grows bigger. People with hyperthyroidism have high metabolic rates, are jumpy and nervous, usually feel hot, and may develop a buildup of fat behind the eyeballs, which causes their eyes to bulge.

Hypothyroid goiter results when there is not enough circulating thyroxine to turn off TSH production. The most common cause of this condition is a deficiency of dietary iodine, without which the follicle cells cannot make thyroxine. Without sufficient thyroxine, TSH levels remain high and stimulate more and more synthesis of thyroglobulin. Because sufficient iodine is not available, however, the thyroglobulin is poorly iodinated. When it is broken down by the follicle cells, it does not yield functional thyroxine (T_3 or T_4). TSH levels remain high and stimulate more and more synthesis of thyroglobulin, and the thyroid gets bigger. The symptoms of hypothyroidism are low metabolism, intolerance of cold, and general physical and mental sluggishness.

Goiter affects about 5 percent of the world's population. The addition of iodine to table salt has greatly reduced the incidence of hypothyroid goiter in industrialized nations, but the condition is still common in the other parts of the world.

Three hormones regulate blood calcium concentrations

The regulation of calcium concentration in the blood is a crucial and difficult task. It is crucial because shifts in blood calcium concentration above or below a narrow range can cause serious problems. When blood calcium falls below this range, the nervous system becomes overly excited, resulting in muscle spasms and even seizures. When blood calcium rises above this range, the nervous system becomes depressed and muscles—including the heart—weaken. Regulation of blood calcium is difficult

because only about 0.1 percent of the calcium in the body is located in the extracellular fluid. About 1 percent is in cells, and almost 99 percent is in the bones. Therefore, the body must maintain a tiny pool of calcium in the blood at a precise concentration, and that tiny pool can be influenced greatly by relatively small shifts in the much larger pools of calcium in the cells and bones.

The body has multiple mechanisms for changing blood calcium levels, including:

- Deposition or absorption of bone
- Excretion or retention of calcium by the kidneys
- Absorption of calcium from the digestive tract

These mechanisms are controlled by the hormones calcitonin, parathyroid hormone, and calcitriol (synthesized from vitamin D).

CALCITONIN REDUCES BLOOD CALCIUM Calcitonin released by the thyroid lowers the concentration of calcium in the blood, mainly by regulating bone turnover (**Figure 41.11**). Bone is continuously remodeled through a dynamic process that involves

41.11 Hormonal Regulation of Calcium Calcitonin, parathyroid hormone (PTH), and vitamin D regulate calcium levels in the blood.

yourBioPortal.com

GO TO Animated Tutorial 41.3 • Hormonal Regulation of Calcium

both resorption of old bone and synthesis of new bone, as we discuss in Section 48.3. Cells called *osteoclasts* break down bone and release calcium into the blood, and cells called *osteoblasts* take up calcium from the blood and deposit it in new bone. Calcitonin decreases the activity of osteoclasts and thereby favors removal of calcium from the blood and its deposition in bone by osteoblasts. The turnover of bone in adult humans is not very high, so calcitonin does not play a major role in calcium homeostasis in adults. It is probably more important in young individuals whose bones are actively growing.

PARATHYROID HORMONE INCREASES BLOOD CALCIUM The **parathyroid glands** are four tiny structures embedded in the posterior surface of the thyroid gland (see Figure 41.11). Their single hormone product, **parathyroid hormone** (also called **PTH** or *parathormone*), is the most important hormone in the regulation of blood calcium levels. Circulating calcium activates receptors in the plasma membrane of the parathyroid cells. When these receptors are active, they inhibit the synthesis and release of PTH. A fall in blood calcium removes this inhibition and triggers the synthesis and release of PTH.

PTH stimulates bone turnover by actions on both osteoclasts and osteoblasts. The end result of these actions of PTH is a net increase of calcium in the blood.

Another mechanism by which PTH raises blood concentrations of calcium is by stimulating the kidneys to reabsorb it rather than excrete it in the urine. In addition, PTH activates the synthesis of calcitriol from vitamin D, which in turn causes the digestive tract to increase its absorption of calcium from food.

VITAMIN D IS A HORMONE A *vitamin* is a substance that the body requires in small quantities but cannot synthesize, and must therefore obtain from the diet. By this definition, **vitamin D** is not a vitamin, because the body can and does synthesize it.

It had long been known that fragile bones were common among people living at high latitudes, where winter days are short and the winter diet often lacked meat, fish, dairy products, and fresh vegetables. Since the condition could be reversed by taking cod-liver oil (which, as it turned out, contains large amounts of vitamin D), scientists assumed that a dietary vitamin was involved. We now know that vitamin D is synthesized in skin cells, where cholesterol is converted into vitamin D (also called *calciferol*) by ultraviolet light. Vitamin D circulates in the blood and acts on distant cells; thus it is actually a hormone.

PTH lowers blood phosphate levels

Bone minerals are made up primarily of calcium and phosphate. Thus, when PTH stimulates the release of calcium from bone, it also causes the release of phosphate. Excessive blood concentrations of both elements can be dangerous. The normal concentrations of calcium and phosphate in the blood are just below the levels at which they precipitate out of solution as calcium phosphate salts. Thus even a small rise may cause such precipitation, leading to maladies such as kidney stones and calcium deposits in the arteries (hardening of the arteries). To re-

duce this risk, PTH acts on the kidneys to increase the elimination of phosphate via the urine.

Insulin and glucagon regulate blood glucose concentrations

Before the 1920s, *diabetes mellitus* was a fatal disease, characterized by weakness, lethargy, and a dramatic loss of body mass. The disease was known to be connected somehow with the **pancreas**—a large gland located just below the stomach (see Figure 41.6)—and with abnormal glucose metabolism, but the links were not clear.

Today we know that diabetes mellitus is caused by a lack of the protein hormone **insulin** (in type I or juvenile-onset diabetes) or by a lack of insulin responsiveness in target tissues (in type II or adult-onset diabetes). Glucose enters cells by diffusion, not active transport, but cell membranes are not very permeable to glucose. Therefore there are proteins called glucose transporters in cell membranes that facilitate the movement of glucose into cells. The glucose transporters that are most common in muscle and adipose tissue are controlled by insulin. When insulin binds to its receptor on the cell membrane, it causes these glucose transporters to move from cytoplasmic vesicles to the cell membrane, making the cell more permeable to glucose. When insulin is not present, these transporters are returned to the cytoplasmic pool through endocytosis.

In the absence of insulin or insulin responsiveness, glucose entry into cells is impaired, and so much glucose accumulates in the blood that it starts to spill over into the urine; urine production also goes up. A high concentration of glucose in the blood increases urine output by two mechanisms. First, it causes water to move from cells into the blood by osmosis, and this increase in blood volume results in increased urine production. Second, the increased glucose in the tubules of the kidneys pulls more water into the urine by osmosis. Thus diabetic individuals can become dehydrated, but more importantly they suffer from a lack of metabolic fuel. Because glucose uptake by muscle and adipose tissue is impaired in the absence of insulin, muscle cells must depend on fat and protein for fuel and adipose tissue cannot replenish its stores of triglycerides. As a result, the body of the untreated diabetic can waste away.

For centuries, the prospects for diabetics were bleak. A change came almost overnight in 1921, when the physician Frederick Banting and a medical student, Charles Best, at the University of Toronto, discovered that they could reduce the symptoms of diabetes by injecting an extract prepared from pancreatic tissue. The active component of this extract was found to be a small protein hormone—insulin—consisting of just 51 amino acids. In the United States today, insulin replacement therapy, using manufactured insulin, allows 1.5 million people with type I diabetes to lead almost normal lives.

ISLETS OF LANGERHANS Insulin is produced in clusters of endocrine cells in the pancreas. These clusters are called **islets of Langerhans** after the German medical student who discovered them. They contain three types of cells, each of which produces a specific hormone:

- Beta (β) cells produce and secrete insulin.
- Alpha (α) cells produce and secrete glucagon, a hormone that has effects mostly opposite from those of insulin.
- Delta (δ) cells produce a hormone called somatostatin.

The rest of the pancreas is made up of exocrine tissue, which produces enzymes and other secretions that travel through ducts to the gut, where they participate in digestion.

After a meal, the concentration of glucose in the blood rises as glucose is absorbed from the food in the gut. This increase stimulates the β cells of the islets to release insulin, which causes target cells throughout the body to use the circulating glucose as fuel and to convert it into storage products, such as glycogen and fat. When the gut contains no more food, the glucose concentration in the blood falls and the islets stop releasing insulin. As a result, most cells shift to using glycogen and fat, rather than glucose, as fuel. If the concentration of glucose in the blood falls substantially below normal, the islet α cells release **glucagon**, which stimulates the liver to break down stored glycogen and release glucose into the blood. These actions are discussed in greater detail in Section 51.4.

SOMATOSTATIN Somatostatin is released from the δ cells of the pancreas in response to rapid increases of glucose and amino acids in the blood. This hormone has paracrine functions within the islets: it inhibits the release of both insulin and glucagon. Its actions outside the pancreas slow the digestive activities of the gut, extending the period during which nutrients are absorbed. Somatostatin is also produced in very small amounts by cells in the hypothalamus. This somatostatin is transported in the portal blood vessels to the anterior pituitary, where it acts as a neurohormone to inhibit the release of growth hormone and thyrotropin.

The adrenal gland is two glands in one

An **adrenal gland** sits above each kidney, just below the middle of your back. Functionally and anatomically, each adrenal gland consists of a gland within a gland (**Figure 41.12**). The core, or **adrenal medulla**, produces two hormones: **epinephrine** (also known as *adrenaline*) and, to a lesser degree, **norepinephrine** (or *noradrenaline*). The medulla develops from nervous tissue and is under the control of the nervous system. Surrounding the medulla is the **adrenal cortex**, which produces steroid hormones. The cortex is under hormonal control, largely by corticotropin produced by the anterior pituitary.

THE ADRENAL MEDULLA The adrenal medulla produces epinephrine and norepinephrine in response to stressful situations, arousing the body to action. As we saw earlier in this chapter, epinephrine increases heart rate and blood pressure and diverts blood flow to active muscles and away from the gut and skin. Norepinephrine has similar functions.

Epinephrine and norepinephrine are both water-soluble, and both bind to the same set of receptors on the surfaces of target cells. These *adrenergic receptors* are of two general types, α -adrenergic and β -adrenergic; each type stimulates different actions

41.12 The Adrenal Is a Gland within a Gland An adrenal gland, consisting of an outer cortex and an inner medulla, sits above each kidney. The medulla and the cortex produce different hormones.

within cells (**Figure 41.13**). The α -adrenergic receptors are the most common on target cells of the sympathetic nervous system, and they respond more strongly to norepinephrine than to epinephrine. The β -adrenergic receptors respond about equally to both epinephrine and norepinephrine. One class of the β -adrenergic receptors are found on cells not innervated by the sympathetic fibers, so they are positioned to respond to circulating epinephrine. Therefore, drugs called *beta blockers* (so named because they selectively block β -adrenergic receptors) can reduce the fight-or-flight response to epinephrine without disrupting the physiological regulatory functions of norepinephrine. Beta blockers are commonly prescribed to reduce the symptoms of anxiety, such as dry mouth and elevated heart rate (palpitations).

THE ADRENAL CORTX The cells of the adrenal cortex use cholesterol to produce three classes of steroid hormones, collectively called **corticosteroids**:

- The *glucocorticoids* influence blood glucose concentrations as well as other aspects of fat, protein, and carbohydrate metabolism.
- The *mineralocorticoids* influence the salt and water balance of the extracellular fluid.
- The *sex steroids* play roles in sexual development, sexual behavior, and anabolism.

In adults, the adrenal cortex secretes sex steroids in only negligible amounts. The major producers of sex steroids are the gonads, as we will see in the following section.

Aldosterone, the main mineralocorticoid (**Figure 41.14A**), stimulates the kidneys to conserve sodium and excrete potas-

(A) Epinephrine

(B) Norepinephrine

41.13 Hormones Can Activate a Variety of Signal Transduction Pathways

Epinephrine and norepinephrine bind to G protein-linked adrenergic receptors that act through different signal transduction pathways. Epinephrine acts equally on both α - and β -adrenergic receptors; norepinephrine acts mostly on α -adrenergic receptors.

sium, as we discuss in Chapter 51. If the adrenal glands are removed from an animal, sodium must be added to its diet, or its sodium will be depleted and it will die.

The main glucocorticoid in humans is **cortisol** (Figure 41.14B), which is critical for mediating the body's metabolic responses to stress. Within minutes of a stressful stimulus (one provoking fear or anger, for example), your blood cortisol level rises. Cells not critical for your fight-or-flight responses are stimulated by cortisol to decrease their use of blood glucose and shift instead to using fats and proteins for energy. This is no time to feel sick, have allergic reactions, or heal wounds, so cortisol also blocks immune system reactions. That is why cortisol and drugs that mimic its action are useful for reducing inflammation and allergic responses.

Cortisol release is controlled from the anterior pituitary by **corticotropin** (also called *adrenocorticotrophic hormone*, or **ACTH**), whose release is controlled in turn by **corticotropin-releasing hormone** from the hypothalamus. Because the cortisol response to stress has this chain of steps, each involving secretion, diffusion, circulation, and cell activation, it is much slower than the epinephrine response to stress. Furthermore, in many cases cortisol acts as a transcription factor to change gene expression, and those changes take time.

Turning off the responses to stress activated by cortisol is as important as turning them on. A study of stress in rats showed that old rats could turn on these stress responses as effectively as young rats, but they had lost the ability to turn them off as rapidly. As a result, they suffered from the well-known consequences of stress seen in humans: digestive system problems, cardiovascular

41.14 Corticosteroids Are Built from Cholesterol Side groups on the sterol backbone give different properties to the different corticosteroid hormones. Examples from each of the three classes of these hormones are shown here.

problems, strokes, impaired immune system function, and increased susceptibility to cancers and other diseases. Further research showed that these stress responses are turned off by the negative feedback action of cortisol on the hypothalamus, which causes a decrease in the release of corticotropin-releasing hormone (see Figure 41.9). Repeated activation of this negative feedback mechanism, either through repeated stress or prolonged medical use of cortisol, leads to a gradual loss of cortisol-sensitive cells in the hypothalamus, and therefore to a decreased ability to terminate the stress response.

Sex steroids are produced by the gonads

The **gonads**—the testes of the male and the ovaries of the female—produce hormones as well as sperm and ova. The male steroids are collectively called **androgens**, and the dominant one is *testosterone*. The female steroids are **estrogens** and **progesterone**. The dominant estrogen is *estradiol*, which is synthesized from testosterone. Males and females both synthesize testosterone, but females have an enzyme (aromatase) that converts testosterone to estradiol (Figure 41.14C).

The sex steroids have important developmental effects: they determine whether a mammalian embryo develops into a phenotypic female or male. After birth, the sex steroids control the maturation of the reproductive organs and the development and maintenance of secondary sexual characteristics, such as breasts and facial hair. The roles they play in adult sexual behavior and reproduction are described in Chapter 43.

EARLY DEVELOPMENT Sex steroids begin to exert their effects in the human embryo in the seventh week of development. Until that time, the embryo has the potential to develop into either sex. In mammals and birds, the instructions for sex determination reside in the genes. In mammals, individuals that receive two X chromosomes normally become females, and individuals that receive an X and a Y chromosome normally become males (see Section 12.4).

These genetic instructions are carried out through the production and action of the sex steroids. In humans, the presence of a Y chromosome normally causes the undifferentiated embryonic gonads to begin producing androgens in the seventh week of development. In response to those androgens, the reproductive system develops into that of a male. If androgens are not produced at that time, female reproductive structures develop (Figure 41.15). In other words, androgens are required to trigger male development in humans, and the default condition is female.

INITIATION OF PUBERTY Sex steroids have dramatic effects at **puberty**—the time of sexual maturation in humans. Sex steroids are produced at low levels by the juvenile gonads, but their production increases rapidly at the beginning of puberty—around the age of 12 to 13 years. Why does this sudden increase occur?

In the juvenile, as in the adult, the production of sex steroids by the gonads is controlled by the tropic hormones **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**, which together are called the **gonadotropins**. The production of these

41.15 Sex Steroids Direct the Development of Human Sex Organs

The sex organs of early human embryos are undifferentiated. Androgens promote the development of male sex organs. In the absence of androgens, female sex organs form.

tropic hormones by the anterior pituitary is under the control of the hypothalamic neurohormone gonadotropin-releasing hormone (GnRH). Before puberty, the gonads can respond to gonadotropins and the anterior pituitary can respond to GnRH, but the hypothalamus produces only very low levels of GnRH. Puberty is initiated by a reduction in the sensitivity of hypothalamic GnRH-producing cells to negative feedback from sex steroids and from gonadotropins. As a result, GnRH release increases, stimulating increased production of gonadotropins and hence increased production of sex steroids.

In females, increasing levels of LH and FSH at puberty stimulate the ovaries to increase their production of the female sex hormones. The increased circulating levels of these hormones initiate the development of the traits of a sexually mature

woman: enlarged breasts, vagina, and uterus; broadened hips; increased subcutaneous fat; pubic hair; and initiation of the menstrual cycle.

In males, an increasing level of LH stimulates groups of cells in the testes to increase their synthesis of testosterone, which in turn initiates the physiological, anatomical, and psychological changes associated with adolescence. The voice deepens, hair begins to grow on the face and body, and the testes and penis grow larger. As we saw at the beginning of this chapter, testosterone also help bones and skeletal muscles grow. FSH in males stimulates production of sperm.

Melatonin is involved in biological rhythms and photoperiodicity

The **pineal gland** is situated between the two hemispheres of the brain and is connected to the brain by a stalk. It produces the amine hormone **melatonin** from the amino acid tryptophan. The pineal gland releases melatonin in the dark and therefore marks the length of the night. Exposure to light inhibits the release of melatonin.

In vertebrates, melatonin is involved in biological rhythms, including **photoperiodicity**—the phenomenon whereby seasonal changes in day length cause physiological changes. Many species, for example, come into reproductive condition when the days begin to lengthen (**Figure 41.16**). Humans are not strongly photoperiodic, but melatonin in humans may play a role in synchronizing daily biological rhythms to the daily cycle of light and dark.

41.16 Melatonin Regulates Seasonal Changes (A) Melatonin release occurs in the dark and is inhibited by exposure to light. The duration of daily melatonin release thus changes as day length (photoperiod) changes, inducing dramatic seasonal physiological changes in some animals. (B) In winter, these Siberian hamsters are white and do not reproduce. In summer, they are mottled brown and breed.

Many chemicals may act as hormones

We have discussed the major endocrine glands and their hormones in this chapter, but many more hormones exist. As we discuss the organ systems of the body in the chapters that follow, we will frequently describe hormones that their tissues produce as well as hormones that control their functions.

41.3 RECAP

In mammals, the major endocrine glands include the hypothalamus, pituitary gland, thyroid gland, parathyroid glands, pancreas, adrenal glands, gonads, and pineal gland. Each of these glands secretes, and responds to, hormones that play crucial roles in controlling physiology and development.

- Describe how thyroxine is produced and how its production and release are controlled. **See pp. 861–862 and Figure 41.10**
- How is the concentration of calcium in the blood regulated? **See pp. 863–864 and Figure 41.11**
- What are the hormonal bases for the two forms of diabetes? **See p. 864**
- What changes in the feedback control of sex steroids result in puberty? **See pp. 867–868**

Studying endocrine systems is not easy. Many hormones are released in very small quantities, and some disappear from the extracellular fluid rapidly. A hormone's receptors may be found on diverse cells around the body, and those cells can respond in different ways to the same hormone. How have we overcome these difficulties to learn how hormones work?

41.4 How Do We Study Mechanisms of Hormone Action?

We can break the study of hormone actions into different sets of problems. First, we must be able to detect, identify, and measure hormones. Second, we must be able to identify and characterize the receptors for hormones. Third, we must understand the signal transduction pathways activated by hormones in different tissues.

Hormones can be detected and measured with immunoassays

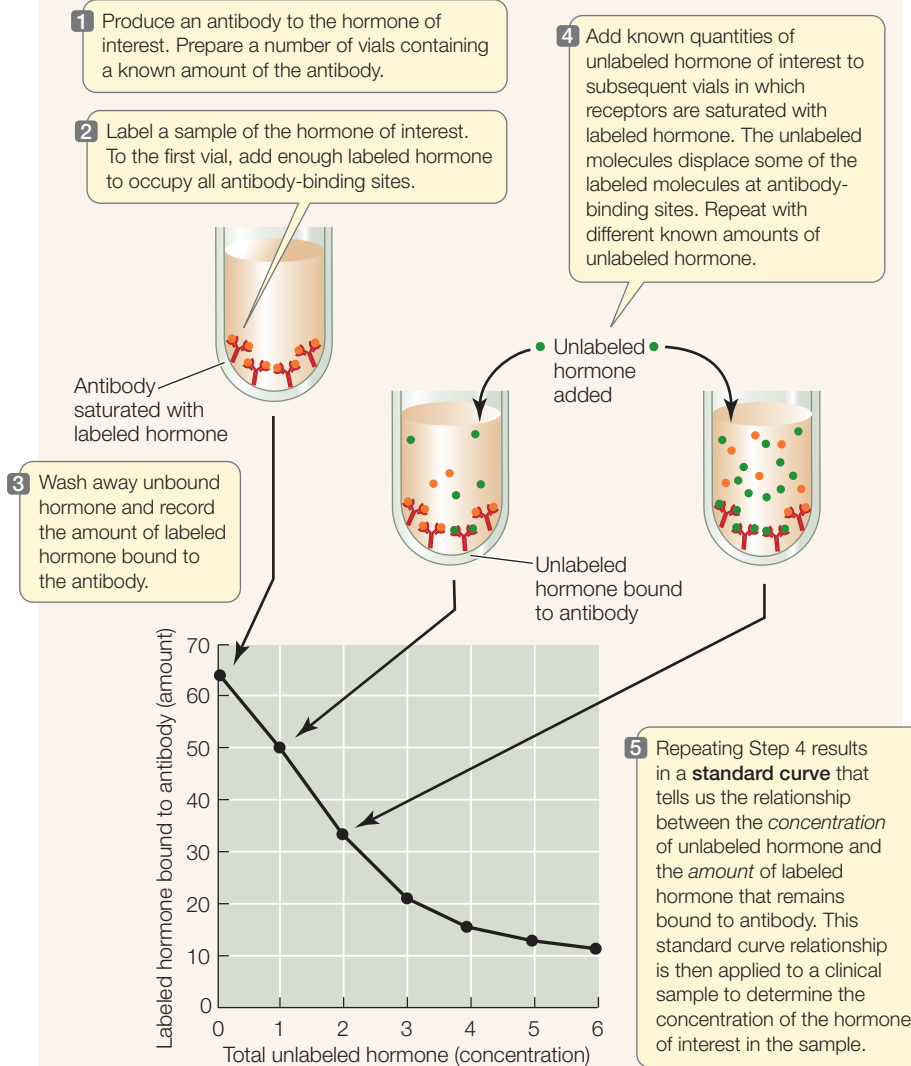

As we have seen, testosterone has many dramatic and diverse effects, yet its concentration in the blood of adult human males is only about 30 to 100 *billionths* of a gram per milliliter. Measuring hypothalamic neurohormones requires calibrations in the range of *trillionths* of a gram per milliliter.

The ability to detect and measure minute quantities of hormone was an important breakthrough. Rosalyn Yalow developed a method called *radioimmunoassay* because it used radioactive la-

TOOLS FOR INVESTIGATING LIFE

41.17 An Immunoassay Allows Measurement of Small Concentrations

An immunoassay uses labeled and unlabeled samples of a purified hormone (or other substance to be measured) and an antibody to that hormone to develop a standard curve against which a sample of unknown concentration can be measured.

Hormones are not simple on–off switches, and an important characteristic of a hormone is the time course over which it acts. This time course can be measured by the hormone’s *half-life* in the blood (defined as the length of time it takes for one-half of the hormone molecules to disappear). Soon after endocrine cells are stimulated to secrete their hormone, the hormone reaches its maximum concentration in the blood. By taking a series of blood samples and using immunoassays, researchers can determine how long it takes for the circulating hormone to drop to half of that maximum concentration. The fight-or-flight response to epinephrine, as we have seen, is relatively quick in its onset and termination; the half-life of epinephrine in the blood is only 1 to 3 minutes. The effects of other hormones, such as cortisol and thyroxine, are expressed over much longer periods, and their half-lives are on the order of days or weeks.

Immunoassays have also facilitated the measurement of dose–response relationships. To evaluate a drug or a natural hormone for therapeutic use, it is critical to know the sensitivity of the body to that drug or hormone. Being able to measure the concentrations of drugs or hormones in the blood makes it possible to construct dose–response curves that help physicians adjust dosages appropriately (**Figure 41.18**).

A hormone can act through many receptors

Different receptors may be involved in mediating the actions of a single hormone. Because there are slight differences among the receptors for a particular hormone, it is possible to create drugs that are very selective in blocking or stimulating specific responses. A number of receptors have been identified, isolated, and purified through biochemical separation techniques. For example, a hormone can be bound to a substrate such as

bel (she used radioactive isotopes of iodine) to track interactions between an antigen (the hormone or other substance of interest to be measured) and an antibody made to that antigen. Today we are more likely to use nonradioactive labels, so the technique is called simply **immunoassay** (**Figure 41.17**). Being able to measure hormones in the blood made it possible to study many important hormonal mechanisms.

41.18 Dose-Response Curves Quantify the Body's Response to a Hormone Between the threshold and maximum doses, a dose-response curve frequently has an S shape. Anything that changes the responsiveness of a system—such as an increase or decrease in the number of receptors in target cells—affects the position of the curve.

resin beads packed into a glass column. When an extract of cells suspected of containing receptors to that hormone is added to the column, the receptors bind to the hormone molecules on the beads. The hormone–receptor complexes can then be washed off the beads and the receptors isolated. This technique is called **affinity chromatography**.

As more receptors are isolated and characterized, researchers discover that they frequently exist in families with common structural features. These common features result from common nucleotide sequences in the receptors' genes. Genomic analyses have led to the discovery of many new receptors. Investigators “scan” the genome for sequences that bear homologies to known receptor gene sequences; when they get a “hit,” they have found a candidate gene for a new receptor. They can then identify the molecule to which that receptor binds (its ligand), describe where the receptor occurs within the body, and characterize the receptor's physiological effects.

Knowing the molecular identity of a receptor and being able to measure its concentration makes it possible to study that receptor's regulation. We saw above that the release of hormones can be under negative feedback control. Similarly, the abundance of receptors for a hormone can be under feedback control. In some cases, continuous high concentrations of a hormone can decrease the number of its receptors, a process known as **downregulation**. **Upregulation** of receptors can occur when hormone secretion is suppressed. The regulation of receptor abundance is an important mechanism controlling the sensitivity of the body to hormonal signaling.

An example of downregulation occurs in type II diabetes mellitus, which is characterized by elevated insulin concentrations in the blood and a loss of insulin receptors. Although genetic factors are probably involved, a possible immediate cause of the disease is an overstimulation of pancreatic release of insulin by excessive carbohydrate intake, which leads to downregulation of the insulin receptors. An example of upregulation may be seen in people who have been on a regular dose of beta blockers (see page 865). As the activity of the β -adrenergic receptors is blocked over time, more receptors are produced. If the person goes off the medication suddenly, the effects of the receptors are amplified, resulting in heightened anxiety. Changes in dosage in the long-term use of such medications thus are usually gradual and carefully supervised.

41.4 RECAP

Studying the mechanisms of hormone action requires the ability to measure hormone concentrations and to identify and characterize hormone receptors.

- Describe how an immunoassay is performed. **See p. 869 and Figure 41.17**
- How are receptors for a particular hormone identified? **See pp. 869–870**

CHAPTER SUMMARY

41.1 What Are Hormones and How Do They Work?

- **Endocrine cells** secrete chemical signals that induce responses in other cells that have receptors for those molecules. In some cases endocrine cells are aggregated into **endocrine glands**.
- **Hormones** are endocrine signals that are secreted from a cell, circulate in the blood, and bind to **target cells** distant from the secreting cell. **Review Figure 41.1**
- The chemical structures of hormones are highly conserved, but through evolution, hormones have acquired different functions in different animal groups. **Review Figure 41.2**
- Two hormones, PTTH and ecdysone, control molting in arthropods. A third hormone, **juvenile hormone**, prevents maturation. When an insect stops producing juvenile hormone, it molts into an adult. **Review Figures 41.3 and 41.4, ANIMATED TUTORIAL 41.1**
- Most hormones are either peptides, proteins, steroids, or amines. Peptide and protein hormones and some amines are water-soluble; steroids and some amines are lipid-soluble.
- Receptors for water-soluble hormones are located on the cell surface. Receptors for most lipid-soluble hormones are inside the cell.
- Hormones can cause different responses in different target cells. **Review Figure 41.5**

41.2 How Do the Nervous and Endocrine Systems Interact?

- In humans, the major endocrine glands are distributed around the body. **Review Figure 41.6, WEB ACTIVITY 41.1**
- The **pituitary gland** is the interface between the nervous and endocrine systems. The **anterior pituitary** develops from embryonic mouth tissue; the **posterior pituitary** develops from the developing brain.
- The posterior pituitary secretes two **neurohormones**: **antidiuretic hormone (ADH)** and **oxytocin**. The anterior pituitary secretes **tropic hormones** (thyrotropin, corticotropin, luteinizing hormone, and follicle-stimulating hormone) as well as **growth hormone**, **prolactin**, melanocyte-stimulating hormone, **endorphins**, and **enkephalins**.
- The anterior pituitary is controlled by neurohormones produced by cells in the **hypothalamus** and transported through **portal blood vessels** to the anterior pituitary. **Review Figures 41.7 and 41.8, ANIMATED TUTORIAL 41.2**
- Hormone release is controlled by negative feedback loops. **Review Figure 41.9**

41.3 What Are the Major Mammalian Endocrine Glands and Hormones?

- The **thyroid gland** is controlled by **thyrotropin** and secretes **thyroxine**, which controls cell metabolism. **Review Figure 41.10**
- The level of calcium in the blood is regulated by three hormones. **Calcitonin** from the thyroid lowers blood calcium by promoting bone deposition. **Parathyroid hormone (PTH)** raises blood calcium by promoting bone turnover and decreasing calcium excretion. **Vitamin D** promotes calcium absorption from the digestive tract. **Review Figure 41.11, ANIMATED TUTORIAL 41.3**
- The **pancreas** secretes three hormones. **Insulin** stimulates glucose uptake by cells and lowers blood glucose, **glucagon** raises blood glucose, and **somatostatin** slows the rate of nutrient processing.
- The **adrenal gland** has two portions, one within the other. The inner portion, the **adrenal medulla**, releases **epinephrine** and **norepinephrine** in response to stress. The outer portion, the **adrenal cortex**, produces three classes of **corticosteroids**: glucocorticoids, mineralocorticoids, and small amounts of sex steroids. **Review Figures 41.12 and 41.13**

- **Aldosterone** is a mineralocorticoid that stimulates the kidneys to conserve sodium and excrete potassium. **Cortisol** is a glucocorticoid that is released in response to stressful stimuli but acts more slowly than the hormones of the adrenal medulla. **Review Figure 41.14**
- Sex hormones (**androgens** in males, **estrogens** and **progestosterone** in females) are produced by the **gonads** in response to tropic hormones. Sex hormones control sexual development, secondary sexual characteristics, and reproductive functions. **Review Figures 41.14 and 41.15**
- The **pineal gland** releases **melatonin**, which is involved in controlling biological rhythms. **Review Figure 41.16**

41.4 How Do We Study Mechanisms of Hormone Action?

- **Immunoassay** techniques are used to measure concentrations of hormones and other substances. **Review Figure 41.17**
- The sensitivity of a cell to hormones can be altered by **down-regulation** or **upregulation** of the receptors in that cell.

SEE WEB ACTIVITY 41.2 for a concept review of this chapter.

SELF-QUIZ

- Before puberty
 - the pituitary secretes luteinizing hormone and follicle-stimulating hormone, but the gonads are unresponsive.
 - the hypothalamus does not secrete much gonadotropin-releasing hormone.
 - males can stimulate massive muscle development through a vigorous training program.
 - testosterone plays no role in development of the male sex organs.
 - genetic females will develop male genitals unless estrogen is present.
- Both epinephrine and cortisol are secreted in response to stress. Which of the following statements is also true for *both* of these hormones?
 - They act to increase blood glucose availability.
 - Their receptors are on the surfaces of target cells.
 - They are secreted by the adrenal cortex.
 - Their secretion is stimulated by corticotropin.
 - They are secreted into the blood within seconds of the onset of stress.
- Growth hormone
 - can cause adults to grow taller.
 - stimulates protein synthesis.
 - is released by the hypothalamus.
 - can be obtained only from cadavers.
 - is a steroid.
- PTH
 - stimulates osteoblasts to lay down new bone.
 - reduces blood calcium levels.
 - stimulates calcitonin release.
 - is produced by the thyroid gland.
 - is released when blood calcium levels fall.
- Steroid hormones
 - are produced only by the adrenal cortex.
 - have only cell surface receptors.
 - are water-soluble.
 - act by altering the activity of proteins in the target cell.
 - act by altering gene expression in the target cell.
- The hormone ecdysone
 - is released from the posterior pituitary.
 - stimulates molting in insects.
 - maintains an insect in larval stages unless PTTH is present.
 - stimulates the secretion of juvenile hormone from the prothoracic glands.
 - keeps the insect exoskeleton flexible to permit growth.
- The posterior pituitary
 - synthesizes oxytocin.
 - is under the control of hypothalamic releasing neurohormones.
 - secretes tropic hormones.
 - secretes neurohormones.
 - is under feedback control by thyroxine.
- Which of the following contributes to the development of goiter?
 - Inadequate iodine in the diet
 - Autoimmune antibodies that stimulate the TSH receptor
 - Lack of feedback from circulating T_3 and T_4
 - Overproduction of thyroglobulin
 - All of the above
- Which of the following is a likely cause of diabetes?
 - Overproduction of insulin by β cells of the pancreas
 - Loss of α cells of the pancreas
 - Loss of insulin receptors
 - Overproduction of glucagon
 - Loss of receptors for somatostatin
- Which statement is true of all hormones?
 - They are secreted by glands.
 - They have receptors on cell surfaces.
 - They may stimulate different responses in different cells.
 - There is a gene that codes for each hormone.
 - When the same hormone occurs in different species, it has the same action.

FOR DISCUSSION

1. Explain how both hyperthyroidism and hypothyroidism can cause goiter. Refer to the roles of the hypothalamus and the pituitary in your answer.
2. Neurons, the cells of the nervous system, do not require insulin. Why might this be so, and why is it important?
3. Various side effects of anabolic steroid abuse were mentioned at the opening of this chapter. Some of these effects are due to the direct action of the steroid, but others are due to the negative feedback action of the steroid. Discuss an example of each and explain possible mechanisms.
4. Compare the characteristics you would expect of a hormone signaling system that controls a short-term process, such as digestion, with the characteristics you would expect of a hormone signaling system that controls a long-term process, such as development.

ADDITIONAL INVESTIGATION

Each spring, male deer grow antlers that they use in male–male competition for mates. Each fall they shed those antlers. Although females of most deer species do not grow antlers, the caribou are an exception. Female caribou grow antlers in the spring but do not shed them in the fall. (Over the winter, they use their antlers to defend patches of food from males.) In addi-

tion, newborn caribou begin to grow antlers after birth. Assuming that antler growth is controlled by hormones, how would you investigate the control of antler growth in caribou? What hormonal assays might you want to use? What hypotheses would you test with respect to the relationship between time of year and antler growth?

The plague of Athens

As a rule, however, there was no ostensible cause; but people in good health were all of a sudden attacked by violent heats in the head, and redness and inflammation in the eyes, the inward parts, such as the throat or tongue, becoming bloody and emitting an unnatural and fetid breath.

The Athenian historian Thucydides wrote these words in 430 BCE. He was describing a rapidly spreading infectious disease, or plague, that was sweeping the city of Athens in ancient Greece, and would ultimately kill about one-third of its inhabitants.

One year earlier, in 431 BCE, the Spartans had surrounded Athens. Sparta was a rival state with a highly disciplined army, while Athens was near a port and had a powerful navy. The Athenian leader Pericles decided to take advantage of his naval supremacy. He instructed his soldiers to abandon the countryside to the Spartans, relying on the navy to keep the enemies out of the city and to keep the Athenians supplied with food. People living in the countryside poured into Athens.

As Athens became more crowded, declining sanitation and close living conditions resulted in the city becoming an incubator for infectious diseases. In his famous *History of the Peloponnesian War*, Thucydides speculated that the plague came to Athens from Africa. His precise clinical description of the disease has provoked great debate among medical historians regarding its nature. In 1994, a burial ground was found near Athens that apparently contained the remains of several dozen people who died in the plague. PCR (polymerase chain reaction) analyses of dental pulp from the skeletons revealed the presence of DNA sequences from the bacterium that causes typhoid fever, and this has been proposed as the cause of the plague. Other scientists disagree, using arguments based on a comparison of Thucydides' account with the clinical description of typhoid fever today.

Whatever the cause, another passage from Thucydides (who was one of the few lucky survivors of the plague) bears noting:

Yet it was with those who had recovered from the disease that the sick and the dying found most compassion. These knew what it was from experience and now had no fear for themselves; for the same man was never attacked twice, never at least fatally.

Two questions arise from this passage: First, how could a person survive the disease? And second, how could the survivors be resistant to further infection?

The Peloponnesian War The blockade of Sparta and its Peloponnesian allies on Athens made the latter crowded and vulnerable to the spread of an infectious disease.

Thucydides The Athenian general wrote a detailed history of the Peloponnesian war and the spread of an infectious disease that killed 1 in 3 Athenians. He survived the disease, presumably because of his immune system.

Almost 2,500 years after Thucydides recorded his observations, we have some answers to these questions. These answers come from studies of the mammalian immune system, which recognizes and fights off pathogens. When Thucydides caught the disease, specialized white blood cells called T cells recognized proteins of the infecting agent on the surfaces of his body's cells. This initiated a series of events that resulted in the killing of infected cells and destruction of the disease agent by antibodies, specific proteins made by a different set of white blood cells called B cells. Some descendants of the T and B cells persisted in his body as "memory cells," which defended him when he was exposed to the disease later. The operation of the mammalian immune system and how its components defend the body are the focus of this chapter.

IN THIS CHAPTER we first describe how the innate, nonspecific immune system prevents most pathogens from entering the body and deals with those that do. Then we look at how the specific, adaptive immune system targets invaders such as the typhoid bacterium, which may have killed the ancient Athenians. We see how the reshuffling of genetic material helps animals fight off the staggering diversity of potential invaders, and finally, we see what happens when this complex and crucial system malfunctions.

CHAPTER OUTLINE

- 42.1** What Are the Major Defense Systems of Animals?
- 42.2** What Are the Characteristics of the Nonspecific Defenses?
- 42.3** How Does Specific Immunity Develop?
- 42.4** What Is the Humoral Immune Response?
- 42.5** What Is the Cellular Immune Response?
- 42.6** How Do Animals Make So Many Different Antibodies?
- 42.7** What Happens When the Immune System Malfunctions?

42.1 What Are the Major Defense Systems of Animals?

Animals have a number of ways of defending themselves against **pathogens**—harmful organisms and viruses that can cause disease. These defense systems are based on the distinction between *self*—the animal's own molecules—and *nonself*, or foreign, molecules. The defensive response involves three phases:

- **Recognition phase.** The organism must be able to discriminate between self and nonself.
- **Activation phase.** The recognition event leads to a mobilization of cells and molecules to fight the invader.
- **Effector phase.** The mobilized cells and molecules destroy the invader.

There are two general types of defense mechanisms:

- **Nonspecific defenses**, or *innate defenses*, provide the first line of defense against pathogens. They typically act very rapidly, and include barriers such as the skin, molecules that are toxic to invaders, and phagocytic cells (**phagocytes**, such as **macrophages**) that ingest invaders. (Recall from Section 6.5 that phagocytosis is a form of endocytosis, in which a cell engulfs a large particle or cell.) This system recognizes broad classes of organisms or molecules and gives a quick response, within minutes or hours. Most animals have nonspecific defenses.
- **Specific defenses** are *adaptive* mechanisms aimed at specific pathogens. For example, a specific defense system can make an antibody protein that will recognize, bind to, and aid in the destruction of a certain virus if that virus ever enters the bloodstream. These systems recognize specific configurations of atoms in a molecule and are typically slow to develop and long-lasting. Specific defense mechanisms are found in vertebrate animals.

Mammals have both kinds of defense mechanism and are the focus of this chapter. In mammals and other vertebrates, the nonspecific and specific mechanisms operate together as a *coordinated* defense system. The nonspecific defenses are the body's first line of defense because the specific defenses often require days or even weeks to become effective.

Blood and lymph tissues play important roles in defense

The components of the mammalian defense system are dispersed throughout the body and interact with almost all of its other tissues and organs. The *lymphoid tissues*, which include the thymus, bone marrow, spleen, and lymph nodes, are essential parts of the defense system (**Figure 42.1**). The blood and lymph are complex systems with nondefensive functions that are discussed in Chapter 50. They each have central roles in defense as well.

The blood and lymph both consist of liquids in which cells are suspended:

- **Blood plasma** is a yellowish solution containing ions, small molecular solutes, and soluble proteins. Suspended in the plasma are red blood cells, white blood cells, and platelets (cell fragments essential to blood clotting). While red blood cells are normally confined to the closed circulatory system (the heart, arteries, capillaries, and veins), white blood cells and platelets are also found in the lymph.
- **Lymph** is a fluid derived from the blood and other tissues that accumulates in intercellular spaces throughout the body. From these spaces, the lymph moves slowly into the vessels of the lymphatic system. Tiny lymph capillaries conduct this fluid to larger ducts that eventually join to-

gether, forming one large vessel, the thoracic duct, which joins a major vein (the left subclavian vein) near the heart. By this system of vessels, the lymph is eventually returned to the blood and the circulatory system.

At many sites along the lymph vessels are small, roundish structures called **lymph nodes**, which contain a type of white blood cell called a **lymphocyte**. As lymph passes through a lymph node, the lymphocytes encounter foreign cells and molecules that have entered the body, and if they are recognized, an immune response is initiated.

White blood cells play many defensive roles

One milliliter of human blood typically contains about *5 billion* red blood cells and *7 million* of the larger white blood cells. All of these cells originate from multipotent stem cells (constantly dividing undifferentiated cells that can form several different cell types) in the bone marrow. Examine **Figure 42.2** and you will see that there are two major families of **white blood cells** (also called *leukocytes*): *phagocytes* and *lymphocytes*. Lymphocytes, which include **B cells** and **T cells**, are smaller than phagocytes and are not phagocytic. Each family contains different types of cells with specialized functions. Natural killer cells and some kinds of phagocytes are also referred to collectively as *granulocytes* because they contain numerous granules (vesicles containing defensive enzymes). Defensive proteins and signals play fundamental roles in the interactions and functioning of these cells.

Immune system proteins bind pathogens or signal other cells

Similar to the actions of hormones, which we discuss in Chapter 41, the cells that defend mammalian bodies work together, interacting with one another and with the cells of invading pathogens. These cell–cell interactions are accomplished by a variety of key proteins, including receptors, other cell surface proteins, and signaling molecules. Four of the major players are listed here, and will be discussed in more detail later in the chapter.

42.1 The Human Lymphatic System A network of ducts and vessels collects lymph from body tissues and carries it toward the heart, where it mixes with blood to be pumped back to the tissues. Other lymphoid tissues, including the thymus, spleen, and bone marrow, are also essential to the body's defense system.

yourBioPortal.com

GO TO Web Activity 42.1 • The Human Defense System

42.2 Blood Cells Multipotent stem cells in the bone marrow can differentiate into red blood cells, platelets, and the various types of white blood cells.

— yourBioPortal.com —

GO TO Animated Tutorial 42.1 • Cells of the Immune System

- **Antibodies** are proteins that bind specifically to certain substances identified by the immune system as nonself or *altered self* (a major histocompatibility protein that has been altered by a pathogen). This binding can inactivate viruses and toxins, and it can act as tag on nonself cells, making them easier for the immune system cells to attack. Antibodies are produced by B cells.
- **Major histocompatibility complex (MHC)** proteins are found in two classes. MHC I proteins are found on the surfaces of most cells in the mammalian body. MHC II proteins are found on most immune system cells. MHC proteins are important self-identifying labels and play a major role in coordinating interactions between lymphocytes and macrophages.
- **T cell receptors** are integral membrane proteins on the surfaces of T cells. They recognize and bind to nonself substances presented with self MHC molecules on the surfaces of other cells.

- **Cytokines** are soluble signaling proteins released by many cell types. They bind to cell surface receptors and alter the behavior of their target cells. Various cytokines activate or inactivate B cells, macrophages, and T cells.

42.1 RECAP

Animals have nonspecific and specific defenses against pathogens. Both kinds of mechanism are based on the ability to differentiate self from nonself. Nonspecific defenses target a broad range of molecules and organisms, while specific defenses target specific configurations of atoms on molecules.

- List the differences between specific and nonspecific defenses. **See p. 874**
- What are the two classes of white blood cells, and how do they function in vertebrate defense systems? **See p. 875 and Figure 42.2**

The outcome of a disease—the life or death of the host—often depends on the success of both rapid, nonspecific responses and long-lasting, specific responses to invading pathogens. We turn now to the nonspecific defenses that protect vertebrates from disease.

42.2 What Are the Characteristics of the Nonspecific Defenses?

Nonspecific defenses are general protection mechanisms that attempt to stop pathogens from invading the body. As noted above, they provide first line of defense, in both time and location. Essentially, they are “ready to go,” in contrast to specific immunity, which takes time to develop after a pathogen or toxin has been recognized as nonself. In mammals, nonspecific mechanisms include physical barriers as well as cellular and chemical defenses (**Table 42.1**).

Barriers and local agents defend the body against invaders

Consider a pathogenic bacterium that causes disease in internal organs and that lands on human skin. The challenges faced

by the bacterium just to reach its target are formidable. First, there is the physical barrier of the skin. Bacteria rarely penetrate intact skin; by the same token, broken skin increases the risk of infection. The saltiness and dryness of skin may not be hospitable to the growth of the invader. On the other hand, there are some bacteria and fungi that normally live and sometimes reproduce in great numbers on our body surfaces without causing disease. They are referred to as **normal flora**. These natural occupants of our bodies form a nonspecific defense because they compete with pathogens for space and nutrients.

Consider a pathogen that lands on the surface of the nose. The mucous membranes found at the inner surfaces of the nose (as well as the digestive, respiratory, and urogenital systems) contain the enzyme **lysozyme**, which attacks the cell walls of many bacteria, causing them to *lyse* (burst open). Mucus in the nose traps airborne microorganisms, and most of those that get past this filter end up trapped in mucus deeper in the respiratory tract. Mucus and trapped pathogens are removed by the beating of cilia in the respiratory passageway, which continuously move a sheet of mucus and its trapped debris up toward the nose and mouth where it can be expelled or swallowed. Sneezing is another way to remove microorganisms from the respiratory tract.

TABLE 42.1
Human Nonspecific Defenses

DEFENSIVE MECHANISM	FUNCTION
Surface barriers	
Skin	Prevents entry of pathogens and foreign substances
Acid secretions	Inhibit bacterial growth on skin
Mucus	Prevents entry of pathogens; produces defensins that kill pathogens
Mucous secretions	Trap bacteria and other pathogens in digestive and respiratory tracts
Nasal hairs	Filter bacteria in nasal passages
Cilia	Move mucus and trapped materials away from respiratory passages
Gastric juice	Concentrated HCl and proteases destroy pathogens in stomach
Acid in vagina	Limits growth of fungi and bacteria in female reproductive tract
Tears, saliva	Lubricate and cleanse; contain lysozyme, which destroys bacteria
Nonspecific cellular, chemical, and coordinated defenses	
Normal flora	Compete with pathogens; may produce substances toxic to pathogens
Fever	Body-wide response inhibits microbial multiplication and speeds body repair processes
Coughing, sneezing	Expels pathogens from upper respiratory passages
Inflammatory response (involves leakage of blood plasma and phagocytes from vessels)	Limits spread of pathogens to neighboring tissues; concentrates defenses; digests pathogens and dead tissue cells; releases chemical mediators that attract phagocytes and lymphocytes to site
Phagocytes (macrophages and neutrophils)	Engulf and destroy pathogens that enter body
Natural killer cells	Attack and lyse virus-infected or cancerous body cells
Antimicrobial proteins	
Interferons	Released by virus-infected cells to protect healthy tissue from viral infection; mobilize specific defenses
Complement proteins	Lyse microorganisms, enhance phagocytosis, and assist in inflammatory and antibody responses

Finally, the mucous membranes produce **defensins**, peptides that are 18–45 amino acids long and contain hydrophobic domains. They are toxic to a wide range of pathogens, including bacteria, microbial eukaryotes, and enveloped viruses. Defensins insert themselves into the plasma membranes of these organisms and make the membranes permeable, thus killing the invaders. Defensins are also produced in phagocytes, where they kill pathogens trapped by phagocytosis. Plants also produce defensins in response to pathogen exposure (see Chapter 39).

Consider a bacterium that lands in the mouth. If it survives the lysozyme in saliva and enters the digestive tract (stomach, small intestine, and large intestine) it is met by other defenses. The gastric juice in the stomach is a deadly environment for many bacteria because of the hydrochloric acid and proteases that are secreted into it. Bacteria cannot normally penetrate the lining of the small intestine, and some pathogens are killed by bile salts secreted into this part of the digestive tract. Any bacteria that survive these lines of defense (which include normal flora) and enter the large intestine are removed quickly with the feces.

All of these barriers and local agents are nonspecific defenses because they act on all invading pathogens in the same way. Most are properties of the tissue, called *epithelial tissue*, that covers surfaces on and within organs. More complex nonspecific defenses await any pathogens that manage to elude this first set of defenses.

Other nonspecific defenses include specialized proteins and cellular processes

Pathogens that penetrate the body's outer and inner surfaces encounter more complex nonspecific defenses. These include the activation of defensive cells and the secretion of various defensive proteins, such as *complement* and *interferon* proteins.

COMPLEMENT PROTEINS Vertebrate blood contains more than 20 different proteins that make up the antimicrobial **complement system**. This system can be activated by various mechanisms, including both nonspecific and specific defense responses. The proteins act in a characteristic sequence, or cascade, with each protein activating the next:

- First, they attach to specific components on the surface of a microbe or to an antibody that has already bound to the microbe's surface. In either case, binding helps phagocytes recognize and destroy the microbe.
- Then, they activate the inflammation response and attract phagocytes to the site of infection.
- Finally, they lyse invading cells (such as bacteria).

INTERFERONS When a cell is infected by a pathogen, it produces small amounts of signaling proteins called **interferons** that increase the resistance of neighboring cells to infection. Interferons are a class of cytokines and have been found in many vertebrates. Various molecules, including double stranded (viral) RNA, induce the production of interferons. Thus interferons are particularly important as a first line of nonspecific defense against viruses. Interferons bind to receptors on the plasma

membranes of uninfected cells, stimulating a signaling pathway that inhibits viral reproduction if the cells are subsequently infected. In addition, interferons stimulate the cells to hydrolyze bacterial or viral proteins to peptides, an initial step in specific immunity (see Section 42.3).

PHAGOCYTES Some phagocytes travel freely in the circulatory and lymphatic systems; others can move out of blood vessels and adhere to certain tissues. Pathogenic cells, viruses, or fragments of these invaders can be recognized by phagocytes, which then ingest them by phagocytosis. Defensins, nitric oxide, and reactive oxygen intermediates inside these phagocytes then kill the pathogens.

NATURAL KILLER CELLS One class of lymphocytes, known as **natural killer cells**, can distinguish virus-infected cells and some tumor cells from their normal counterparts and initiate the apoptosis of these target cells. In addition to this nonspecific action, natural killer cells interact with the specific defense mechanisms by lysing antibody-labeled target cells.

Inflammation is a coordinated response to infection or injury

When tissue is damaged because of infection or injury, the body responds with **inflammation**. This response can happen almost anywhere in the body, internally as well as on the surface. Inflammation is an important phenomenon: it isolates the damaged area to stop the spread of the damage; it recruits cells and molecules to the damaged location to kill the invader; and it promotes healing. The first responders to tissue damage are **mast cells**, which adhere to the skin and the linings of organs, and release numerous chemical signals including:

- **tumor necrosis factor**, a cytokine protein that kills target cells and activates immune cells.
- **prostaglandins**, fatty acid derivatives that play roles in various responses including the widening of blood vessels. Prostaglandins interact with nerve endings and are partly responsible for the pain caused by inflammation.
- **histamine**, an amino acid derivative that leads to itchy, watery eyes, and rashes seen with some types of allergic reactions.

The redness and heat of inflammation result from the dilation and leakiness of blood vessels in the infected or injured area (**Figure 42.3**). Phagocytes enter the inflamed area where they engulf the invaders and dead tissue cells. Phagocytes are responsible for most of the healing associated with inflammation. They produce several cytokines, which (among other functions) signal the brain to produce a fever. This rise in body temperature accelerates lymphocyte production and phagocytosis, thereby speeding the immune response. In some cases, pathogens are temperature-sensitive, and their growth is inhibited. The pain of inflammation results from increased pressure due to swelling, the action of leaked enzymes on nerve endings, and the action of prostaglandins, which increase the sensitivity of the nerve endings to pain.

—yourBioPortal.com—

GO TO Web Activity 42.2 • Inflammation Response

Following inflammation, pus may accumulate. Pus is a mixture of leaked fluid and dead cells: bacteria, neutrophils (the most abundant white blood cells—see Figure 42.2), and damaged body cells. Pus is a normal result of inflammation, and is gradually consumed and further digested by phagocytes called macrophages.

Inflammation can cause medical problems

While inflammation is generally a good thing, sometimes the inflammatory response is inappropriately strong, resulting in some allergies, cases of autoimmunity, and sepsis. In these cases, the response causes more damage than was originally there. We will discuss allergy and autoimmune diseases in Section 42.7. In some cases of severe bacterial infection, the inflammation response does not remain local. Instead, it extends throughout the bloodstream in a condition called *sepsis*. As in a local infection or injury, blood vessels dilate, but they do so throughout the body. The lowering of blood pressure that results is a medical emergency and can be lethal.

The symptoms of swelling, pain, and fever caused by excessive inflammation can be bothersome to the point of incapacitation. Diseases such as rheumatoid arthritis and chronic

obstructive pulmonary disease, and accidents such as athletic injuries result in tissue damage and an inflammatory response. In order to manage excessive inflammation, drugs have been developed that act on the various cytokines and signal pathways to reduce inflammation and its symptoms. For example, the bark of the willow tree, *Salix*, has been known for millennia to contain a potent antidote to fever and swelling. In the nineteenth century the active ingredient, salicylic acid, was isolated and a better version, acetylsalicylic acid, was made. This drug—also called aspirin—works by inhibiting an enzyme on the pathway to the synthesis of prostaglandins. Other anti-inflammatory drugs act on the prostaglandin pathway, on the actions of tumor necrosis factor, and on the actions of histamine.

Cell signaling pathways stimulate the body's defenses

An invading pathogen can be regarded as a signal. In response to that signal, the body produces molecules (complement proteins, interferons, and other cytokines) that regulate phagocytosis and other defense processes. Not surprisingly, the link between signal and response is a signal transduction pathway, similar to the ones we considered in Section 7.3. A key group of receptors is called the **toll-like receptors**. The toll protein was first identified in insects, where it is involved in development and in sensing infection. Comparative genomics has revealed at least ten similar receptors in humans.

Toll-like receptors are part of a protein kinase cascade that ultimately results in the transcription of at least 40 genes in-

42.4 Cell Signaling and Defense Binding of a pathogenic molecule to the toll-like receptor initiates a signal transduction pathway which results in the transcription of genes whose products are involved in specific and nonspecific defenses. CD14 is expressed on the surface of white blood cells, including macrophages and monocytes.

involved in both nonspecific and specific defenses (**Figure 42.4**). The CD14 protein (for cluster of differentiation) is a membrane protein that binds to the toll-like receptor. Among the molecules that stimulate this pathway are bacterial and fungal cell wall fragments. Binding of these fragment molecules to the receptor sets in motion a cascade of molecular changes that results in a change in the three-dimensional structure of the transcription factor NF- κ B. (NF- κ B stands for *nuclear factor kappa light chain enhancer of activated B cells*. It is a key transcription factor in the activation of both the nonspecific and specific immune systems.) The shape change allows NF- κ B to enter the nucleus, bind to the promoters of genes, and activate the transcription of genes encoding defensive proteins.

42.2 RECAP

Nonspecific defenses are the first line of defense against pathogens. These include physical barriers such as the skin; defensive proteins; and coordinated responses such as inflammation.

- How do complement proteins and interferons defend the body against microbes? **See p. 578**
- Describe the inflammation response. **See pp. 878–879 and Figure 42.3**

Often the innate immune system, with its nonspecific defenses, is adequate to prevent or fight off a pathogenic infection. But in

many cases, this system works together with specific immunity, which adapts to a particular pathogen. We now turn to the development and functioning of specific immunity.

42.3 How Does Specific Immunity Develop?

Before the twentieth century, scientists had long suspected that blood was somehow involved in immunity against pathogens. Over a century ago, Emil von Behring and Shibasaburo Kitasato at the University of Marburg in Germany performed a key experiment that pointed to blood as an important factor in specific immunity (**Figure 42.5**). They showed that guinea pigs injected with a sublethal dose of diphtheria toxin developed in their blood serum (the noncellular fluid that remains after blood is clotted) a factor that protected other guinea pigs from a lethal dose of the same toxin. In other words, the recipients had developed **immunity**. Moreover, the immunity was specific: the immune factor made by the guinea pigs protected only against the specific toxin, from one strain of diphtheria-causing bacteria, that they had been injected with.

Based on the animal model, Behring realized that serum protection might work in human diseases as well. It did, and he won the Nobel Prize for his efforts in protecting children against diphtheria. Later, the agent of this immunity was identified as an antibody protein, and the process of developing immunity from antibodies received from another individual was called *passive immunity*.

In this section we outline the main features of the specific immune system, much of which does indeed occur in blood serum. We will consider the two major types of specific responses: the *humoral immune response*, which produces antibodies; and the *cellular immune response*, which destroys infected cells.

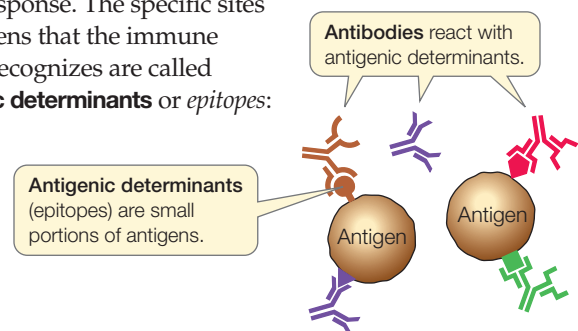

yourBioPortal.com

GO TO Animated Tutorial 42.2 • Pregnancy Test

Adaptive immunity has four key features

Four important features of the adaptive immune system are: specificity; the ability to distinguish self from nonself; the ability to respond to an enormous diversity of nonself molecules; and immunological memory.

SPECIFICITY Lymphocytes (B and T cells) are crucial components of specific immunity. T cell receptors and the antibodies produced by B cells recognize and bind to specific nonself or altered self substances (**antigens**), and this interaction initiates a specific immune response. The specific sites on antigens that the immune system recognizes are called **antigenic determinants** or **epitopes**:

INVESTIGATING LIFE

42.5 The Discovery of Specific Immunity

Until the twentieth century, most people did not survive an attack of the bacterium that causes diphtheria, but a few did. Emil von Behring and Shibasaburo Kitasato performed a key experiment using an animal model, and demonstrated that the factor(s) responsible for immunity against diphtheria were in blood serum.

HYPOTHESIS Serum from guinea pigs injected with a sublethal dose of diphtheria toxin protects other guinea pigs that are exposed to a lethal dose of the toxin.

METHOD

CONCLUSION Serum of toxin-exposed guinea pigs is protective against later exposure to a lethal dose of the toxin from the same genetic strain of bacteria, but not a different strain.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

bind to the antigenic determinants. Each T cell and each antibody is specific for a single antigenic determinant.

For the remainder of the chapter, we will refer to antigenic determinants simply as “antigens.”

DISTINGUISHING SELF FROM NONSELF The human body contains tens of thousands of different proteins, each with a specific three-dimensional structure capable of generating immune responses. Thus every cell in the body bears a tremendous number of antigens. A crucial requirement of an individual’s immune system is that it recognize the body’s own antigens and not attack them. This is accomplished by clonal deletion, which you will encounter in a few pages.

DIVERSITY Challenges to the immune system are numerous. Pathogens take many forms: viruses, bacteria, protists, fungi, and multicellular parasites. Furthermore, each pathogenic species usually exists as many subtly different genetic strains, and each strain possesses multiple surface features. Estimates vary, but a reasonable guess is that humans can respond specifically to 10 million different antigens. Upon recognizing an antigen, the immune system responds by activating lymphocytes of the appropriate specificity. This capacity is accomplished by a special genetic recombination mechanism described in Section 42.6.

IMMUNOLOGICAL MEMORY After responding to a particular type of pathogen once, the immune system “remembers” that pathogen and can usually respond more rapidly and powerfully to the same threat in the future. This **immunological memory** usually saves us from repeats of childhood diseases such as chicken pox. Vaccination against specific diseases works because the immune system “remembers” the antigens that were introduced into the body.

All four of these features of specific immune defense characterize both the humoral immune response and the cellular immune response.

Two types of specific immune responses interact: an overview

The specific immune system mounts two types of responses against invaders: the humoral immune response and the cellular immune response. B cells that make antibodies are the workhorses of the humoral immune response, and cytotoxic

An antigenic determinant is a specific portion of a large molecule, such as a certain sequence of amino acids that may be present in a protein. Antigens are usually proteins or polysaccharides, and there can be multiple antigens on a single invading bacterium. A single antigenic molecule can have multiple, different antigenic determinants. The host animal responds to the presence of an antigen with highly specific defenses involving T cell receptors and antibodies. These receptors and soluble proteins

42.6 The Specific Immune System Humoral immunity involves the production of antibodies by B cells. Cellular immunity involves the activation of cytotoxic T cells that bind to cells expressing the antigen. For further details, see Figure 42.13.

(killer) T cells are the workhorses of the cellular immune response. These two responses operate simultaneously and cooperatively, sharing many mechanisms. A key event early in these two processes is the exposure of the antigen's three-dimensional structure to the immune system. This occurs when an antigenic molecule, or a fragment of the molecule, is inserted into the plasma membrane of a cell and the unique epitope structure protrudes from the membrane, where it is exposed to nearby T or B cells. Many different types of cell can "present" the antigen to the immune system in this way, and they are collectively referred to as **antigen-presenting cells**. **Figure 42.6** provides an overview of antigen presentation and the roles of T and B cells in the immune response. The key player integrating the two responses is the *T-helper* (T_H) cell. By binding to the antigen on a presenting cell, the T_H cell stimulates events in both responses.

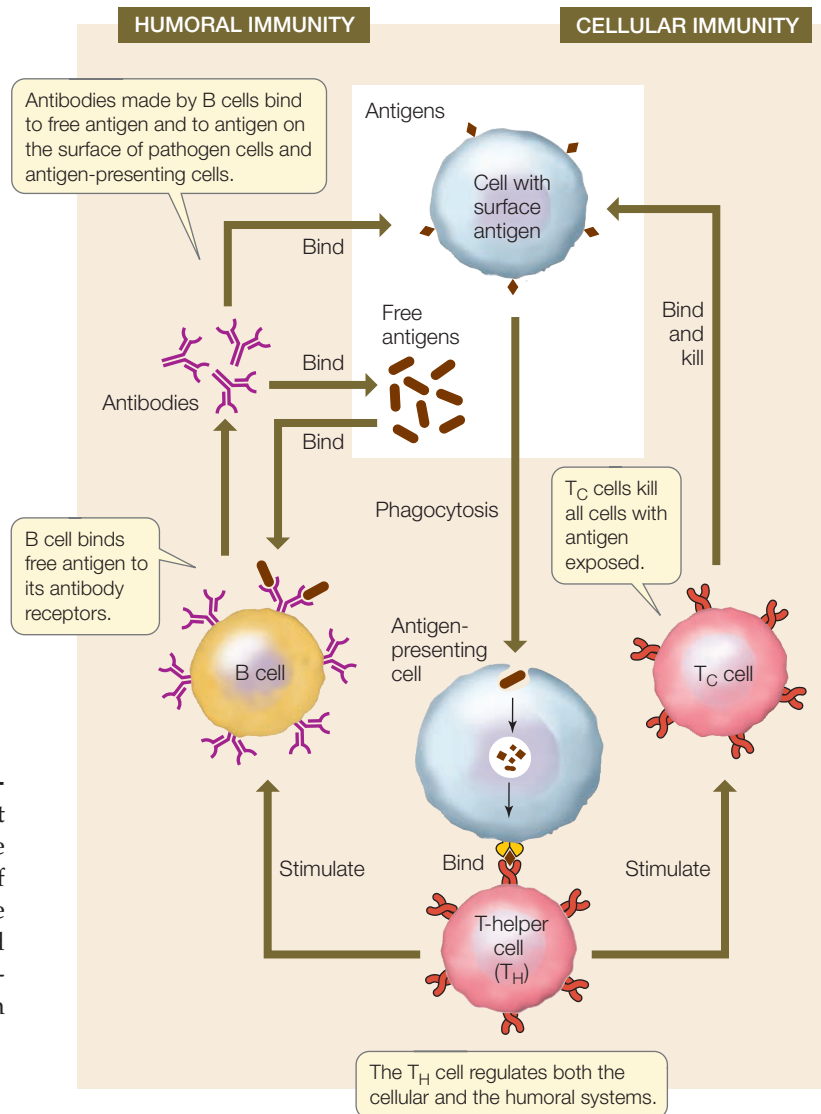

HUMORAL IMMUNE RESPONSE In the **humoral immune response** (from the Latin *humor*, "fluid"), antibodies react with antigens on pathogens in blood, lymph, and tissue fluids. An animal can produce a staggering diversity of antibodies capable of binding to almost any conceivable antigen the animal encounters. Antibodies are secreted by B cells and travel free in the blood and lymph. A particular B cell also possesses receptors on its surface with the same specificity as the antibodies it produces.

The first time a specific antigen invades the body, it may be presented and then detected by binding to a B cell receptor. This binding activates the B cell, which makes and secretes multiple copies of the antibody.

CELLULAR IMMUNE RESPONSE The **cellular immune response** is directed against antigens that have become established within a cell of the host animal. It detects and destroys virus-infected or mutated cells, such as cancer cells expressing unique proteins caused by mutations.

T cells within the lymph nodes, the bloodstream, and the intercellular spaces carry out the cellular immune response. These T cells have integral membrane proteins—T cell receptors—that recognize and bind to antigens. T cell receptors are rather similar to antibodies in structure and function, each including specific molecular configurations that bind to specific antigens.

Once a T cell is bound to an antigen, it initiates an immune response that typically results in the total destruction of the antigen-containing cell.

Genetic changes and clonal selection generate the specific immune response

Before the reactions just described for the humoral and cellular immune responses can take place, the body needs to generate a vast diversity of lymphocytes that have the ability to bind different antigens. How does this tremendous diversity arise? How do lymphocytes specific for certain antigens proliferate? The answers lie in the processes of DNA rearrangement and **clonal selection**. These processes generate the enormous numbers of different receptors with antibody-like specificities in the

42.7 Clonal Selection in B Cells The binding of an antigen to a specific receptor on the surface of a B cell stimulates that cell to divide, producing a clone of genetically identical cells to fight that invader.

B and T lymphocytes, even before the body encounters antigens for these receptors.

- *Diversity is generated primarily by DNA changes*—chromosomal rearrangements and other mutations—that occur just after the B and T cells are formed in the bone marrow. Each B cell is able to produce only one kind of antibody; thus there are millions of different B cells. Similarly, there are millions of different T cells with specific T cell receptors. We will describe the mechanisms for the formation of these antibodies and receptors later in the chapter. For now, keep in mind that the adaptive immune system is “predeveloped”—*all of the machinery available to respond to an immense diversity of antigens is already there, even before the antigens are ever encountered.*
- *Antigen binding “selects” a particular B or T cell for proliferation.* When an antigen fits the surface receptor on a B cell and binds to it, that B cell is activated. It divides to form a clone of cells (a genetically identical group derived from a single cell), all of which produce and secrete antibodies with the same specificity as the receptor (**Figure 42.7**). Binding, activation, and proliferation also apply to T lymphocytes. When a foreign or abnormal cell antigen binds to a T cell receptor, that binding activates the proliferation of T cells with that particular receptor. Binding and activation select a particular lymphocyte, while proliferation generates the clone, hence the term “clonal selection.”

Immunity and immunological memory result from clonal selection

The first time a vertebrate animal is exposed to a particular antigen there is a time lag (usually several days) before the B-cell-produced antibody molecules and T cells specific to that antigen slowly increase. But for years afterward—sometimes for life—the immune system “remembers” that particular antigen. How does this happen?

The answer lies in the fact that activated lymphocytes divide and differentiate to produce *two types* of daughter cells: effector cells and memory cells.

- **Effector cells** carry out the attack on the antigen. Effector B cells, called **plasma cells**, secrete antibodies. Effector T cells release cytokines and other molecules that initiate reactions that destroy nonself or altered cells. Effector cells live only a few days.
- **Memory cells** are long-lived cells that retain the ability to start dividing on short notice to produce more effector and more memory cells. Memory B and T cells may survive in the body for decades, rarely dividing.

These two types of lymphocytes can respond to an antigen in two different ways:

- When the body first encounters a particular antigen, a **primary immune response** is activated, in which the “naïve” (previously unexposed to antigen) lymphocytes that recognize that antigen proliferate to produce clones of effector and memory cells.
- After a primary immune response to a particular antigen, subsequent encounters with the same antigen will trigger a much more rapid and powerful **secondary immune response**. The memory cells that bind with that antigen proliferate, launching a huge army of plasma cells and effector T cells.

Vaccines are an application of immunological memory

You will recall Behring’s experiment on using the serum of diphtheria-exposed animals to protect other animals from the disease (see Figure 42.5). As we noted, he later used this method on people to cause passive immunity. Now we can contrast this with *active immunity*, in which the immune system develops a specific response, including memory cells that lead to long-term

protection. The animals that survived diphtheria and donated serum in Berhing’s experiment had active immunity.

Thanks to active immunity and immunological memory, exposure to many diseases, such as chicken pox, provides a natural immunity to those diseases. Furthermore, it is possible to provide artificial immunity against many life-threatening diseases by **vaccination**: the introduction of antigen into the body in a form that does not cause disease.

Vaccination initiates a primary immune response, generating memory cells without making the person ill. Later, if a pathogen carrying the same antigen attacks, specific memory cells already exist. They recognize the antigen and quickly overwhelm the invaders with a massive production of lymphocytes and antibodies.

Because the antigens used for immunization or vaccination are produced by pathogenic organisms, they must be altered so that they cannot cause disease but are still able to provoke an immune response. There are three principal ways to do this:

- *Inactivation* involves killing the pathogen with heat or chemicals.
- *Attenuation* involves reducing the virulence of a virus by repeatedly infecting cells with it in the laboratory; this results in mutations in the virus that render it nontoxic but still recognized as nonself.
- *Recombinant DNA technology* can be used to produce peptide fragments that bind to and activate lymphocytes but do not have the harmful part of a protein toxin.

For most of the 70 or so bacteria, viruses, fungi, and parasites known to cause serious human diseases, vaccines are already available or will be in the next few years (**Table 42.2**). Vaccination has completely or almost completely wiped out some deadly diseases, including smallpox, diphtheria, and polio, in industrialized countries.

Animals distinguish self from nonself and tolerate their own antigens

Normally, the body is *tolerant* of its own molecules—the same molecules that would generate an immune response in another individual. This occurs primarily during the early differentiation of T and B cells, when they encounter self antigens. Any immature B or T cell that shows the potential to mount an immune response

TABLE 42.2		
Some Human Pathogens for which Vaccines are Available		
INFECTIOUS AGENT	DISEASE	VACCINATED POPULATION
Bacteria		
<i>Bacillus anthracis</i>	Anthrax	Those at risk in biological warfare
<i>Bordetella pertussis</i>	Whooping cough	Children and adults
<i>Clostridium tetani</i>	Tetanus	Children and adults
<i>Corynebacterium diphtheriae</i>	Diphtheria	Children
<i>Haemophilus influenzae</i>	Meningitis	Children
<i>Mycobacterium tuberculosis</i>	Tuberculosis	All people
<i>Salmonella typhi</i>	Typhoid fever	People in areas exposed to agent

Varicella-zoster virus	Chicken pox	Children

against self antigens undergoes programmed cell death (apoptosis) within a short time. This process is called **clonal deletion**.

42.3 RECAP

The specific immune system reacts against nonself or altered self molecules called antigens. The system generates amazing diversity. Immunological memory arises from clonal selection.

- How does an antigen initiate a specific immune response? **See pp. 881–882**
- Describe clonal selection. How does it contribute to immunological memory? **See pp. 882–883 and Figure 42.7**
- How do vaccines make use of immunological memory? **See pp. 883–884**

Now that we understand the general features of the specific immune system, let’s focus in more detail on the B lymphocytes and the humoral immune response.

42.4 What Is the Humoral Immune Response?

Every day, billions of B cells survive the test of clonal deletion and are released from the bone marrow into the circulation. B cells are the basis for the humoral immune response.

yourBioPortal.com

GO TO Animated Tutorial 42.3 • Humoral Immune Response

Some B cells develop into plasma cells

A B cell begins by making a receptor protein on its cell surface. As we have seen, if a B cell is activated by antigen binding to this receptor, it gives rise to clones of plasma cells and memory cells. The plasma (effector B) cells secrete antibodies into the bloodstream (see Figure 42.7).

Usually, for a naïve B cell (one that has not yet been exposed to antigen) to develop into an antibody-secreting plasma cell, a T-helper cell (T_H) with the same specificity must also bind to the antigen (see Figure 42.6). The division and differentiation of the B cell is stimulated by the receipt of chemical signals from the T_H cell. Thus, as we will see in Section 42.5, the B cell also functions as an antigen-presenting cell.

As plasma cells develop, the number of ribosomes and the amount of endoplasmic reticulum in their cytoplasm increase greatly (Figure 42.8). These increases allow the cells to synthesize and secrete large amounts of antibody proteins—up to 2,000

42.8 A Plasma Cell A prominent nucleus with a large amount of heterochromatin (dark brown) and a cytoplasm crowded with rough endoplasmic reticulum (purple) are features of a cell that is actively synthesizing and exporting proteins. In this case, a B cell is making a specific antibody. Whole blocks of genes not needed for this specialized function are kept inactive in the heterochromatin.

per second! *All the plasma cells arising from a given B cell produce antibodies that are specific for the antigen that originally bound to the parent B cell.* Thus antibody specificity is maintained as B cells proliferate.

Different antibodies share a common structure

Antibodies belong to a class of proteins called **immunoglobulins**. There are several types of immunoglobulins, but all contain a tetramer consisting of four polypeptide chains (Figure 42.9). In each immunoglobulin molecule, two of these polypeptides are identical *light chains*, and two are identical *heavy chains*.

42.9 The Structure of An Immunoglobulin Four polypeptide chains (two light, two heavy) make up an immunoglobulin molecule. Here we show both diagrammatic (A) and space-filling (B) representations of immunoglobulin.

yourBioPortal.com

GO TO Web Activity 42.3 • Immunoglobulin Structure

Disulfide bonds hold the chains together. Each polypeptide chain has a constant region and a variable region:

- The amino acid sequences of the **constant regions** are similar among the immunoglobulins. They determine the destination and function—the class—of each immunoglobulin.
- The amino acid sequences of the **variable regions** are different for each specific immunoglobulin. Their three-dimensional antigen-binding sites are determined by their secondary structures, and are responsible for antibody specificity.

The two antigen-binding sites on each immunoglobulin molecule are identical, making the antibody *bivalent* (*bi*, “two”; *va-lent*, “binding”). This ability to bind two antigen molecules at once, along with the existence of multiple epitopes on each antigen, permits antibodies to form large complexes with the antigens. For example, one antibody might bind two molecules of an antigen. Another antibody might bind the same antigen at a different epitope. It may bind one of the antigen molecules that is already bound to the first antibody, along with a third antigen molecule. A third antibody may bind one of the antigen molecules that is already part of the complex, and a fourth antigen molecule. This binding of multiple antigens and multiple antibodies can result in large complexes that are easy targets for ingestion and breakdown by phagocytes.

There are five classes of immunoglobulins

While the variable regions are responsible for the specificity of an immunoglobulin, the constant regions of the heavy chain determine the class of the immunoglobulin—for example, whether it

will be an integral membrane receptor or a soluble antibody that is secreted into the bloodstream. The five immunoglobulin classes are described in **Table 42.3**. The most abundant class is IgG; these soluble antibody proteins make up about 80 percent of the total immunoglobulin content of the bloodstream. They are made in greatest quantity during a secondary immune response. IgG molecules defend the body in several ways. For example, after some IgG molecules bind to antigens, they become attached by their heavy chains to macrophages. This attachment permits the macrophages to destroy the antigens by phagocytosis.

Monoclonal antibodies have many uses

The specificity of antibodies suggested to scientists that they might be useful for detecting specific substances in the laboratory. Suppose that a physician wishes to measure the level of the hormone estrogen in a woman’s blood. Because hormones are present in such minute amounts, their concentrations cannot usually be measured effectively by conventional chemical methods. A more sensitive method is needed. One way would be to add an antibody specific for estrogen to a sample of the patient’s blood and observe how much antigen–antibody complex formed.

However, the immune response to a complex antigen is polyclonal—that is, most antigens carry many different antigenic determinants and will produce a complex mixture of antibodies, each made by a different clone of B cells. Furthermore, as emphasized in our study of biochemistry, many biological molecules share regions of similar structure—all human steroid hormones, for example, have a similar multi-ring structure (see Fig-

TABLE 42.3				
Antibody Classes				
CLASS	GENERAL STRUCTURE		LOCATION	FUNCTION
IgG	Monomer		Free in blood plasma; about 80 percent of circulating antibodies	Most abundant antibody in primary and secondary immune responses; crosses placenta and provides passive immunization to fetus
IgM	Pentamer		Surface of B cell; free in blood plasma	Antigen receptor on B cell membrane; first class of antibodies released by B cells during primary response
IgD	Monomer		Surface of B cell	Cell surface receptor of mature B cell; important in B cell activation
IgA	Dimer		Saliva, tears, milk, and other body secretions	Protects mucosal surfaces; prevents attachment of pathogens to epithelial cells
IgE	Monomer		Secreted by plasma cells in skin and tissues lining gastrointestinal and respiratory tracts	Binds to mast cells and basophils to sensitize them to subsequent binding of antigen, which triggers release of histamine that contributes to inflammation and some allergic responses

ure 3.22). A polyclonal group of antibodies targeted to estrogen might be uninformative because some of the antibodies would bind to any steroid hormone present in the blood sample. More useful would be a clone of B cells that produce large amounts of an antibody that binds to only one specific epitope—a **monoclonal antibody**. How could such a clone be produced?

A clone of cells that produce a single antibody can be made artificially by fusing a single B cell (which has a finite lifetime and makes a lot of antibody) with a tumor cell (which has an infinite lifetime and can be grown in culture). The resulting hybrid cell, called a **hybridoma**, makes a specific monoclonal antibody and proliferates in culture (**Figure 42.10**). In order to produce useful monoclonal antibodies by this approach, the hybridoma clones must be screened to isolate those producing antibodies that are specific for the target molecule. Recently, new methods have been developed for producing monoclonal antibodies using recombinant DNA technology. These approaches do not require the injection of live animals with antigen, the isolation of their B cells, or the production and screening of hybridomas.

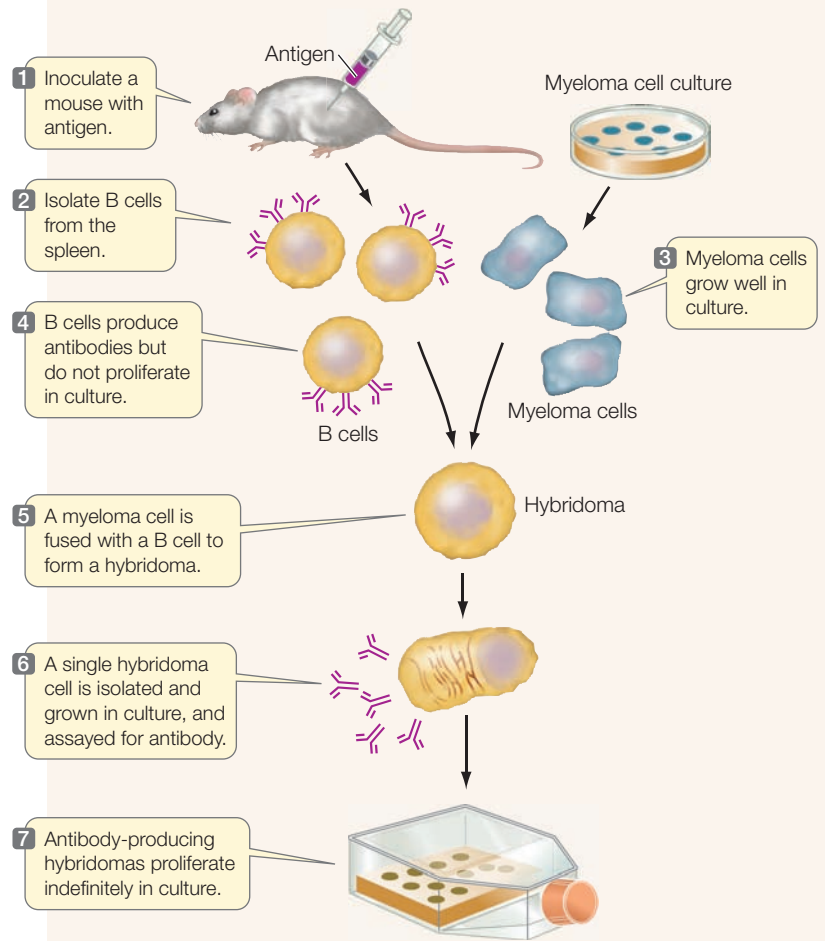

Monoclonal antibodies have many applications:

- **Immunoassays** use monoclonal antibodies to detect tiny amounts of molecules in tissues and fluids. For example, this technique is used in pregnancy tests to detect human chorionic gonadotropin, the hormone made by the developing embryo.
- **Immunotherapy** uses monoclonal antibodies targeted against antigens on the surfaces of cancer cells. The coupling of a radioactive ligand or toxin to the antibody makes it into a medical “smart bomb.” In a related approach, binding of the antibody itself is enough to trigger a cellular immune response that destroys the cancer. This is the case with trastuzumab (Herceptin®), a monoclonal antibody that binds to a growth factor receptor on some breast cancer cells.

TOOLS FOR INVESTIGATING LIFE

42.10 Creating Hybridomas for the Production of Monoclonal Antibodies

Cancerous myeloma cells and normal B cells can be fused so that the proliferative properties of the myeloma cells are combined with the ability to produce specific antibodies.

42.4 RECAP

The humoral immune response is based on the synthesis by B cells of specific antibodies directed against antigens. The specificity of an antibody derives from the amino acid sequence of its variable regions. Monoclonal antibodies are specific to one epitope on an antigen and can be produced artificially for use in diagnostics and therapy.

- How does a B cell respond to an antigen? **See p. 885**
- How is the structure related to the function of an antibody molecule? **See pp. 885–886 and Figure 42.9**
- What are monoclonal antibodies? How are they used? **See pp. 886–887 and Figure 42.10**

By making antibodies, B cells are the major players in the humoral immune response. We now turn to the cellular immune response, where T cells are active at all stages.

42.5 What Is the Cellular Immune Response?

Two types of effector T cells (T-helper cells and cytotoxic T cells) are involved in the cellular immune response, along with proteins of the major histocompatibility complex, the MHC proteins, which underlie the immune system’s tolerance for the body’s own cells.

yourBioPortal.com

GO TO Animated Tutorial 42.4 • Cellular Immune Response

T cell receptors bind to antigens on cell surfaces

Like B cells, T cells possess specific membrane receptors. The T cell receptor is not an immunoglobulin, however, but a glycoprotein with a molecular weight of about half that of an IgG. It is made up of two polypeptide chains, each encoded by a separate gene (Figure 42.11). Thus the two chains have distinct regions with constant and variable amino acid sequences. As in the immunoglobulins, the variable regions provide the site for specific binding to antigens. But there is one major difference: whereas antibodies bind to an intact antigen such as a protein, T cell receptors bind to a piece of an antigen, such as a peptide from the protein displayed on the surface of an antigen-presenting cell.

When a T cell is activated by contact with a specific antigen, it proliferates and forms a clone. Its descendants differentiate into two types of effector T cells:

- **Cytotoxic T cells**, or T_C cells, recognize virus-infected or mutated cells and kill them by inducing lysis (see page 890).
- **T-helper cells** (T_H cells, also called helper T cells) assist both the cellular and the humoral immune responses.

How do T lymphocytes recognize surface antigens on cells without attacking the body’s own cells? The answers to these questions involve a group of proteins encoded by the *MHC* genes.

MHC proteins present antigen to T cells

Since recognition between biological molecules involves three-dimensional structure (think of enzymes, receptors, and antibodies), it makes sense that recognition at the cellular level must also involve structure—in this case, the cell surface. Several types of mammalian cell surface proteins are involved in this process, but we will focus here on the products of a cluster of genes called the *major histocompatibility complex*, or MHC.

The MHC proteins are plasma membrane glycoproteins. Their major role is to present antigens or fragments of antigens to a T cell receptor in such a way that it can distinguish be-

42.11 A T Cell Receptor The receptors on T lymphocytes are smaller than those on B lymphocytes, but their two polypeptides contain both variable and constant regions. As with the B cell receptors, the constant region fixes the receptor in the plasma membrane, while the variable regions establish the specificity for binding to antigen.

TABLE 42.4

The Interaction between T Cells and Antigen-Presenting Cells

PRESENTING CELL TYPE	ANTIGEN PRESENTED	MHC CLASS	T CELL TYPE	T CELL SURFACE PROTEIN
Any cell	Intracellular protein fragment	Class I	Cytotoxic T cell (T_C)	CD8
Macrophages and B cells	Fragments from extracellular proteins	Class II	Helper T cell (T_H)	CD4

tween self and nonself antigens. In humans, there are three genetic loci for MHC class I proteins and three for MHC class II proteins. Each of these six loci has as many as 100 different alleles. With so many possible allele combinations, it is not surprising that different people are very likely to have different MHC genotypes. So the unique three-dimensional structure of the MHC protein is important in self-tolerance: the T cell receptor binds to the MHC and the antigen together.

There are two classes of MHC proteins. Both function to present antigens to the different T lymphocytes:

- **Class I MHC** proteins are present on the surface of every nucleated cell in the animal body. When cellular proteins are degraded into small peptide fragments by a proteasome (see Figure 16.24), an MHC I protein may bind to a fragment and carry it to the plasma membrane. There, the MHC I protein is oriented in such a way that the bound fragment is exposed to the outside of the cell, where both the MHC and the fragment can interact with T_C cells. The T_C cells have a surface protein called CD8 that recognizes and binds to MHC I.
- **Class II MHC** proteins are found mostly on the surfaces of B cells, macrophages, and other antigen-presenting cells (see Figure 42.2). When one of these cells ingests a nonself antigen such as a virus, the antigen is broken down in a phagosome. An MHC II molecule may bind to one of the fragments and carry it to the cell surface, where it is presented to a T_H cell (Figure 42.12). T_H cells have a surface protein called CD4 that recognizes and binds to MHC II.

The information on MHC proteins, the cellular origins of antigens, and T lymphocytes is summarized in Table 42.4. To accomplish their role in antigen presentation, both MHC I and MHC II proteins have an antigen-binding site, which can hold a peptide of about 10–20 amino acids. The T cell receptor recognizes not just the antigenic fragment, but the MHC I or MHC II molecule to which the fragment is bound.

MHC proteins play a vital role in the selection of T cells during their development:

1. **Binding to self MHC molecules.** The ultimate goal is for the T cell receptor to bind not to the antigen alone but to the antigen–MHC complex. Here, there is positive selection for T

42.12 Macrophages Are Antigen-Presenting Cells A fragment of an antigen is displayed by MHC II on the surface of a macrophage. T cell receptors on a specific T-helper cell can then bind to and interact further with the antigen–MHC II complex.

cells that bind. Any T cells that do not recognize self MHC (do not bind to the antigen-presenting cell) are eliminated soon after they develop; the rest of the T cells go on to the next selection step.

2. *Binding to self peptides bound to self MHC.* Here, there is negative selection for T cells that bind, thereby eliminating the further production of T cells that react to self antigens. Both of these selection events occur in the thymus gland (see Figure 41.6).

T-helper cells and MHC II proteins contribute to the humoral immune response

When a T_H cell survives the selection processes and binds to an antigen-presenting macrophage, it releases cytokines, which ac-

tivate the T_H cell to proliferate, producing a clone of T_H cells with the same specificity. The steps to this point constitute the activation phase of the humoral immune response, and they occur in the lymphoid tissues. Next comes the effector phase, in which the T_H cells activate naïve B cells with the same specificity to produce antibodies.

B cells are also antigen-presenting cells. B cells take up antigens bound to their surface immunoglobulin receptors by endocytosis, break them down, and display antigenic fragments on class II MHC proteins. When a T_H cell binds to the displayed antigen–MHC II complex, it releases cytokines that cause the B cell to produce a clone of plasma cells (Figure 42.13A). Finally, the plasma cells secrete antibodies, completing the effector phase of the humoral immune response.

Cytotoxic T cells and MHC I proteins contribute to the cellular immune response

Class I MHC proteins play a role in the cellular immune response that is similar to the role played by class II MHC proteins in the humoral immune response. In a virus-infected or mutated cell, foreign or abnormal proteins or peptide fragments combine with MHC I molecules. The resulting complex is displayed on the cell surface and presented to T_C cells. When a T_C cell recognizes and binds to this antigen–MHC I complex, it is activated to proliferate (Figure 42.13B).

In the effector phase of the cellular immune response, T_C cells recognize and bind to cells bearing the same antigen–MHC I complex. These bound T_C cells produce a substance called *perforin*, which lyses the bound target cell. In addition, the T_C cells can bind to a specific receptor (called Fas) on the target cell that initiates apoptosis in that cell. These two mechanisms, cell lysis and programmed cell death, work in concert to eliminate the antigen-containing host cell. Because T_C cells recognize self MHC proteins complexed with nonself antigens, they help rid the body of its own virus-infected cells.

In addition to the binding of an antigen–MHC complex to its receptors, a T cell must receive a second signal for activation. This *co-stimulatory* signal occurs after the initial specific binding. It involves the interaction between another receptor on the T cell surface and a protein called B7 on certain antigen-presenting cells. This second binding event leads to T cell activation, including cytokine production and proliferation.

Regulatory T cells suppress the humoral and cellular immune responses

As we describe in Chapter 40, *homeostasis*—the maintenance of internal constancy—is a hallmark of animal biology. A third class of T cells called **regulatory T cells (Tregs)** ensures that the immune response does not spiral out of control. Like T_H and T_C cells, Tregs are made in the thymus gland, express the T cell receptor, and become activated if they bind to antigen–MHC complexes. But Tregs are different in one important way: the antigens that Tregs recognize are *self antigens*. The activation of Tregs causes them to secrete the cytokine *interleukin 10*, which blocks T cell activation and leads to apopto-

(A)

(B)

**42.13 Phases of the Humoral and Cellular Immune Responses**

Both the humoral and the cellular immune responses have activation and effector phases, all of which involve T cells.

42.14 Tregs and Tolerance A special class of T cells called regulatory T cells (Tregs) inhibit the activation of the immune system in response to self antigens.

sis of the T_C and T_H cells that are bound to the same antigen-presenting cell (**Figure 42.14**).

The important role of Tregs is to maintain homeostasis by mediating tolerance to “self” antigens. Thus they constitute one of the mechanisms for distinguishing self from nonself. How do we know this? There are two lines of evidence for the role of Tregs. As in many other biological studies, the cause-and-effect relationships were worked out using experimental manipulations and genetics:

- If Tregs are experimentally destroyed in the thymus of a mouse, the mouse grows up with an out-of-control immune system, mounting strong immune responses to self antigens (*autoimmunity*—see Section 42.7).
- In humans, a rare X-linked inherited disease occurs when a gene critical to Treg function is mutated. An infant with this disease, called IPEX (*immune dysregulation, polyen-*

docrinopathy and enteropathy, X-linked), mounts an immune response that attacks the pancreas, thyroid, and intestine. Most affected individuals die within the first few years of life.

MHC proteins are important in tissue transplants

In humans, one consequence of the major histocompatibility complex became important with the development of organ transplant surgery. Because the proteins produced by the MHC are specific to each individual, they act as nonself antigens if transplanted into another individual. An organ or a piece of tissue transplanted from one person to another is recognized as nonself by the host body and soon provokes an immune response; the tissue is then killed, or “rejected,” by the host’s cellular immune system. But if the transplant is performed immediately after birth, or if it comes from a genetically identical person (an identical twin), the material is recognized as self and is not rejected.

The rejection problem can be overcome by treating a patient with a drug, such as cyclosporin, that suppresses the immune system. Cyclosporin blocks the activation of a transcription factor that is essential for T cell development. However, this approach compromises the ability of transplant recipients to defend themselves against pathogens. This problem must be managed by the use of antibiotics and other drugs to combat infections that develop.

42.5 RECAP

The cellular immune response acts against antigens expressed on the surfaces of virus-infected or mutated body cells. Specific receptors on T cells bind to antigen-MHC complexes displayed on the cell surface. During development, T cells are selected that recognize self MHC proteins. Tregs suppress immune responses to self antigens.

- What are the roles of a T cell receptor in cellular immunity? **See p. 888**
- What parts do MHC proteins play in the cellular immune response? **See pp. 888–889**
- What occurs during the cellular immune response to a virus-infected cell? **See p. 889 and Figure 42.13**

We have alluded to genes that encode various components of the immune system and to the tremendous diversity in these components. We will now consider the genetic mechanisms that make this diversity possible.

42.6 How Do Animals Make So Many Different Antibodies?

Each mature B cell makes one—and only one—specific antibody with a specific amino acid sequence targeted to a single antigen. As we have seen, there are millions of possible epitopes to which a human is exposed or can be exposed. With millions of possible amino acid sequences in immunoglobu-

lins, the molecular genetic explanation would be that there are millions of genes, each one coding for one antibody molecule. A simple calculation using approximate numbers shows that this is impossible:

one immunoglobulin heavy chain = 500 amino acids coded for by 1500 bp DNA

one immunoglobulin light chain = 200 amino acids coded for by 600 bp DNA

therefore,

one antibody (2 each identical light and heavy chains) = 2100 bp DNA

10 million different antibodies = 21 billion bp DNA

This is 7 times the size of the entire human genome! There must be another way to generate antibody diversity.

It turns out that instead of a single gene encoding each immunoglobulin, the genome of the differentiating B cell has a limited number of alleles for several *regions* or *domains* of the protein, and that *combinations of these alleles* generate diversity. In this section we will describe the unusual process of shuffling this genetic deck to generate the enormous immunological diversity that characterizes each individual mammal. Then we will see how similar events produce five classes of immunoglobulins with different cellular locations or functions in the body.

Antibody diversity results from DNA rearrangement and other mutations

Each gene encoding an immunoglobulin chain is in reality a “supergene” assembled by means of genetic recombination from several clusters of smaller genes scattered along part of a chromosome (**Figure 42.15**). Every cell in the body has hundreds of immunoglobulin genes located in separate clusters that are potentially capable of participating in the synthesis of both the variable and constant regions of immunoglobulin chains. In most body cells and tissues, these genes remain intact and separated from one another. But during B cell development, these genes are cut out, rearranged, and joined together in DNA recombination events. One gene from each cluster is chosen randomly for joining, and the others are deleted (**Figure 42.16**).

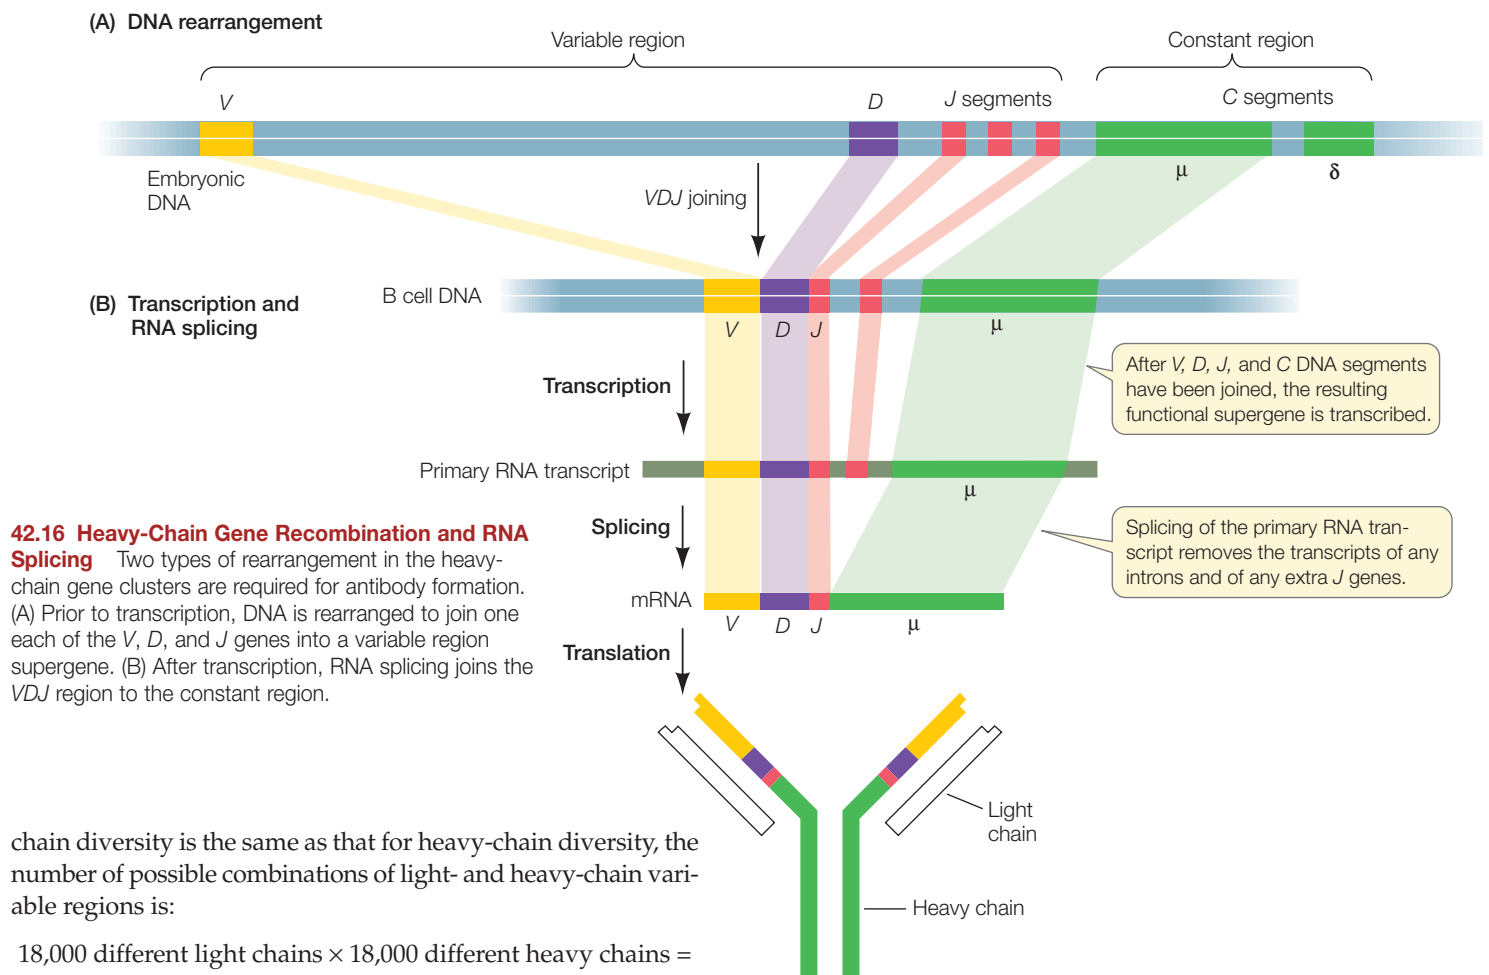

In this manner, a unique immunoglobulin supergene is assembled from randomly selected “parts.” Each B cell precursor assembles two supergenes, one for a specific heavy chain and the other, assembled independently, for a specific light chain. This remarkable example of irreversible cell differentiation generates an enormous diversity of immunoglobulins from the same starting genome. It is a major exception to the generalization that all somatic cells derived from the fertilized egg have identical DNA.

In both humans and mice, the gene clusters encoding immunoglobulin heavy chains are on one pair of chromosomes and those for light chains are on two others. Two families of genes encode the variable region of the light chain, and three families encode the variable region of the heavy chain.

Figure 42.15 illustrates the gene families that encode the constant and variable regions of the heavy chain in mice. There are multiple genes that encode each of three parts of the variable region: 100 *V*, 30 *D*, and 6 *J* genes. Each B cell randomly selects one gene from each of these clusters to make the final coding sequence (*VDJ*) of the heavy-chain variable region. So the number of different heavy chains that can be made through this random recombination process is quite large:

$$100 V \times 30 D \times 6 J = 18,000 \text{ possible combinations}$$

Now consider that the light chains are similarly constructed, with a similar amount of diversity made possible by random recombination. If we assume that the degree of potential light-

42.16 Heavy-Chain Gene Recombination and RNA Splicing

Two types of rearrangement in the heavy-chain gene clusters are required for antibody formation. (A) Prior to transcription, DNA is rearranged to join one each of the V, D, and J genes into a variable region supergene. (B) After transcription, RNA splicing joins the VDJ region to the constant region.

chain diversity is the same as that for heavy-chain diversity, the number of possible combinations of light- and heavy-chain variable regions is:

$$18,000 \text{ different light chains} \times 18,000 \text{ different heavy chains} = 324 \text{ million possibilities!}$$

There are other mechanisms that generate even more diversity:

- When the DNA sequences that encode the V, D, and J regions are rearranged so that they are next to one another, the recombination event is not precise, and errors occur at the junctions. This *imprecise recombination* can create frameshift mutations, generating new codons at the junctions, with resulting amino acid changes.
- After the DNA sequences are cut out and before they are joined, the enzyme *terminal transferase* often adds some nucleotides to the free ends of the DNA pieces. These additional bases create insertion mutations.
- There is a relatively high *spontaneous mutation rate* in immunoglobulin genes. Once again, this process creates many new alleles and adds to antibody diversity.

When we include these possibilities with the millions of combinations that can be made by random DNA rearrangements, it is not surprising that the immune system can mount a response to almost any natural or artificial substance.

Once the pretranscriptional processing is completed, each supergene is transcribed and then translated to produce an immunoglobulin light chain or heavy chain. These combine to form an active immunoglobulin protein.

This genetic system is capable of still other kinds of changes. The B cell or plasma cell can switch the immunoglobulin class it produces while retaining its antigen specificity.

The constant region is involved in immunoglobulin class switching

Table 42.3 describes the different classes of immunoglobulins and their functions. Generally, a B cell makes only one class at a time. But **class switching** can occur, in which a B cell changes the immunoglobulin class it synthesizes. For example, a B cell making IgM can switch to making IgG.

Early in its life, a B cell produces IgM molecules, which are the receptors responsible for its recognition of a specific antigen. At this time, the constant region of the heavy chain is encoded by the first constant region gene, the μ gene (see Figure 42.16). If the B cell later becomes a plasma cell during a humoral immune response, another deletion occurs in the cell's DNA, positioning the variable region genes (consisting of the same V, D, and J genes) next to a constant region gene farther away on the original DNA molecule (Figure 42.17). Such a DNA deletion results in the production of a new immunoglobulin with a different constant region of the heavy chain, and therefore a different function (see Table 42.3). However, this immunoglobulin has the same variable regions, and therefore the same antigen specificity, as the IgM produced by the parent B cell. The new immunoglobulin protein falls into one of the four classes (IgA, IgD, IgE, or IgG), depending on which of the constant region genes is placed adjacent to the variable region genes.

42.17 Class Switching: Exchanging C Regions The supergene produced by joining V, D, J, and C genes (see Figure 42.16) may later be modified, causing a different C region to be transcribed. This modification, known as class switching, is accomplished by deletion of part of the constant region gene cluster. Shown here is class switching from IgM to IgG.

What triggers class switching, and what determines the class to which a given B cell will switch? T-helper (T_H) cells direct the course of an immune response and determine the nature of the attack on the antigen. These T cells induce class switching by sending cytokine signals. The cytokines bind to receptors on the target B cells, generating signal transduction cascades that result in recombination and altered expression of the immunoglobulin genes.

42.6 RECAP

The immune system can make millions of immunoglobulins with different specificities by rearranging the genes that encode the variable regions of the heavy and light chains. Additional mechanisms create mutations that provide for further diversity in the immunoglobulins. The class of the immunoglobulin molecule can be changed by recombination of the genes coding for the constant region of the heavy chain.

- How can millions of antibodies with different specificities be generated from a relatively small number of genes? See pp. 892–893 and Figures 42.15 and 42.16
- What is the role of the constant region of the immunoglobulin in class switching? See pp. 893–894 and Figure 42.17

Given the numerous and complex cellular interactions that activate the immune system and generate antibody diversity, you may have perceived many points at which the immune system could fail. We now turn to several situations in which one or more components of this complex system malfunction.

42.7 What Happens When the Immune System Malfunctions?

Sometimes the immune system fails us in one way or another. It may overreact, as in an allergic reaction; it may attack self antigens, as in an autoimmune disease; or it may function weakly or not at all, as in an immune deficiency disease.

Allergic reactions result from hypersensitivity

An **allergic reaction** arises when the human immune system overreacts to (is hypersensitive to) a dose of antigen. Although the antigen itself may present no danger to the host, the inappropriate immune response may produce inflammation and other symptoms, which can cause serious illness or even death. Allergic reactions are the most familiar examples of this phenomenon. Two types of allergic reactions involve immediate hypersensitivity and delayed hypersensitivity.

IMMEDIATE HYPERSENSITIVITY Immediate hypersensitivity arises when an allergic individual is exposed to an antigen (in this case referred to as an allergen) from the environment, such as a food, pollen, or the venom of an insect. In response to the allergen, the individual makes large amounts of IgE. When this happens, mast cells in tissues and basophils in the blood bind the constant end of the IgE. If that individual is exposed to the same allergen again, binding of the allergen to the IgE causes the mast cells and basophils to rapidly release a large amount of histamine (Figure 42.18). This results in symptoms such as dilation of blood vessels, inflammation, and difficulty breathing. If not treated with antihistamines, a severe allergic reaction can lead to death. It is not known why some people produce excessive amounts of IgE in response to allergens. There is some evidence for genetic factors predisposing people to allergic responses.

Allergy to pollen can be treated using a process called *desensitization*. The process involves injecting small amounts of the allergen (typically just an extract of the offending plant tissue) into the skin—enough to stimulate IgG production but not enough to stimulate IgE production. The next time the person is exposed to the allergen, IgG binds to it, tying it up before IgE can bind it and exert its harmful effects.

Desensitization does not work for food allergens because the IgE response to those substances is so strong that even a small amount of antigen provokes it. The best approach for those with food allergies—there are an estimated 3 million in the U.S.—is to avoid foods containing the allergens. This can be difficult, but food labels listing all the ingredients are helpful. Molecular biologists are beginning to identify the antigens that act as allergens, with the hope of developing vaccines or genetically modified foods that lack the allergenic epitopes.

42.18 An Allergic Reaction An allergen is an antigen that stimulates B cells to make large amounts of IgE antibodies, which bind to mast cells and basophils. When the body encounters the allergen again, these cells produce large amounts of histamine, which have harmful physiological effects.

DELAYED HYPERSENSITIVITY Delayed hypersensitivity is an allergic reaction that does not begin until hours after exposure to an antigen. In this case, the antigen is taken up by antigen-presenting cells and a T cell response is initiated. An example is the rash that develops after exposure to poison ivy.

Autoimmune diseases are caused by reactions against self antigens

Errors in the selection of T cells in the thymus can result in T cells that bind to antigen–MHC complexes that carry self antigens. Although the precise origin of **autoimmunity** is not known, there are several hypotheses:

- *Failure of clonal deletion.* A clone of lymphocytes making antibodies against self antigens that should have been destroyed by Tregs and apoptosis is not destroyed.
- *Molecular mimicry.* T cells that recognize a nonself antigen, such as a virus, also recognize something on the self antigen that has a similar structure.

Autoimmunity does not always result in disease, but a number of autoimmune diseases are common:

- People with *systemic lupus erythematosus* (SLE) have antibodies to many cellular components, including DNA and nuclear proteins. These antinuclear antibodies can cause serious damage when they bind to normal tissue antigens and

form large circulating antigen–antibody complexes, which become stuck in tissues and provoke inflammation.

- People with *rheumatoid arthritis* have difficulty in shutting down a T cell response. An inhibitory protein called CTLA4 blocks T cells from reacting to self antigens. People with rheumatoid arthritis may have low CTLA4 activity, which results in inflammation of the joints due to the infiltration of excess white blood cells.
- *Hashimoto's thyroiditis* is the most common autoimmune disease in women over 50. Immune cells attack thyroid tissue, resulting in fatigue, depression, weight gain, and other symptoms.
- *Insulin-dependent diabetes mellitus*, or type I diabetes, occurs most often in children. It is caused by an immune reaction against several proteins in the cells of the pancreas that manufacture the protein hormone insulin. This reaction kills the insulin-producing cells, so people with type I diabetes must take insulin daily in order to survive.

AIDS is an immune deficiency disorder

There are a number of inherited and acquired *immune deficiency disorders*. In some individuals, T or B cells never form; in others, B cells lose the ability to give rise to plasma cells. In either case, the affected individual is unable to mount an immune response and thus lacks a major line of defense against pathogens. The T_H cell is perhaps the most central component of the immune system because of its essential roles in both the humoral and cellular immune responses (see Figure 42.6). This cell is the target of **human immunodeficiency virus (HIV)**, the retrovirus that results in **acquired immune deficiency syndrome (AIDS)**.

HIV can be transmitted from person to person in body fluids containing the virus (such as blood, semen, vaginal fluid, or breast milk). The recipient tissue is either blood (by transfusion) or a mucous membrane lining an organ (the mucus contains a high concentration of lymphocytes). HIV initially infects macrophages, T_H cells, and antigen-presenting dendritic cells in the blood and tissues. At first there is an immune response to the viral infection, and T_H cells are activated. But because HIV

42.19 The Course of an HIV Infection An HIV infection may be carried, unsuspected, for many years before the onset of symptoms.

infects the T_H cells, they are killed both by HIV itself and by T_C cells that lyse infected T_H cells. Consequently, T_H cell numbers decline after the first month or so of infection. Meanwhile, the extensive production of HIV by infected cells activates the humoral immune system. Antibodies bind to HIV and the complexes are removed by phagocytes. The HIV level in blood goes down. There is still a low level of infection, however, because of the depletion of T_H cells (**Figure 42.19**). This process reaches a low, steady-state level called the “set point.” This point varies among individuals and is a strong predictor of the rate of progression of the disease. For most people it takes 8–10 years, even without treatment, for the more severe manifestations of AIDS to develop. In some it can take as little as a year; in others, 20 years.

During this dormant period, people carrying HIV generally feel fine, and their T_H cell levels are adequate for them to mount immune responses. Eventually, however, the virus destroys the T_H cells, and their numbers fall to the point where the infected person is susceptible to infections that the T_H cells would normally eliminate. These infections result in conditions such as Kaposi’s sarcoma, a skin tumor caused by a herpesvirus; pneumonia caused by the fungus *Pneumocystis jirovecii*; and lymphoma tumors caused by the Epstein–Barr virus. These conditions result from *opportunistic infections* because the pathogens take advantage of the crippled immune system of the host. They lead to death within a year or two.

The molecular biology of HIV and its life cycle have been intensively studied (see Figure 16.6). Drug treatments are focused on inhibiting the viral proteins, such as *reverse transcriptase* that makes cDNA from the viral RNA, and *viral protease* that cuts the large precursor viral protein into its final active proteins. Combinations of such drugs result in long-term survival. Unfortunately, like many medical treatments, HIV drugs are not available to all who need them—particularly in poor regions of the

world where AIDS is prevalent. As a result, there are about 2 million deaths per year worldwide from AIDS.

42.7 RECAP

Failures of the immune system include allergic reactions (caused by hypersensitivity to antigens), autoimmune diseases (caused by reactions against self antigens), and immune deficiency disorders.

- How does immediate hypersensitivity develop? **See p. 894 and Figure 42.18**
- What is an autoimmune disease? Give an example. **See p. 895**
- Describe the course of events in the human immune system during HIV infection. **See pp. 895–896 and Figure 42.19**

CHAPTER SUMMARY

42.1 What Are the Major Defense Systems of Animals?

- Animal defenses against pathogens are based on the body’s ability to distinguish between self and nonself.
- **Nonspecific (innate) defenses** are inherited mechanisms that protect the body from many kinds of pathogens. They typically act rapidly.
- **Specific defenses** are adaptive mechanisms that respond to specific pathogens. They develop more slowly than nonspecific defenses but are long-lasting.

- Many defenses are implemented by cells and proteins carried in the blood plasma and lymph. **Review Figure 42.1, WEB ACTIVITY 42.1**
- White blood cells fall into two broad groups. **Phagocytes** include **macrophages** that engulf pathogens by phagocytosis. **Lymphocytes**, which include **B cells** and **T cells**, participate in specific responses. **Review Figure 42.2, ANIMATED TUTORIAL 42.1**

42.2 What Are the Characteristics of the Nonspecific Defenses?

- An animal's nonspecific defenses include physical barriers such as the skin, and competing resident microorganisms known as **normal flora**. **Review Table 42.1**
- The **complement system** consists of more than 20 different antimicrobial proteins that act to alter membrane permeability and kill targeted cells.
- Circulating defensive cells, such as phagocytes and **natural killer cells**, eliminate invaders.
- The **inflammation response** activates several types of cells and proteins that act against invading pathogens. **Mast cells** release **histamines**, which cause blood vessels to dilate and become "leaky." **Review Figure 42.3, WEB ACTIVITY 42.2**
- A cell signaling pathway involving the **toll-like receptor** stimulates the body's defenses. **Review Figure 42.4**

42.3 How Does Specific Immunity Develop?

SEE ANIMATED TUTORIAL 42.2

- The specific immune response recognizes specific **antigens**, responds to an enormous diversity of **antigenic determinants**, distinguishes self from nonself, and remembers the antigens it has encountered.
- Each antibody and each T cell is specific for a single antigenic determinant. **T cell receptors** bind to antigens on the surfaces of virus-infected cells and abnormal cells.
- The **humoral immune response** is directed against pathogens in the blood, lymph, and tissue fluids. The **cellular immune response** is directed against an antigen established within a host cell. Both responses are mediated by antigenic fragments being presented on a cell surface along with the proteins of the **major histocompatibility complex**.
- **Clonal selection** accounts for the specificity and diversity of the immune response and for **immunological memory**. **Review Figure 42.7**
- An activated B or T lymphocyte produces **effector cells** that attack the antigen, and **memory cells** that are long-lived and rarely divide. Effector B cells are called **plasma cells** and secrete specific **antibodies**.
- **Vaccination** is inoculation with modified pathogens or antigens that provoke an immune response but are not pathogenic.

42.4 What Is the Humoral Immune Response?

SEE ANIMATED TUTORIAL 42.3

- B cells are the basis of the humoral immune response. Naïve B cells are activated by binding of antigen and by stimulation by T_H cells with the same specificity, and then form plasma cells. These cells synthesize and secrete specific antibodies.
- The basic unit of an **immunoglobulin** is a tetramer of four polypeptides: two identical light chains and two identical heavy chains, each consisting of a **constant region** and a **variable region**. **Review Figure 42.9, WEB ACTIVITY 42.3**

- The variable regions determine the specificity of an immunoglobulin, and the constant regions of the heavy chain determine its **class**. There are five classes of immunoglobulins with different body locations and functions. **Review Table 42.3**
- A **monoclonal antibody** can be made by fusing a B cell with a tumor cell to form a **hybridoma**. **Review Figure 42.10**

42.5 What Is the Cellular Immune Response?

SEE ANIMATED TUTORIAL 42.4

- T cells are the effectors of the cellular immune response. T cell receptors are somewhat similar in structure to the immunoglobulins, having variable and constant regions. **Review Figure 42.11**
- There are three types of T cells. **Cytotoxic T cells** recognize and kill virus-infected cells or mutated cells. **T-helper cells** direct both the cellular and humoral immune responses. **Regulatory T cells** inhibit the other T cells from mounting an immune response to self antigens.
- The genes of the major histocompatibility complex (MHC) encode membrane proteins that bind antigenic fragments and present them to T cells. **Review Figures 42.12 and 42.13**
- Organ transplants are rejected when the host's immune system recognizes MHC proteins on transplanted tissue as nonself and initiates an immune defense attacking the foreign tissue.

42.6 How Do Animals Make So Many Different Antibodies?

SEE ANIMATED TUTORIAL 42.5

- B cell genomes undergo random recombinations of genes coding for regions of the immunoglobulin polypeptide chains so that each cell can produce a specific antibody protein. The immunoglobulin chains derive from "supergenes" that are constructed from different combinations of *V*, *D*, *J*, and *C* genes. This DNA rearrangement and rejoining yields millions of different immunoglobulin chains. **Review Figures 42.15 and 42.16**
- Once a B cell becomes a plasma cell, it may undergo **class switching**, in which a deletion of one or more constant region genes results in the production of an immunoglobulin with a different constant region and a different function. **Review Figure 42.17**

42.7 What Happens When the Immune System Malfunctions?

- An **allergic reaction** is an inappropriate immune response caused by immediate or delayed **hypersensitivity** to certain antigens. **Review Figure 42.18**
- Autoimmune diseases result when the immune system produces B and T cells that attack self antigens.
- Immune deficiency disorders result from failure of one or another part of the immune system. **AIDS** is an acquired immune deficiency disorder arising from depletion of the T_H cells as a result of infection with HIV. **Review Figure 42.19**

SELF-QUIZ

- Phagocytes kill harmful bacteria by
 - endocytosis.
 - producing antibodies.
 - complement proteins.
 - T cell stimulation.
 - inflammation.
- Which statement about immunoglobulins is true?
 - They help antibodies do their job.
 - They recognize and bind antigenic determinants.
 - They encode some of the most important genes in an animal.
 - They are the chief participants in nonspecific defense mechanisms.
 - They are a specialized class of white blood cells.
- Which statement about an antigenic determinant is *not* true?
 - It is a specific chemical grouping.
 - It may be part of many different molecules.
 - It is the part of an antigen to which an antibody binds.
 - It may be part of a cell.
 - A single protein has only one on its surface.
- T cell receptors
 - are the primary receptors for the humoral immune system.
 - are carbohydrates.
 - cannot function unless the animal has previously encountered the antigen.
 - are produced by plasma cells.
 - are important in combating viral infections.
- According to the clonal selection theory,
 - an antibody changes its shape to match the antigen it meets.
 - an individual animal contains only one type of B cell.
 - an individual animal contains many types of B cells, each producing one kind of antibody.
 - each B cell produces many types of antibodies.
 - many clones of antiself lymphocytes appear in the blood-stream.
- Immunological tolerance
 - depends on exposure to an antigen.
 - develops late in life and is usually life-threatening.
 - disappears at birth.
 - results from the activities of the complement system.
 - results from DNA splicing.
- The extraordinary diversity of antibodies results in part from
 - the action of monoclonal antibodies.
 - the splicing of protein molecules.
 - the action of cytotoxic T cells.
 - the rearrangement of genes.
 - their remarkable nonspecificity.
- Which of the following play(s) no role in the B cell response?
 - T-helper cells
 - Growth factors
 - Macrophages
 - Reverse transcriptase
 - Products of class II MHC genes
- The major histocompatibility complex
 - codes for specific proteins found on the surfaces of cells.
 - plays no role in T cell immunity.
 - plays no role in antibody responses.
 - plays no role in skin graft rejection.
 - is encoded by a single locus with multiple alleles.
- Which of the following is important in the immune deficiency caused by HIV?
 - Pneumonia infection by bacteria
 - Activated T_H cell infection by HIV
 - Circulating free HIV in blood plasma
 - Antibodies made against HIV-infected cells
 - Increase in T cells

FOR DISCUSSION

- Describe the part of an antibody molecule that interacts with an antigen. How is it similar to the active site of an enzyme? How does it differ from the active site of an enzyme?
- Contrast immunoglobulins and T cell receptors with respect to their structures and functions.
- Discuss the diversity of antibody specificities in an individual in relation to the diversity of enzymes. Does every cell in an animal contain genetic information for all the organism's enzymes? Does every cell contain genetic information for all the organism's immunoglobulins?
- The gene family determining MHC on the cell surface in humans is on a single chromosome. A father's MHC type is A1, A3, B5, B7, D9, D11. A mother's genotype is A2, A4, B6, B7, D11, D12. Their child is A1, A4, B6, B7, D11, D12. What are the parents' haplotypes—that is, which alleles are linked on each of the two chromosomes of each parent? Assuming there is no recombination among the genes determining the MHC type, can these same two parents have a child who is A1, A2, B7, B8, D10, D11?

ADDITIONAL INVESTIGATION

Development of an effective HIV vaccine requires that the person being vaccinated develop both cellular and humoral immu-

nity against HIV. Explain what this means in terms of studies you would do on people given a potential new vaccine.

Explosive sex

Producer of valuable honey and pollinator of many crucial plants, the common honey bee, *Apis mellifera*, has been the subject of study and fascination for humans throughout recorded history. The unique sex life of these social insects is among their most intriguing aspects.

More than 99 percent of female honey bees do not reproduce. They exist to help just one female—the queen—reproduce. At any given time, there is only one queen in a hive. She lays all of the eggs, which is a full-time job. She also determines whether or not an egg will be fertilized. Fertilized eggs develop into females; unfertilized eggs develop into males. Wait, you say, it's the *male* that fertilizes the egg! Yes, the male's sperm fertilizes the egg, but in

this case the female—the queen bee—stores sperm after mating and controls its delivery to her eggs.

Eventually, every hive must have a new queen. Sometimes the old queen dies. Other times, in a phenomenon known as *swarming*, the queen and a retinue of workers leave their current hive to start a new one. Whether the queen dies or leaves, a new queen must be produced. The remaining worker bees enlarge a few cells in the honeycomb that contain fertilized eggs laid by the old queen. The larvae that hatch from those eggs are fed special food that stimulates their growth and development into prospective queens.

The first queen to pupate and emerge from her royal chamber kills any other aspiring queens. She then leaves the hive for her mating flight. Males from all around get the message that a virgin queen is available and congregate around her. While in flight, she mates with 15 to 20 males, and each coupling is an event. After a male manages to insert his penis into her vagina, he literally explodes, leaving inside the female not only his sperm but also his sex organs (the latter will drop out later). This process is repeated with other males, which also die as a result. The queen returns to the hive with a lifetime supply of sperm and sets about laying eggs.

The queen lives for about 2 years and lays as many as 3,000 eggs each day. If she releases sperm, the eggs will be fertilized and develop into sterile females that will devote their lives to feeding her, maintaining the hive, foraging for nectar and pollen, and raising their sisters. Unfertilized eggs develop into males, which hang around the hive doing nothing useful until they take off to search for a receptive queen—an unlikely event. It is thus in the

A Unique Reproductive Strategy Among honey bees and other hymenopteran insects, the only reproductive female is the queen, seen here in the center as she deposits eggs in the comb. The female workers that attend her are sterile.

Swarming Means a New Queen Bee When a honey bee colony swarms, the queen leaves the hive and takes a retinue of workers with her. A new queen will emerge to take over the old hive, at which time a few males will get to perform their one brief function—fertilizing a virgin queen—before they die.

queen's best interest to limit the number of males she produces.

Natural selection has resulted in some amazing adaptations, none more so than those involved in reproduction. Sexual or asexual, bizarre or otherwise, the anatomy, physiology, biochemistry, and behavior surrounding the urge to propagate one's species are fascinating fields of study.

IN THIS CHAPTER we will examine the diverse ways in which animals produce offspring. First we examine asexual reproduction, in which only a single parent is involved. We then turn to sexual reproduction, in which an egg and a sperm unite to create a new diploid individual. Finally, we focus on the anatomy, function, and endocrine control of the human reproductive system, as well as technologies used to limit or enhance human fertility.

CHAPTER OUTLINE

- 43.1** How Do Animals Reproduce without Sex?
- 43.2** How Do Animals Reproduce Sexually?
- 43.3** How Do the Human Male and Female Reproductive Systems Work?
- 43.4** How Can Fertility Be Controlled?

43.1 How Do Animals Reproduce without Sex?

Sexual reproduction is a nearly universal trait in animals, although many species can also reproduce asexually and some reproduce only asexually. Offspring produced asexually are genetically identical to one another and to their parents. Asexual reproduction is efficient because no time or energy is wasted on mating and every member of the population can convert resources into offspring. However, asexual reproduction does not generate genetic diversity as sexual reproduction does, and this diversity is the raw material that enables natural selection to shape adaptations in response to environmental change. When such changes occur, the lack of genetic diversity can be disadvantageous to a species.

A variety of animals, mostly invertebrates, reproduce asexually. They tend to be species that are attached to their substrate and cannot search for mates or that live in sparse populations and rarely encounter potential mates. Asexually reproducing species are likely to be found in relatively constant environments where genetic diversity is less important for species success. In fact, asexual reproduction is a good way to preserve a genotype that is successful in a particular environment, as long as that environment does not change. Three common modes of asexual reproduction are *budding*, *regeneration*, and *parthenogenesis*.

Budding and regeneration produce new individuals by mitosis

Many simple multicellular animals produce offspring by **budding**. New individuals form as outgrowths or buds from the bodies of older animals. A bud grows by mitotic cell division, and the cells differentiate before the bud breaks away from the parent (**Figure 43.1A**). The bud is genetically identical to the parent, and it may grow as large as the parent before it becomes independent.

Regeneration is usually thought of as the replacement of damaged tissues or lost limbs, but in some cases pieces of an organism can regenerate complete individuals. Echinoderms, for example, have remarkable abilities to regenerate. If sea stars (starfishes) are cut into pieces, each piece that includes an arm and a portion of the central disc can grow into a new animal (**Figure 43.1B**). In the early 1900s, oyster fishermen in Narragansett Bay tried to eliminate the sea stars that were preying on their oysters. Whenever they encountered a sea star, they chopped it up with knives and threw it back into the water. As a result, the sea star population increased explosively.

Regeneration can occur when an animal is broken by an outside force such as wave action in the intertidal zone. In some

43.1 Two Forms of Asexual Reproduction (A) Budding: A new individual forms as an outgrowth from an adult hydra. (B) Regeneration: A single severed arm and a piece of the central disc of a mature sea star can regenerate into an entire animal.

(B) *Fromia* sp.

cases, breakage occurs in the absence of external forces. Some species of segmented marine worms develop segments with rudimentary heads bearing sensory organs. The segments then break apart, and each one forms a new worm.

(B)

Parthenogenesis is the development of unfertilized eggs

Not all eggs must be fertilized to develop. A common mode of asexual reproduction in arthropods is the development of offspring from unfertilized eggs. This phenomenon, called **parthenogenesis**, also occurs in some species of fishes, amphibians, and reptiles. Most species that reproduce parthenogenetically also engage in sexual reproduction or at least sexual behavior at other times.

In some species, parthenogenesis is part of the mechanism that determines sex. As we saw at the beginning of this chapter, in honey bees (as well as in most ants and wasps), males develop from unfertilized eggs and are haploid. Females develop from fertilized eggs and are diploid.

Parthenogenetic reproduction in some species requires sexual behavior even though sperm are not delivered to the female reproductive tract and eggs are not fertilized. One case that has been investigated extensively by David Crews and his students at the University of Texas is parthenogenetic reproduction in a species of whiptail lizard. This species has no males, but females can act as males, engaging in all aspects of courtship display and mating, although no sperm are produced or transferred (**Figure 43.2**). Whether a specific female acts as a female or as a male depends on cyclical hormonal states. When estrogen levels are high, she acts as a female. When her progesterone level peaks, she acts as a male. The stimulation resulting from the sexual activity triggers the release of eggs from the ovaries.

43.2 Sexual Behavior May Be Required for Asexual Reproduction

(A) Parthenogenetic whiptail lizards are all females, but they take turns acting the male role in reproductive behavior. The stimulation from sexual behavior is necessary for ovulation to occur. (B) The stage of the ovarian cycle determines the role an individual whiptail plays.

43.1 RECAP

Most animals reproduce sexually, but many can also or can only reproduce asexually, through budding, regeneration, or parthenogenesis.

- Explain why asexual reproduction might be disadvantageous for an animal living in a changing environment. **See p. 900**
- How is parthenogenesis related to sex determination in honey bees? **See p. 901**

Asexual reproduction is an efficient way to use resources. However, the fact that sexual reproduction produces genetic diversity must be a tremendous advantage, because most species reproduce sexually.

43.2 How Do Animals Reproduce Sexually?

Given the efficiency of asexual reproduction in perpetuating an organism's genome, the prevalence of sexual reproduction is somewhat surprising. Even the evolution of meiosis—an extremely complicated process in comparison to mitosis—has been the subject of much speculation and debate among evolutionary biologists. And of course, mating behaviors involve costs and risks. Costs include time and energy for finding, attracting, and competing for a mate as well as the opportunity costs of detracting from other activities such as feeding and caring for existing offspring. Risks include increased exposure to predation and the potential for physical damage. Despite these disadvantages, most eukaryotic organisms reproduce sexually. Thus it would seem that the production of genetic diversity is an evolutionary advantage that overwhelms “the cost of sex” (see Section 21.4).

Sexual reproduction requires the joining of two haploid sex cells to form a diploid individual. These haploid cells, or *gametes*, are produced through **gametogenesis**, a process that involves meiotic cell divisions. Two events in meiosis contribute to genetic diversity: *crossing over* between homologous chromosomes and the *independent assortment* of chromosomes (see Sections 11.5 and 12.1). Sexual reproduction itself also contributes to genetic diversity. The genetic variation among the gametes of a single individual and the genetic variation between any two parents produce an enormous potential for genetic variation between any two offspring of a sexually reproducing pair of individuals.

Sexual reproduction in animals consists of three fundamental steps:

- **Gametogenesis**: making gametes
- **Spawning or mating**: bringing gametes together
- **Fertilization**: fusing gametes

The process of gametogenesis is very similar across sexually reproducing animal species. Processes of fertilization are also rather similar in widely different species. Therefore, while our discussion of gametogenesis will focus generally on mammals, and our discussion of fertilization will feature sea urchins, the

facts would not be dramatically different were we to consider many other animal groups. Adaptations for spawning and mating, in contrast, show incredible anatomical, physiological, and behavioral diversity across species.

Gametogenesis produces eggs and sperm

Gametogenesis occurs in the **gonads**, which are **testes** (singular *testis*) in males and **ovaries** (singular *ovary*) in females. The tiny gametes of males, the **sperm**, move by beating their flagella. The larger gametes of females, called eggs or **ova** (singular *ovum*), are nonmotile.

Gametes are produced from **germ cells**, which have their origin in the earliest cell divisions of the embryo and remain distinct from all the other cells of the body (the *somatic cells*). Germ cells are sequestered in the body of the embryo until its gonads begin to form. The germ cells then migrate to the developing gonads, where they take up residence and proliferate by mitosis, producing **spermatogonia** (singular *spermatogonium*) in males and **oogonia** (singular *oogonium*) in females. Spermatogonia and oogonia are diploid and multiply by mitosis.

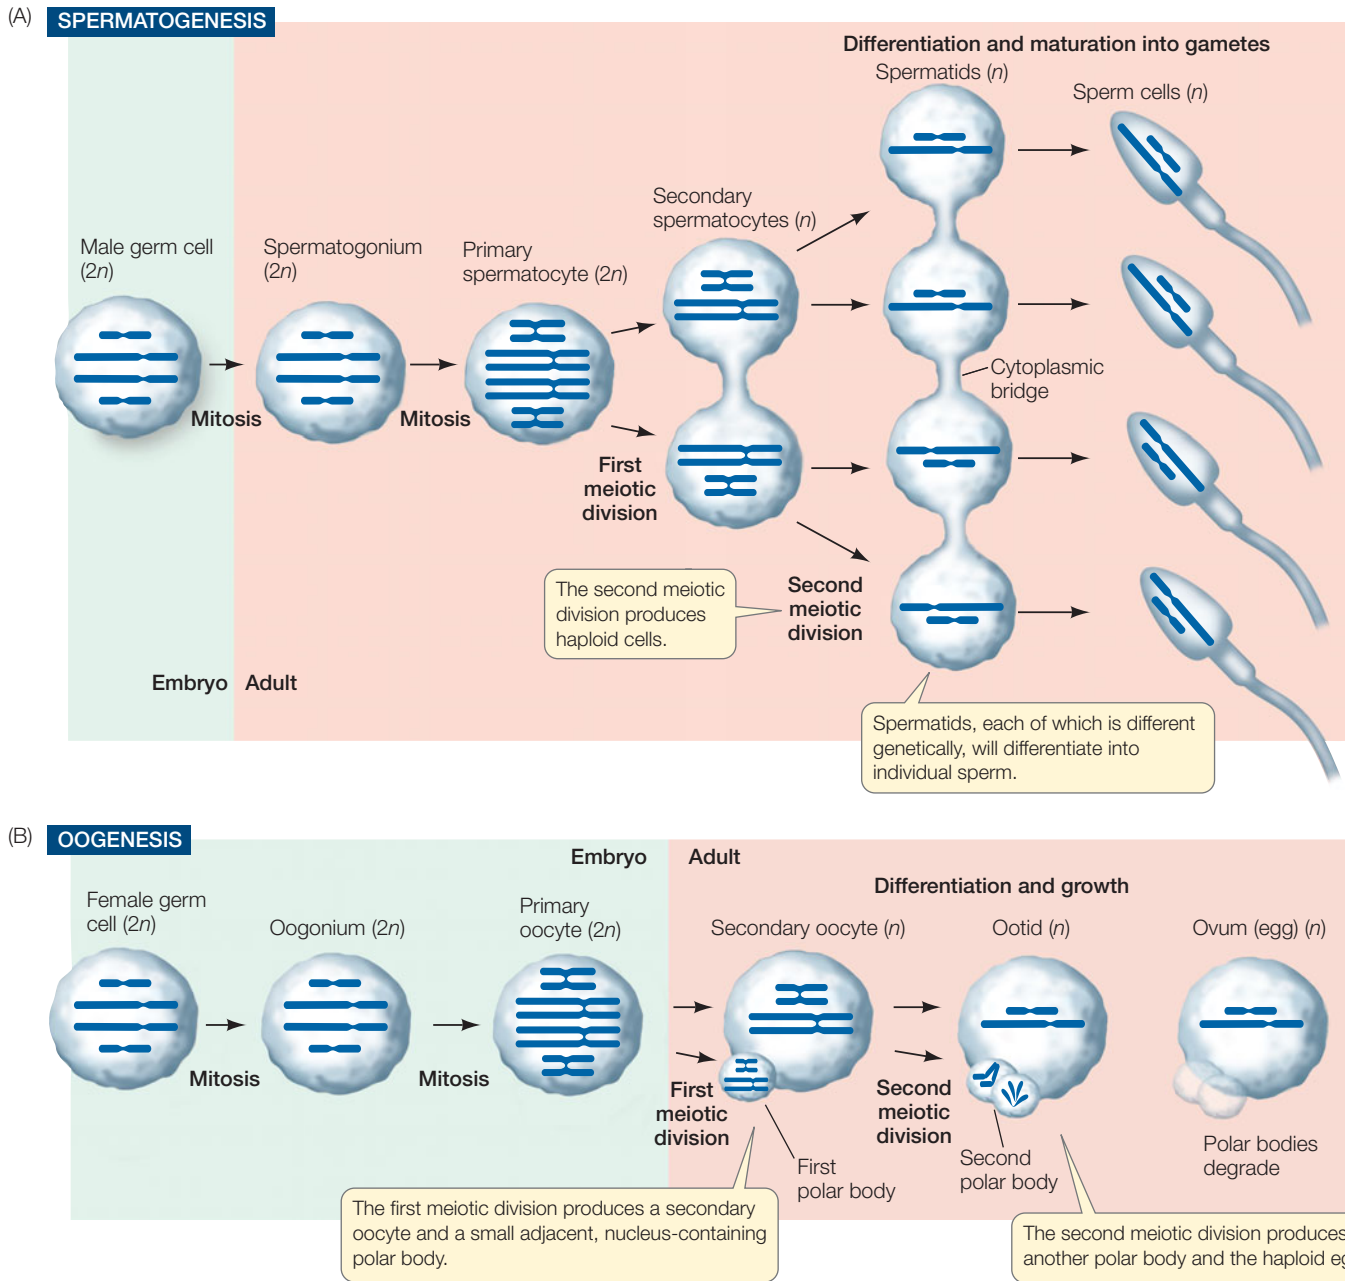

In the next step in gametogenesis, meiotic cell division reduces the chromosomes to the haploid number (see Section 11.5). The spermatogonia and oogonia that enter meiosis are **primary spermatocytes** and **primary oocytes**. Although the steps of meiosis are similar in males and females, gametogenesis differs between the sexes.

SPERMATOGENESIS The initial proliferation of male germ cells into spermatogonia proceeds by mitosis in the embryo. As illustrated in **Figure 43.3A**, primary spermatocytes then undergo the first meiotic division to form **secondary spermatocytes**. The second meiotic division produces four haploid **spermatids** for each primary spermatocyte that enters meiosis. In mammals, the progeny of primary spermatocytes remain connected by *cytoplasmic bridges* after each division.

One reason that mammalian spermatocytes remain in cytoplasmic contact throughout their development is the asymmetry of sex chromosomes in males. Half the secondary spermatocytes receive an X chromosome, the other half a Y chromosome. The Y chromosome contains fewer genes than the X chromosome, and some of the products of genes found only on the X chromosome are essential for spermatocyte development. By remaining in cytoplasmic contact, all four spermatocytes can share the gene products of the X chromosomes, although only half of them have an X chromosome.

A spermatid bears little resemblance to a mature sperm. Through further differentiation (*spermiogenesis*), the spermatid becomes compact, streamlined, and grows a flagellum to become motile. We will look at the production of human sperm in the next section.

OOGENESIS Oogonia, like spermatogonia, proliferate through mitosis (**Figure 43.3B**). The resulting primary oocytes immediately enter prophase of the first meiotic division. In many species, including humans, the oocyte experiences developmental arrest at this point and may remain in that state for days,

43.3 Gametogenesis Male and female germ cells proliferate by mitosis and produce diploid spermatogonia and oogonia that mature into primary spermatocytes and oocytes before entering meiosis. (A) Spermatogonia continue to divide by mitosis in adults, producing a steady supply of spermatocytes that divide meiotically to produce haploid spermatids, which differentiate into sperm. In many species, the progeny of spermatocytes remain in contact through cytoplasmic bridges until the sperm mature. (B) In mammals, oogonia cease division in the embryo, and primary oocytes remain arrested in prophase I of meiosis until they are ovulated and fertilized. Each oocyte will produce one haploid ootid which matures into an ovum.

months, or years. In the human female, this period of arrest is at least 10 years (i.e., until puberty), and some primary oocytes remain in prophase I for up to 50 years (i.e., until menopause). In contrast, spermatogenesis continues, uninterrupted, to completion once the primary spermatocyte has differentiated.

During this prolonged prophase I, or shortly before it ends, the primary oocyte grows larger through increased production of ribosomes, RNA, cytoplasmic organelles, and energy stores. At this point, the primary oocyte acquires all the energy, raw materials, and RNA that the ovum will need to survive its first cell divisions after fertilization. In fact, the nutrients in the egg must maintain the embryo until it is either nourished by the maternal circulatory system or can feed on its own.

When a primary oocyte resumes meiosis, its nucleus completes the first meiotic division near the surface of the cell. The daughter cells of this division receive grossly unequal shares of cytoplasm. This asymmetry represents another major difference from spermatogenesis, in which cytoplasm is apportioned equally. The daughter cell that receives almost all the cytoplasm

becomes the **secondary oocyte**, and the one that receives almost none forms the **first polar body** (see Figure 43.3B).

The second meiotic division of the large secondary oocyte is also accompanied by an asymmetrical division of the cytoplasm. One daughter cell forms the large, haploid **ootid**, which eventually differentiates into a mature ovum, and the other forms the **second polar body**. Polar bodies degenerate, so the end result of oogenesis is only one mature egg for each primary oocyte that entered meiosis. However, that egg is a large, well-provisioned cell.

A second period of arrested development occurs after the first meiotic division forms the secondary oocyte. The egg may be expelled from the ovary in this condition. In many species,

43.4 Fertilization of the Sea Urchin Egg

(A) Sea urchin eggs are protected by a jelly layer and a proteinaceous vitelline envelope. Sperm must penetrate both to reach the egg plasma membrane. Many sperm attach to the vitelline envelope, but only one penetrates the egg cell membrane and achieves fertilization. Circled numbers match structures with the events shown in panel B. (B) The acrosomal reaction allows a sea urchin sperm to recognize an egg of the same species and pass through its protective layers. Enzymes from the egg's cortical granules trigger the slow block to polyspermy.

yourBioPortal.com

GO TO Animated Tutorial 43.1 • Fertilization in a Sea Urchin

In the **acrosomal reaction**, the acrosomal membrane breaks down, releasing enzymes that digest a path through the egg's protective jelly coat.

Polymerization of actin creates the **acrosomal process**, which contacts egg plasma membrane, triggering the **fast block to polyspermy** (a change in electrical charge on the membrane).

Species-specific recognition molecules (in this case, bindin) on the acrosomal process bind to corresponding receptor molecules on the vitelline envelope.

Sperm and egg cell membranes fuse. Activated bindin receptors stimulate Ca²⁺ release, causing cortical granules to fuse with the plasma membrane. Sperm organelles enter the egg cytoplasm.

Cortical granule enzymes dissolve the bonds between the vitelline envelope and the plasma membrane, initiating the **slow block to polyspermy**.

Substances released by the cortical granules absorb H₂O and swell.

Enzymes remove sperm-binding receptors. The vitelline envelope hardens, forming a fertilization envelope.

including humans, the second meiotic division is not completed until the egg is fertilized by a sperm.

Fertilization is the union of sperm and egg

The union of the haploid sperm and the haploid egg in **fertilization** creates a single diploid cell, called a **zygote**, which will develop into an embryo. Fertilization does more, however, than just restore the full genetic complement of the animal. The processes associated with fertilization help the egg and sperm get together, prevent the union of the sperm and egg of different species, and guarantee that only one sperm will enter and activate the egg metabolically. Fertilization involves a complex series of events:

- The sperm and the egg recognize each other.
- The sperm is *activated*, enabling it to gain access to the plasma membrane of the egg.
- The plasma membrane of the egg fuses with the plasma membrane of a single sperm.
- The egg blocks entry of additional sperm.
- The egg is metabolically activated and stimulated to start development.
- The egg and sperm nuclei fuse to create the diploid nucleus of the zygote.

SPECIFICITY IN SPERM-EGG INTERACTIONS Specific recognition molecules mediate interactions between sperm and eggs. These molecules ensure that the activities of sperm are directed toward eggs and not other cells, and they help prevent eggs from being fertilized by sperm from the wrong species. The latter function is particularly important in aquatic species that release eggs and sperm into the surrounding water, as the eggs of such animals may readily be exposed to sperm of other species. The sea urchin is a good example of such a species, and its mechanisms of fertilization have been well studied.

The eggs of sea urchins release chemical attractants that increase the motility of sperm and cause them to swim toward the egg. These chemical attractants are species-specific. For example, eggs of one species of sea urchin release a specific peptide consisting of 14 amino acids. As this peptide diffuses from the egg, it binds to receptors on the sperm of the same species. The sperm respond by increasing their mitochondrial respiration and motility. Before exposure to the peptide, the sperm swim in tight little circles, but after binding to the peptide, they swim energetically up the concentration gradient of the peptide until they reach the egg that is releasing it.

When sperm reach an egg, they must get through two protective layers before they can fuse with the egg plasma membrane. The eggs of sea urchins are covered with a **jelly coat**, which surrounds a proteinaceous **vitelline envelope** (Figure 43.4A). The success of a sperm's assault on these protective layers depends on a membrane-enclosed structure at the front of the sperm head called an **acrosome**.

The acrosome, which contains enzymes and other proteins, forms a cap over the sperm nucleus. When the sperm makes contact with an egg of its own species, substances in the jelly coat trigger an *acrosomal reaction*, which begins with the breakdown of the plasma membrane covering the sperm head and the underlying acrosomal membrane (Figure 43.4B). The acrosomal enzymes are released and digest a hole through the jelly coat.

As a result of the polymerization of actin triggered by the acrosomal reaction, a structure called the *acrosomal process* extends out of the head of the sperm. The acrosomal process is coated with species-specific recognition molecules called *bindin*, and there are bindin receptors on the vitelline envelope of the egg. The interaction of these two molecules enables the sperm to contact the egg plasma membrane. That contact results in fusion of the sperm and egg plasma membranes and the formation of a *fertilization cone* that engulfs the sperm head, bringing it into the egg cytoplasm. The sperm mitochondrion, which largely constitutes the mid-piece of the sperm, is also drawn into the egg cytoplasm, but it degrades and disappears so that the mitochondria and mitochondrial genes of the new urchin are derived only from the egg.

In animals that practice internal fertilization, mating behaviors help guarantee species specificity, but egg-sperm recognition mechanisms still exist. The mammalian egg is surrounded by a thick layer called the **cumulus**, which consists of a loose assemblage of maternal cells in a gelatinous matrix (Figure 43.5). Beneath the cumulus is a glycoprotein envelope called the **zona pellucida**, which is functionally similar to the vitelline envelope of sea urchin eggs. When mammalian sperm are deposited in the female reproductive tract, they are metabolically activated and made capable of an acrosomal reaction

43.5 Barriers to Sperm This human egg, like other mammalian eggs, is surrounded by the cumulus and zona pellucida, both of which a sperm must penetrate to fertilize the egg. Only one sperm will penetrate the zona pellucida and fuse with the plasma membrane.

should they encounter an egg. An activated sperm can penetrate the cumulus and interact with the zona pellucida.

Unlike the jelly coat of sea urchin eggs, the cumulus of mammalian eggs does not trigger the acrosomal reaction. When sperm make contact with the zona pellucida, a species-specific glycoprotein binds to recognition molecules on the head of the sperm. This binding triggers the acrosomal reaction, releasing acrosomal enzymes that digest a path through the zona pellucida. When the sperm head reaches the egg plasma membrane, other proteins facilitate its adhesion to and fusion with the egg plasma membrane.

The importance of the zona pellucida and its sperm-binding molecules as a species-specific recognition mechanism was revealed in experiments on mammalian eggs and sperm in culture dishes. When the zona was stripped from human eggs and the eggs were exposed to hamster sperm, fertilization took place, resulting in a hamster–human hybrid zygote. The hybrid zygote did not survive its first cell division, but the experiment demonstrated that a recognition mechanism in mammalian species resides in the zona pellucida.

BLOCKS TO POLYSPERMY The fusion of the sperm and egg plasma membranes and the entry of the sperm into the egg initiate a programmed sequence of events. The first responses to sperm entry are **blocks to polyspermy**—that is, mechanisms that prevent more than one sperm from entering the egg. If more than one sperm enters the egg, the embryo is unlikely to survive.

Blocks to polyspermy have been studied extensively in sea urchin eggs, which can be fertilized in a dish of seawater. Within seconds after the sperm membrane contacts the egg membrane, an influx of sodium ions changes the electric charge difference across the egg's plasma membrane. This *fast block to polyspermy* prevents the fusion of any other sperm with the egg plasma membrane, but it is transient. The change in membrane electrical charge lasts only about a minute, but that is enough time to allow a slower block to sperm entry to develop.

The *slow block to polyspermy* involves converting the vitelline envelope to a physical barrier that sperm cannot penetrate. Before fertilization, the vitelline envelope is bonded to the egg plasma membrane. Just under the plasma membrane are vesicles called *cortical granules* (see Figure 43.4), which contain enzymes and other proteins.

The sea urchin egg, like all animal cells, contains calcium ions sequestered in its endoplasmic reticulum. Sperm entry into the egg stimulates the release of calcium ions from the endoplasmic reticulum and into the egg cytoplasm. This increase in cytosolic calcium causes the egg's cortical granules to fuse with the plasma membrane and release their contents. Cortical granule enzymes break the bonds between the vitelline envelope and the plasma membrane, and other proteins released from the cortical granules attract water into the space between them. As a result, the vitelline envelope rises to form a *fertilization envelope*. Cortical granule enzymes also degrade sperm-binding molecules on the surface of the fertilization envelope and cause it to harden, thus preventing additional sperm from contacting the egg's plasma membrane.

In mammals, sperm entry does not cause a rapid change in membrane potential, but it does trigger a release of calcium from the endoplasmic reticulum. As in the sea urchin, the increased calcium causes the cortical granules to fuse with the egg plasma membrane. A fertilization envelope does not form around the mammalian egg, but the cortical granule enzymes destroy the sperm-binding molecules in the zona pellucida. The rise in cytosolic calcium also signals the egg to complete meiosis. The stage is set for the first cell division.

Getting eggs and sperm together

As we have just seen, sexual reproduction requires the production of haploid gametes (gametogenesis) and the joining together of those gametes to form a diploid zygote (fertilization). Spawning and mating behaviors get eggs and sperm close enough together that fertilization can occur. Fertilization can occur externally or internally.

EXTERNAL FERTILIZATION In an aquatic environment, animals can bring their gametes together by simply releasing them into the water. This practice, called spawning, results in **external fertilization**. Many aquatic animals are not very mobile, but they produce huge numbers of gametes that can travel far from the point of release. A female oyster, for example, will release millions of eggs when she spawns, and the number of sperm produced by a male oyster is astronomical.

Numbers alone, however, do not guarantee that gametes will meet. The reproductive activities of the males and females of a population must be synchronized, since released gametes have a limited life span. Seasonal breeders may use day length, changes in temperature, or changes in weather to time the production and release of their gametes. Mutual stimulation is also important. Release of gametes into the water by one individual can stimulate others to spawn.

Behavior can play an important role in bringing gametes together even when fertilization is external. Many species travel great distances to congregate with potential mates and release their gametes at the same time in a suitable environment. Salmon are an extreme example. They hatch and develop in freshwater streams and then migrate to the ocean where they remain for years. When they are grown, they travel hundreds of miles to spawn back in the stream where they hatched. Males and females expend great amounts of energy to swim up the streams to the spawning grounds, where they pair up, prepare a depression in the streambed gravel, and together release their sperm and eggs. As the gametes drift down into the gravel, fertilization occurs.

INTERNAL FERTILIZATION Terrestrial animals cannot simply release their gametes into the environment. Sperm can move only through liquid, and delicate gametes released into air would dry out and die. Terrestrial animals avoid these problems by **internal fertilization**, the release of sperm into the female reproductive tract. Some aquatic animals also practice internal fertilization, but it is ubiquitous in terrestrial animals.

Animals have evolved an astonishing diversity of behavioral and anatomical adaptations for internal fertilization. As we saw above, gametogenesis occurs in the gonads, which are the *primary sex organs*. All additional anatomical components of an animal's reproductive system are called *accessory sex organs*. An obvious accessory sex organ in males of many species is the **penis**, which enables the male to deposit sperm in the female's **vagina**, the entry to her reproductive tract. Accessory sex organs include a variety of glands, tubules, ducts, and other structures.

Copulation is the physical joining of male and female accessory sex organs. Transfer of sperm in internal fertilization can also be indirect. Males of many invertebrate species (for example, mites and scorpions) and a few vertebrates (salamanders) deposit *spermatophores*—packets of sperm—in the environment. The packets protect the sperm from desiccation. When a female mite encounters a spermatophore from a potential mate, she straddles it and opens a pair of plates in her abdomen so that the tip of the spermatophore enters her reproductive tract and allows the sperm to enter.

Male squids and spiders play a more active role in spermatophore transfer. The male spider secretes a drop containing sperm onto a bit of web, then uses a special structure on his foreleg to pick up the sperm-containing web and insert it through the female's genital opening. Male squids use one specialized tentacle to pick up a spermatophore and insert it into the female's genital opening.

Most male insects copulate and transfer sperm to the female's vagina through a penis. The **genitalia**—external sex organs—of insects often have species-specific shapes that ensure that the male and female genitalia match in a lock-and-key fashion. This mechanism ensures a tight, secure fit between the mating pair during the prolonged period of sperm transfer. In some insect species in which females mate with more than one male, the males have elaborate structures on their penises that can scoop sperm deposited by other males out of a female's reproductive tract, replacing it with their own.

An individual animal can function as both male and female

In most species, gametes are produced by individuals that are either male or female. Species that have separate male and female members are called **dioecious** species (from the Greek for “two houses”). In some species, however, a single individual may produce both sperm and eggs. Such species are called **monoecious** (“one house”) or **hermaphroditic**, species.

Almost all invertebrate groups contain some hermaphroditic species. An earthworm is an example of a *simultaneous hermaphrodite*, meaning an individual is both male and female at the same time. When two earthworms mate, they exchange sperm, and as a result, the eggs of each are fertilized (see Figure 32.13C). Some vertebrates are *sequential hermaphrodites*, meaning that an individual may function as a male or a female at different times in its life. An example is the anemone fish, or clown fish (**Figure 43.6**), a species that lives in small groups within large

43.6 When Size Determines Sex Anemone fish (also known as clown fish) live in groups of about a dozen centered on a single sea anemone. All anemone fish are born male, and the largest one in the group becomes a functional female. Thus any one fish may function as a male and as a female at different times in its life.

sea anemones. All anemone fish are born male. The largest one in a group becomes a functional female. If that fish is removed from the group, the next largest male becomes a female. Also, the second-largest anemone fish in the group is the only male in breeding condition.

What is the evolutionary advantage of hermaphroditism? Some simultaneous hermaphrodites, such as parasitic tapeworms, have a low probability of meeting a potential mate—it may be the only tapeworm in the host. Although tapeworms can fertilize their own eggs, most simultaneous hermaphrodites must mate with another individual; but because every member of the population is both male and female, the probability of encountering a possible mate is double what it would be in strictly monoecious species. In some sequential hermaphrodites, all siblings are either male or female at the same time, thus reducing the incidence of inbreeding.

The evolution of vertebrate reproductive systems parallels the move to land

The earliest vertebrates evolved in aquatic environments. The closest living relatives of those earliest vertebrates are modern-day fishes. They remain exclusively aquatic animals, and most practice external fertilization. The most primitive of the fishes, the lampreys and hagfishes, simply release their gametes into the environment. In most fishes, however, mating behaviors bring females and males into close proximity at the time of ga-

mete release. In sharks and rays, fins have evolved into claspers that hold the male and female together and enable sperm to be transferred directly into the female reproductive tract.

Amphibians were the first vertebrates to live in terrestrial environments. They dealt with the challenge of a dry environment by returning to water to reproduce, as most amphibians still do today.

Reptiles were the first vertebrate group to solve the problem of reproduction in the terrestrial environment. Their solution, the **amniote egg**, is shared with the birds (see Section 33.4). A chicken egg is a good example of an amniote egg. It contains a supply of food (yolk) and water for the developing embryo. A hard shell protects the embryo and impedes water loss while allowing the diffusion of oxygen into the egg and carbon dioxide out of the egg (**Figure 43.7A**). The eggshell creates an obvious problem for fertilization. Sperm cannot penetrate the shell, so they must reach the egg before the shell forms. Hence internal fertilization and the evolution of accessory sex organs were necessary for the evolution of the amniote egg.

Male snakes and lizards have paired *hemipenes*, which can be filled with blood and thereby extruded from the male's body. Only one hemipenis is inserted into the female's reproductive tract at a time. It is usually rough or spiny at the end to achieve a secure hold while sperm are transferred down a groove on its surface. Retractor muscles pull the hemipenis back into the male's body when mating is completed. Some evolutionarily ancient bird species have erectile penises that channel sperm along a groove into the female's reproductive tract. Birds with more recent evolutionary origins, however, do not have erectile penises; instead, the male and female simply bring their genital openings close together to transfer sperm. Usually this involves the male standing on the female's back (**Figure 43.7B**).

All mammals practice internal fertilization, and with the exception of the prototherian mammals, the developing embryo is retained for some time in the female reproductive tract. Pro-

totherian mammals (the monotremes; see Figure 33.24) lay eggs. The other mammals (the *therians*) vary enormously as to the developmental stage of their offspring at the time of birth.

Animals with internal fertilization are distinguished by where the embryo develops

Two patterns of care and nurture of the embryo have evolved in animals: *oviparity* (egg laying) and *viviparity* (live bearing).

Oviparous animals lay eggs in the environment, and their embryos develop outside the mother's body. Oviparous terrestrial animals such as insects, reptiles, and birds protect their eggs from desiccation with waterproof membranes or shells. Oviparity is possible because eggs are stocked with abundant nutrients to supply the needs of the embryo. Some oviparous animals engage in various forms of parental behavior to protect their eggs, but until the eggs hatch, the embryos depend entirely on the nutrients stored in the egg.

Viviparous animals retain the embryo within the mother's body during its early developmental stages. Although examples of viviparity exist in all vertebrate groups except the crocodiles, turtles, and birds (even some sharks retain fertilized eggs in their bodies and give birth to free-living offspring), there is a big difference between viviparity in mammals and in other species.

All mammals except the prototherians are viviparous and have a specialized portion of the female reproductive tract, the **uterus** or *womb*, that holds the embryo and interacts with it to produce a **placenta**, which enables the exchange of nutrients and wastes between the blood of the mother and that of the embryo. Very few non-mammalian species have evolved such a connection between the embryo and the mother.

In most non-mammalian viviparous animals, such as garter snakes and the well-known aquarium fish the guppy, fertilized

43.7 The Shelled Egg The shelled egg was a major evolutionary step that allows reptiles and birds to reproduce in the terrestrial environment. (A) A female green sea turtle has deposited her eggs in the sand. (B) The shelled egg requires that sperm meet egg before the shell forms. Terrestrial animals thus must practice internal fertilization, as these European bee-eaters are doing.

eggs are retained in the mother's body until they hatch. These embryos still receive nutrition from stores in the egg, so this reproductive adaptation is called **ovoviviparity**.

43.2 RECAP

Sexual reproduction involves gametogenesis, mating, and fertilization. Fertilization can be external or internal and involves mechanisms for ensuring that only one sperm from the right species enters the egg.

- Describe the steps by which a sea urchin sperm penetrates the egg. **See Figure 43.4**
- Explain how polyspermy is prevented and why it is crucial to do so. **See p. 906 and Figure 43.4**
- What reproductive adaptations made life on land possible? **See p. 908**

Now that we have covered some of the general aspects of gametogenesis and fertilization and have briefly discussed the great diversity of mating systems, we will next consider the human reproductive systems in detail.

43.3 How Do the Human Male and Female Reproductive Systems Work?

In this section we describe the structures and functions of the male and female reproductive systems in mammals, using human beings as our prime example. We also discuss the hormonal regulation of both male and female systems. Our discussion includes the primary sex organs (testes in males and ovaries in females) that produce gametes and serve endocrine functions. It also includes the accessory sex organs: the ducts through which the gametes pass, the various glands that empty into those ducts, and the external genitalia. We also discuss *secondary sexual characteristics*, which are not directly involved in reproduction but are responsible for the major differences in external appearance of men and women and are important in mating.

Male sex organs produce and deliver semen

Semen is the product of the male reproductive system. Besides sperm, semen contains a complex mixture of fluids and molecules that support the sperm and facilitate fertilization. Sperm make up less than 5 percent of the volume of the semen.

The male reproductive organs are diagrammed in **Figure 43.8**. Sperm are produced in the testes, the paired male gonads. The testes of most mammals are located outside the body cavity in a pouch of skin called the **scrotum**.

Why should the testes be located outside the body cavity? The optimal temperature for spermatogenesis in most mammals is slightly lower than the normal body temperature. The scrotum

(B) Side view

yourBioPortal.com

GO TO Web Activity 43.1 • The Human Male Reproductive Tract

keeps the testes at this optimal temperature. Muscles in the scrotum contract in a cold environment, bringing the testes closer to the warmth of the body; in a hot environment they relax, cooling the testes by suspending them farther from the body.

Spermatogenesis takes place within the **seminiferous tubules**, which are tightly coiled in each testis (**Figure 43.9A**). Between the seminiferous tubules are clusters of **Leydig cells**, or **interstitial cells**, which produce testosterone (**Figure 43.9B**). Spermatogonia reside in the outer regions of the tubule, just under the basement membrane. Moving inward from these outer layers toward

the lumen of the tubule, we find germ cells in successive stages of spermatogenesis (**Figure 43.9C**). These germ cells are intimately associated with **Sertoli cells**, which provide nutrients for the developing sperm.

When the second meiotic division is complete, each primary spermatocyte has given rise to four spermatids (see **Figure 43.3A**), which develop into spermatozoa as they continue to migrate toward the lumen of the seminiferous tubule. The nucleus becomes compact, and the surrounding cytoplasm is lost. A flagellum, or sperm tail, develops. The mitochondria, which will provide energy for tail motility, become condensed into a midpiece between the head and the tail. An acrosome forms over the nucleus in the head of the sperm. Immature sperm are shed into the lumen of the seminiferous tubule.

From the seminiferous tubules, sperm move into the **epididymis** (see **Figure 43.8**), where they mature and become motile. The epididymis connects to the **urethra** via the **vas deferens**

(plural *vasa deferentia*) and the **ejaculatory duct**. The urethra originates in the bladder, runs through the penis, and opens to the outside of the body at the tip of the penis. It serves as the common final duct for the urinary and reproductive systems. The components of the semen other than sperm come from several accessory glands. About 60 percent of the volume of semen is secreted by the paired **seminal vesicles**, which empty into the vas deferens just before it joins the urethra. Seminal fluid is thick because it contains mucus and fibrinogen, a protein also found in the blood, where it can polymerize to form blood clots. Seminal fluid also contains the monosaccharide fructose, an energy source for the sperm.

The **prostate gland** surrounds the urethra and contributes about 30 percent of the volume of the semen. Prostate fluid is alkaline, so it neutralizes the acidity in the male and female reproductive tracts and makes those environments more hospitable to sperm. The prostate also secretes a clotting enzyme that causes the fibrinogen from the seminal vesicles to convert the semen into a coagulum (gelatinous mass), facilitating its propulsion into and retention in the upper regions of the female reproductive tract. Another enzyme in the prostate fluid, profibrinolysin, is inactive when secreted but is activated shortly after it enters the female reproductive tract. Active fibrinolysin dissolves the clotted semen and liberates the sperm.

The **bulbourethral glands** produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen at the climax of sexual intercourse. Secretions of the bulbourethral glands precede the climax of the sex act and can carry with them residual sperm from prior sexual activity. Therefore, it is possible for pregnancy to occur even if the penis is withdrawn from the vagina just before climax (a rather ineffective birth control practice known as *coitus interruptus*).

The penis and the scrotum are the male genitalia. The shaft of the penis is covered with normal skin, but the highly sensitive tip, the **glans penis**, is covered with thinner, more sensitive skin that is especially responsive to sexual stimulation. A fold of skin called the *foreskin* covers the glans of the human penis. The procedure known as *circumcision* removes a portion of the foreskin.

Sexual stimulation triggers responses in the nervous system that result in penile **erection**. Nerve endings release a gaseous neurotransmitter, nitric oxide (NO), onto blood vessels leading into the penis. NO stimulates production of the second messenger cGMP (see Figure 7.17), which causes these vessels to dilate. The increased blood flow that results fills and swells shafts of spongy, erectile tissue located along the length of the penis. The enlargement of these blood-filled cavities compresses the vessels that normally carry blood out of the penis. As a result, the erectile tissue becomes more and more engorged with blood. The penis becomes hard and erect, facilitating its insertion into the vagina. Many species of mammals, but not humans, have a bone in the penis, but these species still depend on erectile tissue for copulation.

At the climax of copulation, about 2 to 6 milliliters of semen are propelled through the vasa deferentia and the urethra in two steps, emission and ejaculation. During **emission**, rhythmic contractions of smooth muscles in the vasa deferentia and accessory glands move the semen into the urethra at the base of the penis.

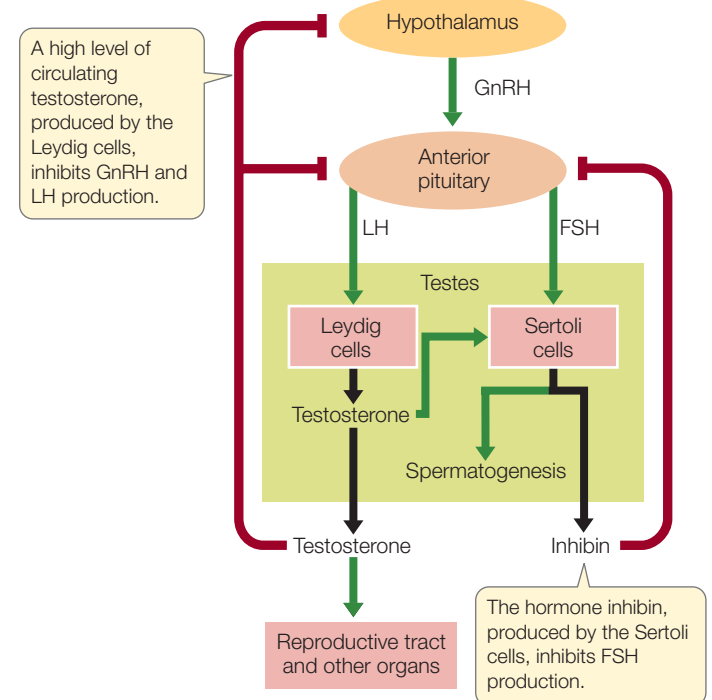

Ejaculation is caused by contractions of other muscles at the base of the penis surrounding the urethra. These contractions force the coagulum of semen through the urethra and out of the penis. The muscle contractions of ejaculation are accompanied by feelings of intense pleasure known as **orgasm**. They are also accompanied by transient increases in heart rate, blood pressure, breathing, and skeletal muscle contractions throughout the body.

After ejaculation, NO release decreases and enzymes break down cGMP, causing the blood vessels flowing into the penis to constrict. The blood pressure in the erectile tissue decreases, relieving the compression of the blood vessels leaving the penis, and the erection declines.

Erectile dysfunction (ED), or *impotence*, is the inability to achieve or sustain an erection. ED may have different causes, including cardiovascular disease. Drugs used to treat ED act by inhibiting the breakdown of cGMP, thus enhancing the effect of NO released in the penis, which improves the ability to achieve and maintain an erection.

Male sexual function is controlled by hormones

Spermatogenesis and maintenance of male secondary sexual characteristics such as facial hair and a deep voice depend on testosterone produced by the Leydig cells of the testes. As described in Section 41.3, increased production of testosterone at puberty results from an increased release of gonadotropin-releasing hormone (GnRH) by the hypothalamus, which stimulates anterior pituitary cells to increase their secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Figure 43.10). Higher levels of LH stimulate the Leydig cells

43.10 Male Reproductive Hormones The male reproductive system is under hormonal control by the hypothalamus and the anterior pituitary. Red lines indicate inhibition; green lines indicate stimulation.

to increase their production and release of testosterone. Testosterone exerts negative feedback on the anterior pituitary and the hypothalamus. At the time of puberty, the sensitivity of the hypothalamus to negative feedback from testosterone declines, and the level of circulating testosterone increases.

Increased testosterone in pubertal boys causes the development of pubic and facial hair, a deeper voice, enlarged genitals, and an increased growth rate. Testosterone also promotes increased muscle mass and maturation of the testes. Continued production of testosterone after puberty is essential for the maintenance of secondary sexual characteristics and the production of sperm.

Spermatogenesis is controlled by the influence of FSH and testosterone on the Sertoli cells in the seminiferous tubules. The Sertoli cells also produce a hormone called *inhibin*, which exerts negative feedback on the anterior pituitary cells that produce and secrete FSH.

Female sex organs produce eggs, receive sperm, and nurture the embryo

When a mammalian egg matures, it is released from the ovary directly into the body cavity. But the egg does not go far. The ovaries are close to the *fimbria*, the undulating, fringed openings of the **oviducts** (also known as the *Fallopian tubes*). The fimbria draw the released egg into an oviduct (**Figure 43.11**), where fertilization takes place. Whether or not the egg is fertilized, cilia lining the oviduct propel the egg slowly toward the uterus, a muscular, thick-walled cavity shaped in humans like an upside-down pear. The uterus is where the embryo develops if the egg is fertilized. At the bottom, the uterus narrows into a region called the **cervix**, which leads into the vagina.

In humans, two sets of skin folds surround the opening of the vagina and the opening of the urethra, through which urine passes. The inner, more delicate folds are the *labia minora*; the outer, thicker folds are the *labia majora*. At the anterior tip of the labia minora is the *clitoris*, a small bulb of erectile tissue that has the same developmental origins as the penis. The clitoris is highly sensitive and plays an important role in sexual response. The labia minora and the clitoris become engorged with blood in response to sexual stimulation.

43.11 Reproductive Tract of the Human Female The female reproductive organs are shown (A) from the front and (B) from the side.

The external opening of an infant's vagina is usually, but not always, partly covered by a thin membrane, the *hymen*. Eventually the hymen can be torn by vigorous physical activity or by first sexual intercourse; it can sometimes make first intercourse difficult or painful for the woman.

To fertilize an egg, sperm deposited in the vagina swim and are propelled by contractions of the female reproductive tract through the cervical opening, the uterus, and most of the oviduct. The egg (actually a secondary oocyte) is fertilized in the upper region of the oviduct. Fertilization stimulates the completion of the second meiotic division, after which the haploid

yourBioPortal.com

GO TO Web Activity 43.3 • The Human Female Reproductive Tract

nuclei of the sperm and the egg can fuse to produce a diploid zygote nucleus.

Still in the oviduct, the zygote undergoes its first few cell divisions to become a **blastocyst**. The blastocyst moves down the oviduct to the uterus, where it attaches itself to the epithelial lining of the uterus, or **endometrium**. Once attached, the blastocyst burrows into the endometrium—a process called *implantation*—and interacts with it to form the placenta, as we will see in Chapter 44. The placenta nurtures the embryo and produces hormones that help sustain pregnancy.

As an egg matures in the ovary, the endometrium thickens. If no blastocyst arrives in the uterus, the endometrium regresses or is sloughed off. Thus the female reproductive cycle actually consists of two linked cycles: an *ovarian cycle* that produces eggs and hormones, and a *uterine*, or *menstrual*, cycle that prepares the endometrium for the arrival of a blastocyst.

The ovarian cycle produces a mature egg

An **ovarian cycle** is about 28 days long in the human female, but it varies considerably among individuals. During the first half of each cycle, at least one primary oocyte matures into a secondary oocyte (egg) and is expelled from the ovary (*ovulation*). During the second half of the cycle, cells in the ovary that were associated with the maturing oocyte develop endocrine functions and then regress if the egg is not fertilized. The progression of these events is shown diagrammatically in **Figure 43.12A**.

A newborn baby girl has about a million primary oocytes in each ovary. By the time she reaches puberty, she has only about 200,000; the rest have degenerated. During a woman's

fertile years, her ovaries go through about 450 ovarian cycles. During each cycle, several oocytes begin to mature, but usually only one matures completely and is released; the others degenerate. At around the age of 50, a woman reaches **menopause**—the end of fertility—and may have few if any oocytes left in each ovary.

Each primary oocyte in the ovary is surrounded by a layer of ovarian cells. An oocyte and its surrounding cells constitute the functional unit of the ovary, the **follicle** (**Figure 43.12B**). Between puberty and menopause, 6 to 12 follicles begin to mature each month. In each follicle, the oocyte enlarges and the surrounding follicular cells proliferate. After about a week, one follicle is larger than the rest, and it continues to grow, while the others cease to develop. In the enlarged follicle, the follicular cells nurture the growing egg, supplying it with nutrients, growth factors, and hormonal stimulation.

In humans, after 2 weeks of follicular growth, **ovulation** occurs: the follicle ruptures and the egg is released. Following ovulation, the follicle cells that remain in the ovary continue to proliferate and form a mass of endocrine tissue about the size of a marble. This structure is the *corpus luteum* (plural *corpora lutea*). It functions as an endocrine gland, producing estrogen and progesterone for about 2 weeks. It then degenerates, unless a blastocyst implants in the endometrium.

The uterine cycle prepares an environment for the fertilized egg

The **uterine cycle** parallels the ovarian cycle and consists of a buildup and then a breakdown of the endometrium (**Figure 43.13**). About 5 days into the ovarian cycle, the endometrium starts to grow in preparation for receiving a blastocyst. The uterus

43.12 The Ovarian Cycle (A) The ovarian cycle progresses from the development of a follicle to ovulation and finally to growth and degeneration of the corpus luteum. (B) This micrograph shows a mature mammalian follicle; the oocyte is in the center.

43.13 The Ovarian and Uterine Cycles

During a woman's ovarian and uterine cycles, coordinated changes occur in (A) gonadotropin release by the anterior pituitary, (B) the ovary, (C) the release of female sex steroids, and (D) the uterus. The cycles begin with the onset of menstruation; ovulation is at midcycle (yellow bar).

[yourBioPortal.com](#)

The Ovarian and Uterine Cycles

attains its maximal state of preparedness about 5 days after ovulation and remains in that state for another 9 days. If a blastocyst has not arrived by that time, the endometrium begins to break down, and the sloughed-off tissue, including blood, flows from the body through the vagina—the process of **menstruation** (from *menses*, the Latin word for “months”).

The uterine cycles of most mammals other than humans do not include menstruation; instead, the uterine lining typically is resorbed. In these species, the most obvious correlate of the ovarian cycle is a state of sexual receptivity called **estrus** around the time of ovulation. You may be aware of the bloody discharge that occurs in dogs at the time of estrus. This discharge is not the same as menstruation—in fact it is exactly the opposite. Bleeding in dogs occurs during the *proliferation* of the uterine lining, which occurs just before ovulation. When the female mammal comes into estrus, or “heat,” she actively solicits male attention and may be aggressive to other females. Humans are unusual among mammals in that females are potentially sexually receptive throughout their ovarian cycles and at all seasons of the year.

Hormones control and coordinate the ovarian and uterine cycles

The ovarian and uterine cycles are coordinated and timed by the same hormones that initiate sexual maturation. Gonadotropins (FSH and LH) secreted by the anterior pituitary are the central elements of this control. Before puberty (that is, before about 11 years of age), the secretion of FSH and LH is low and the ovaries are inactive. At puberty, the hypothalamus increases its release of GnRH, stimulating the anterior pituitary to secrete FSH and LH.

In response to FSH and LH, ovarian tissue grows and produces estrogen. The rise in estrogen causes the maturation of the accessory sex organs and the development of female secondary sexual characteristics. Between puberty and menopause,

FSH and LH are under control of GnRH from the hypothalamus and the ovarian hormones estrogen and progesterone (part C).

FSH stimulates the development of follicles; the LH surge causes ovulation and then the development of the corpus luteum.

Estrogen and progesterone stimulate the development of the endometrium in preparation for pregnancy.

(A) Gonadotropins (from anterior pituitary)

(B) Events in ovary (ovarian cycle)

(C) Ovarian hormones and the uterine cycle

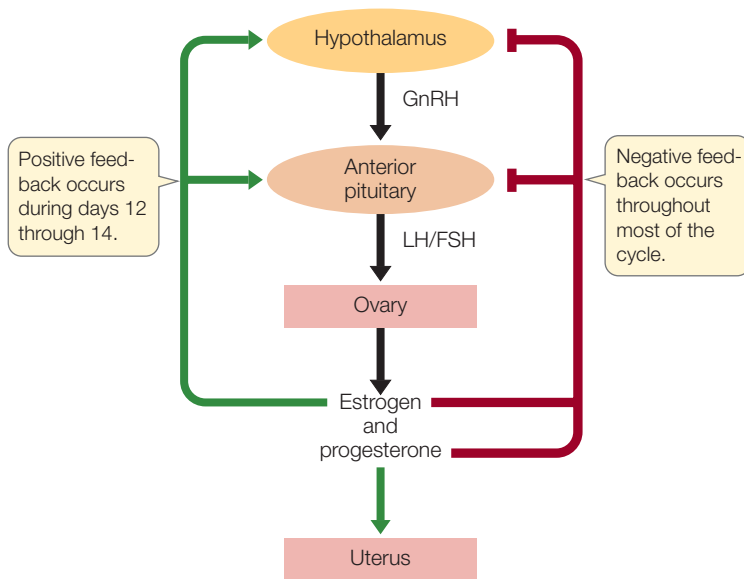

interactions of GnRH, gonadotropins, and sex steroids control the ovarian and uterine cycles.

Menstruation marks the beginning of each uterine and ovarian cycle. A few days before menstruation begins, the anterior pituitary begins to increase its secretion of FSH and LH. In response, some 10 to 20 follicles begin to mature in the ovaries, and these follicles steadily increase their production of estrogen. After about a week, all but one of the follicles wither away.

Estrogen exerts negative feedback control on gonadotropin release by the anterior pituitary during the first 12 days of the ovarian cycle. Then, on about day 12, estrogen exerts positive rather than negative feedback control on the pituitary (**Figure 43.14**). As a result, a surge of LH and a lesser surge of FSH occur (see **Figure 43.13A**). The LH surge triggers the mature follicle to rupture and release its egg, and it stimulates the cells of the ruptured follicle to develop into a corpus luteum.

The corpus luteum becomes an endocrine gland. Estrogen and especially progesterone secreted by the corpus luteum following ovulation are crucial to continued growth and mainte-

43.14 Hormones Control the Ovarian and Uterine Cycles The ovarian and uterine cycles are under a complex series of positive and negative feedback controls involving several hormones.

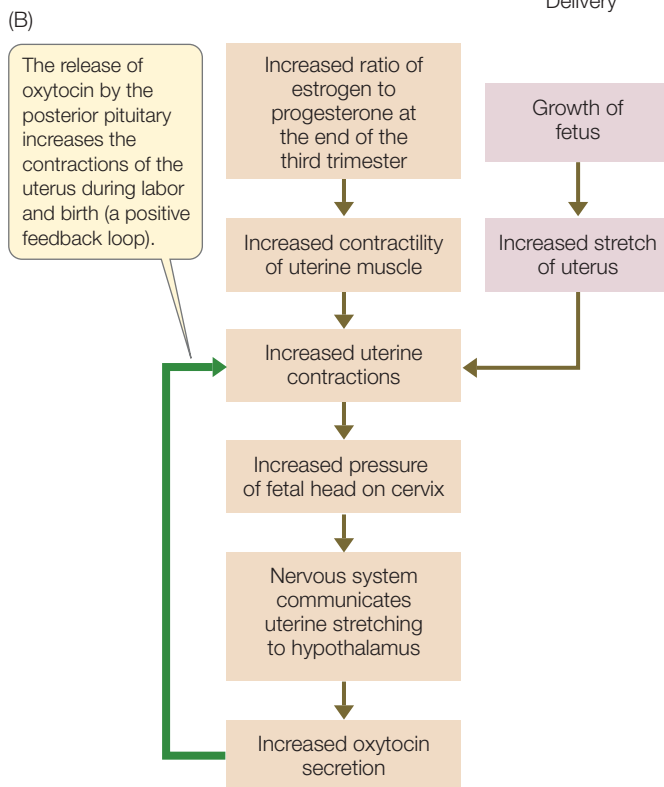

nance of the endometrium. In addition, these sex steroids exert negative feedback control on the pituitary, inhibiting gonadotropin release and thus preventing new follicles from beginning to mature.

If the egg is not fertilized, the corpus luteum degenerates on about day 26 of the cycle. Without production of progesterone by the corpus luteum, the endometrium sloughs off and menstruation occurs. The decrease in circulating steroids also releases the hypothalamus and pituitary from negative feedback control, so GnRH, FSH, and LH all begin to increase. The increase in these hormones induces the next round of follicle development, and the ovarian cycle begins again.

In pregnancy, hormones from the extraembryonic membranes take over

If the egg is fertilized and a blastocyst arrives in the uterus and implants in the endometrium, a new hormone comes into play. A layer of cells covering the blastocyst begins to secrete **human chorionic gonadotropin**, or **hCG** (Figure 43.15A). This gonadotropin, a molecule similar to LH, stimulates the corpus luteum to continue to produce estrogen and progesterone to support the growth and maintenance of the endometrium and thereby prevent menstruation. Because it is present only in the blood of pregnant women, the presence of hCG is the basis for pregnancy testing. Pregnancy tests use an antibody to detect hCG in urine; they take only minutes, and can be done at home.

43.15 Pregnancy and Childbirth (A) When a fertilized ovum implants in the uterus, cells surrounding it produce human chorionic gonadotropin, which acts like LH and keeps the corpus luteum functioning as an endocrine gland. The ovarian and uterine cycles are put on hold for the duration of pregnancy. (B) Both mechanical and hormonal signals are involved in stimulating the uterine contractions of labor and delivery. (C) A new person is delivered into the world headfirst.

(C)

Blastocyst and endometrial tissues form the placenta, which produces estrogen and progesterone (eventually replacing the corpus luteum as the most important source of these sex steroids). Continued high levels of estrogen and progesterone prevent the pituitary from secreting gonadotropins; thus, the ovarian cycle ceases for the duration of pregnancy. (This mechanism underlies the action of birth control pills, which contain synthetic hormones resembling estrogen and progesterone that exert negative feedback control on the hypothalamus and pituitary.)

Childbirth is triggered by hormonal and mechanical stimuli

Throughout pregnancy, the muscles of the uterine wall periodically undergo slow, weak, rhythmic contractions called *Braxton Hicks contractions*. These contractions become stronger during the third trimester of pregnancy and are sometimes called *false labor contractions*. True labor contractions usually mark the beginning of childbirth. Both hormonal and mechanical stimuli contribute to the onset of labor.

Progesterone inhibits and estrogen stimulates contractions of uterine muscle. Toward the end of the third trimester, the estrogen–progesterone ratio shifts in favor of estrogen. The onset of labor is marked by increased secretion of the hormone oxytocin by the posterior pituitaries of both mother and fetus. Oxytocin is a powerful stimulant of uterine muscle contraction. Manufactured oxytocin is used to induce labor when that is necessary.

Mechanical stimuli come from the stretching of the uterus by the fully grown fetus and the pressure of the fetal head on the cervix. These mechanical stimuli increase the release of oxytocin by the mother's posterior pituitary, which in turn increases the activity of uterine muscle, which causes even more pressure on the cervix. This positive feedback loop converts the weak, slow, rhythmic Braxton Hicks contractions into stronger labor contractions (**Figure 43.15B**).

In the early stage of labor, hormonal changes and pressure created by the contractions cause the cervix to dilate (expand) until it is large enough to allow the baby to pass through. Gradually the contractions become more frequent and more intense. This stage of labor lasts an average of 12 to 15 hours in a first pregnancy; it is usually 8 hours or less in subsequent ones.

The second stage of labor, called *delivery*, begins when the cervix is fully dilated to a diameter of about 10 centimeters (**Figure 43.15C**). The baby's head moves into the vagina; passage of the fetus through the vagina is assisted by the mother's bearing down ("pushing") with her abdominal and other muscles. Once the head and shoulders of the baby clear the cervix, the rest of its body eases out rapidly, but it is still connected to the placenta by the umbilical cord. Once the baby clears the birth canal, it starts breathing and is independent of its mother's circulation. The umbilical cord may then be clamped and cut. The segment still attached to the baby dries up and sloughs off in a few days, leaving behind its distinctive signature, the belly button—more properly called the *umbilicus*. The detachment and expulsion of the placenta and fetal membranes take from a few minutes to an hour, and may be accompanied by uterine contractions. If the baby suckles at the breast immediately fol-

lowing birth, its suckling stimulates additional secretion of oxytocin, which augments uterine contractions that reduce the size of the uterus and help stop bleeding.

43.3 RECAP

The reproductive systems of men and women produce gametes and hormones, and these functions are controlled by hypothalamic and anterior pituitary hormones. In women, the hormonal control of reproductive functions produces linked ovarian and uterine cycles.

- Describe the path the human sperm and ovum take in moving from their respective gonads to the point at which fertilization occurs. **See Figures 43.8 and 43.11**
- In males, increased production of GnRH at puberty stimulates the release of what two hormones of the anterior pituitary? What effect do these hormones have? **See p. 911**
- Explain the events in the ovarian cycle that result in release of a single ovum each month. What events prepare the uterus to receive the egg? **See Figures 43.12 and 43.13**

Understanding the physiology of human reproduction has led to numerous methods and technologies for controlling it, either to prevent unwanted pregnancies or to overcome infertility.

43.4 How Can Fertility Be Controlled?

Sexual issues and sexual behavior are dominant aspects of our society, and reproductive technologies have had huge impacts on our sexual and reproductive lives.

Human sexual responses have four phases

The responses of both women and men to sexual stimulation consist of four phases: excitement, plateau, orgasm, and resolution. As sexual *excitement* begins in a woman, her heart rate and blood pressure rise, muscular tension increases, breasts swell, and nipples become erect. Her external genitals, including the sensitive clitoris, swell as they become filled with blood, and the walls of the vagina secrete lubricating fluid that facilitates copulation. In the *plateau* phase, her blood pressure and heart rate rise further and her breathing becomes rapid. The sensitivity once focused in the clitoris spreads over the external genitals, and the clitoris itself becomes even more sensitive. *Orgasm* may last as long as a few minutes, and unlike men, some women can experience several orgasms in rapid succession. During the *resolution* phase, blood drains from the genitals, and body physiology returns to close to normal.

In the man, the excitement phase is marked by an increase in blood pressure, heart rate, and muscle tension (just like in the woman) and by penile erection. In the plateau phase, breathing

becomes rapid, the diameter of the glans increases, and a few drops of a lubricating fluid from the bulbourethral gland may ooze from the penis. Continued stimulation of the nerve endings in the glans and in the skin along the shaft of the penis eventually trigger orgasm. Massive spasms of the muscles in the genital area and contractions in the accessory reproductive organs result in ejaculation. Within a few minutes after ejaculation, the penis shrinks to its former size and body physiology returns to resting conditions.

The male sexual response also includes a *refractory period* immediately after orgasm. During this period, which may last from minutes to hours, a man cannot achieve a full erection or another orgasm, regardless of the intensity of sexual stimulation. This refractory period is believed to be controlled by the anterior pituitary hormone prolactin (see Figure 41.2), which is released during orgasm. We say “believed” because the study shown in **Figure 43.16** is not conclusive; it compares the data from a single subject who displayed an unusual physiological characteristic with averaged data from a group of typical individuals. In Chapter 1 we learned the importance of statistical tests to establish whether an observed result could be due to chance alone, but we can’t perform the necessary tests with a sample size of only one. This problem frequently crops up in medical science when there is an effort to find an explanation for a highly unusual trait or disease. In such cases, data from even a single individual is of interest and can lead to additional studies and experiments.

Humans use a variety of methods to control fertility

According to a recent study, almost half of the more than 6 million pregnancies that occur in the United States each year are unintended. For women of college age, a single act of unprotected intercourse in the 2 days prior to ovulation carries a chance of conception as high as 50 percent.

The only failure-proof methods of preventing pregnancy are complete abstinence from sexual activity or the surgical removal of the gonads. Since those options are not acceptable to most people, they turn to other methods to prevent pregnancy. Many of these methods prevent fertilization or implantation (*conception*) and are therefore referred to as **contraception**. Most methods are used by the woman, some are used by the man; they also vary enormously in their effectiveness. **Table 43.1** lists some of the most commonly used contraceptive methods and their relative failure rates.

Once a fertilized egg is successfully implanted in the uterus, any termination of the pregnancy is called an **abortion**. A *spontaneous abortion* is the medical term for what most people call a

INVESTIGATING LIFE

43.16 Prolactin and the Male Refractory Period

Men experience a refractory period immediately after achieving orgasm, during which most men cannot achieve a full erection. A study done in Germany on a single individual who was able to achieve multiple orgasms indicated that the hormone prolactin may control the onset of refraction.

HYPOTHESIS Release of prolactin during copulation induces a refractory period in males.

METHOD

1. Catheterize subjects and withdraw blood samples (9 normal subjects; 1 multiorgasmic subject).
2. Induce orgasms 30 minutes apart.
3. Withdraw blood samples following orgasms.
4. Analyze all blood samples for levels of prolactin.

RESULTS

CONCLUSION In normal men, blood levels of prolactin rise following ejaculation. The multiorgasmic male showed no increase in prolactin levels, which may explain the lack of a refractory period in this individual.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

miscarriage. Spontaneous abortions are common early in pregnancy and are usually the result of either a chromosomal abnormality in the fetus or to a breakdown in the process of implantation. Many spontaneous abortions occur before the woman even realizes she is pregnant.

Abortions that result from medical intervention may be performed either for therapeutic purposes or for fertility control. A therapeutic abortion may be necessary to protect the health of the mother, or it may be performed because prenatal testing reveals that the fetus has a severe defect. Of the approximately 3 million unintended pregnancies in the United States each year, almost half are ended by abortion.

TABLE 43.1
Methods of Contraception

METHOD	MODE OF ACTION	FAILURE RATE ^a	COMMENTS
Unprotected	No form of birth control	85	High risk of pregnancy, especially for women 15–30.
NONTECHNOLOGICAL METHODS			
Rhythm method	The couple abstains from intercourse between days 10 and 20 of the ovarian cycle (peak fertility).	15–35	High failure rate due to miscalculation and/or variation of individual cycles.
Coitus interruptus	The man withdraws his penis prior to ejaculation, so no sperm is deposited in the vagina.	20–40	Requires self-control, especially by the male partner. Very high failure rate.
BARRIER METHODS^b			
Condom	A sheath of impermeable material (often latex) is fitted over the erect penis. Semen is trapped in the condom, so no sperm is deposited in the vagina.	15	If fitted correctly, an intact condom can prevent pregnancy and provide protection against sexually transmitted diseases (STDs), including HIV (AIDS).
Spermicidal jellies	Applied inside the vagina, these chemical compounds kill or immobilize sperm.	25	Used alone, spermicidal compounds have a fairly high failure rate.
Diaphragms, cervical caps	Inserted by the woman prior to intercourse, these items work by blocking the cervix so that sperm cannot pass into the uterus.	10–15	Approximately the same failure rate as condom use by males, but do not protect against STDs. Can be used in conjunction with spermicidal jelly for extra protection.
HORMONE-BASED CONTRACEPTIVES			
Oral hormones (“the pill”)	A daily pill for females containing a combination of synthetic estrogens and progesterone (progestin). These hormones mimic pregnancy to the extent that the ovarian cycle and ovulation are suspended. The uterine cycle is allowed to continue by including a week of non-hormone administration every 21–28 days.	0–3	Requires medical consultation and prescription. Taken correctly, oral contraceptives are extremely effective. In the U.S., more than 12 million women use them each year; they are sometimes prescribed to treat menstrual disorders.
Non-orally administered hormones	Making use of same hormonal actions as the pill, these methods include long-acting injections, patches that release hormones transdermally (through the skin), and a hormone-containing vaginal ring.	<1	Same as oral contraceptives. A slightly lower failure rate because the woman does not have to remember to take a daily pill.
Progestin-only pill (Plan B®)	An oral contraceptive meant to be taken within 72 hours <i>after</i> unprotected sex. A high dose of progestin in two pills prevents ovulation in the same manner birth control pills do.	5–40 ^c	Not an “abortion pill,” this drug will not terminate an existing pregnancy. Currently available to women over 17 without a prescription.
IMPLANTATION BLOCKERS			
Intrauterine device (IUD)	A medical professional inserts a small plastic or metal device into the uterus. The resulting inflammation reaction (see Chapter 42) releases prostaglandins, which prevent implantation of the fertilized egg.	0.5–5	A highly effective contraceptive, it is the most widely used birth control device in China (and hence the world). With medical monitoring, can remain in place for several years.
Mifepristone (RU-486)	Also known as the “morning after” or “abortion pill,” this drug blocks progesterone receptors necessary to maintain the endometrium during implantation and pregnancy.	0.5–6	Prevents implantation when taken up to several days after unprotected intercourse. Can end a pregnancy up to the time of the first missed menstrual period. In the U.S., available from specialized providers.
STERILIZATION			
Vasectomy	The vasa deferentia (see Figure 43.8A) are cut and tied off so that sperm can no longer pass into the urethra. Sperm continue to be produced but are reabsorbed by the man’s body. Male hormone levels and sexual responses are not affected.	0–0.15	A simple surgical procedure performed under local anesthetic in a doctor’s office. Although it can theoretically be reversed, vasectomy should be considered permanent.
Tubal ligation	The oviducts (see Figure 43.11A) are tied off so that eggs cannot reach the uterus and sperm cannot reach the egg. As with vasectomy, hormone levels and sexual responses are not affected.	0–0.05	This surgical procedure is somewhat more complex than vasectomy. It is often performed in conjunction with childbirth when a woman has decided that her family is complete.

^a “Failure rate” refers to the number of pregnancies per 100 women per year.

^b All of these barrier methods are routinely available without medical prescription.

^c Failure rate varies widely depending on when taken.

In a medical abortion, the cervix is dilated and some of the endometrium, along with the implanted fetus, is removed from the uterus. When performed in the first trimester of a pregnancy, a medical abortion carries less risk of death to the mother than a full-term pregnancy. The risk rises after the first 12 weeks of pregnancy but remains less than that of a full-term pregnancy through the second trimester.

Reproductive technologies help solve problems of infertility

About 15 percent of the couples in the United States are infertile; they can't have children. There are many reasons for infertility, and they are equally distributed between men and women. A number of technologies have been developed to overcome barriers to both conceiving and bearing a child.

The simplest treatment available is **artificial insemination**, in which the physician positions sperm in the female's reproductive tract. This technique is useful if the male's sperm count is low, if his sperm lack motility, or if problems in the female's reproductive tract prevent the normal movement of sperm up to and through the oviducts. Artificial insemination is used widely in the production of domesticated animals such as cattle.

More recent advances, called **assisted reproductive technologies**, or **ARTs**, involve procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg-sperm mixtures in the appropriate location in the female's reproductive tract for development to take place. The first successful ART was *in vitro fertilization* (IVF). In IVF, the female is treated with hormones that stimulate many follicles in her ovaries to mature. Eggs are collected from these follicles, and sperm are collected from the male. Eggs and sperm are combined in a culture medium outside the body, where fertilization takes place. The resulting embryos can be injected into the mother's uterus in the blastocyst stage or kept frozen for implantation later. The first "test-tube baby" resulting from IVF was born in England in 1978. Since then, more than 3 million babies have been produced by this ART.

A major cause of failure of IVF is failure of sperm to gain access to the egg plasma membrane (see Figure 43.4). To solve this problem, methods have been developed to inject a sperm cell directly into the cytoplasm of an egg. In *intracytoplasmic sperm injection* (ICSI), an egg is held in place by suction applied to a polished glass pipette. A slender, sharp pipette is then used to penetrate the egg and inject a sperm (**Figure 43.17**). This ART was used successfully for the first time in 1992 by researchers in Belgium; now thousands of these procedures are performed in U.S. clinics each year, with a success rate of about 25 percent.

IVF, coupled with techniques of genetic analysis, can eliminate the risk that adults who are carriers of genetic diseases will produce affected children. It is now possible to take a cell from a human embryo at the 4- or 8-cell stage (see Figure 44.4) without damaging its developmental potential. The sampled cell can

43.17 Intracytoplasmic Sperm Injection In this procedure, sperm are injected directly into a mature egg cell. The fertilized egg is then placed in the female reproductive tract, where it can implant and develop into a fetus.

be subjected to molecular analysis to determine whether it carries the harmful gene. This procedure, called preimplantation genetic diagnosis (PGD), makes it possible to determine whether an embryo produced by IVF carries the genetic defect of concern.

43.4 RECAP

Controlling fertility is an important aspect of modern human life. Decreasing the probability of pregnancy is achieved through methods that prevent sperm and egg from meeting and from preventing implantation. Pregnancies can be facilitated through medical technology.

- What are the four phases of the human sexual response? **See p. 916**
- Which method of contraception is the only one to offer protection against sexually transmitted diseases (STDs)? **See Table 43.1**

The fertilized egg of a sexually reproducing organism is a single cell containing all the genetic information needed to create a new organism. Chapters 19 and 20 introduced some of the molecular aspects of the process of development in multicellular animals. Chapter 44 describes the physical events of animal development.

CHAPTER SUMMARY

43.1 How Do Animals Reproduce Without Sex?

- Asexual reproduction produces offspring that are genetically identical to their parent and to one another; it produces no genetic diversity.
- Means of asexual reproduction include **budding**, **regeneration**, and **parthenogenesis**. Review Figures 43.1 and 43.2

43.2 How Do Animals Reproduce Sexually?

- Sexual reproduction consists of three basic steps: gametogenesis; spawning and mating; and fertilization.
- **Gametogenesis** and fertilization are similar in all animals, but spawning and mating includes a great variety of anatomical, physiological, and behavioral adaptations.
- In sexually reproducing species, genetic diversity is created by crossing over and independent assortment of chromosomes during gametogenesis. Fertilization also contributes to genetic diversity.
- Gametogenesis occurs in **testes** and **ovaries**. In spermatogenesis (the production of **sperm**) and oogenesis (the production of eggs), the **germ cells** proliferate mitotically, undergo meiosis, and mature into gametes.
- Each **primary spermatocyte** can produce four haploid sperm through the two divisions of meiosis. Review Figure 43.3A
- **Primary oocytes** immediately enter prophase of the first meiotic division, and in many species, including humans, their development is arrested at this point. Each **oogonium** produces only one egg. Review Figure 43.3B
- Fertilization involves sperm activation, species-specific binding of sperm to egg, the acrosomal reaction, digestion of a path through the protective coverings of the egg, and fusion of sperm and egg plasma membranes. Fusion of these two membranes triggers **blocks to polyspermy**, which prevent additional sperm from entering the egg, and in mammals, signal the egg to complete meiosis and begin development. Review Figure 43.4, ANIMATED TUTORIAL 43.1
- **External fertilization** is common in aquatic species. **Internal fertilization** is necessary in terrestrial species and usually involves **copulation**.
- The shelled egg of amniotes is an important evolutionary adaptation that allows reptiles and birds to reproduce in the terrestrial environment.
- **Hermaphroditic** or **monoecious** species have both male and female reproductive systems in the same individual, either sequentially or simultaneously. **Dioecious** species have separate male and female individuals.
- Animals can be classified as **oviparous** or **viviparous**, depending on whether the early stages of development occur outside or inside the mother's body.

43.3 How Do the Human Male and Female Reproductive Systems Work?

- Men produce **semen** and deliver it into the woman's reproductive tract. Semen consists of sperm suspended in seminal fluid, which nourishes the sperm and facilitates fertilization.
- Sperm are produced in the **seminiferous tubules** of the testes, mature in the **epididymis**, and are delivered to the **urethra** through the **vasa deferentia**. Other components of semen are produced in the **seminal vesicles**, **prostate gland**, and **bulbourethral gland**. Review Figures 43.8 and 43.9, WEB ACTIVITY 43.1
- All components of the semen join in the urethra at the base of the **penis** and are ejaculated through the erect penis by muscle contractions at the culmination of copulation.
- Spermatogenesis depends on testosterone secreted by the Leydig cells of the testes, which are under the control of hormones produced in the anterior pituitary and the hypothalamus. The production of these hormones is controlled by negative feedback from testosterone and another hormone, inhibin, produced by the **Sertoli cells** of the testes. Review Figure 43.10, WEB ACTIVITY 43.2
- Eggs mature in the woman's ovaries and are released into the **oviducts**. Sperm deposited in the **vagina** during copulation move up through the **cervix** and **uterus** into the oviducts. Fertilization occurs in the upper regions of the oviducts. Review Figure 43.11, WEB ACTIVITY 43.3
- The maturation and release of eggs constitute an **ovarian cycle**. In women, this cycle takes about 28 days. The **uterine cycle** prepares the uterus for receipt of a blastocyst. If no blastocyst is implanted, the lining of the uterus sloughs off in the process of **menstruation**. Review Figure 43.13, ANIMATED TUTORIAL 43.2
- Both the ovarian and the uterine cycles are under the control of hypothalamic and pituitary hormones, which in turn are under the feedback control of estrogen and progesterone. Review Figure 43.14
- Childbirth is initiated by hormonal and mechanical stimuli that increase the contraction of uterine muscle. Review Figure 43.15

43.4 How Can Fertility Be Controlled?

- Human sexual responses consist of four phases: excitement, plateau, orgasm, and resolution. In addition, men have a refractory period during which renewed excitement is not possible. Review Figure 43.16
- Methods of **contraception** include abstention from copulation and the use of technologies that decrease the probability of fertilization. Review Table 43.1
- **Assisted reproductive technologies (ARTs)** have been developed to increase fertility.

SELF-QUIZ

1. A species in which the individual possesses both male and female reproductive systems is termed
 - a. dioecious.
 - b. parthenogenetic.
 - c. hermaphroditic.
 - d. monoecious.
 - e. ovoviviparous.
2. The major advantage of internal fertilization is that
 - a. it ensures paternity.
 - b. it permits the fertilization of many gametes.
 - c. it reduces the incidence of destructive competitive interactions among the members of a group.
 - d. it increases the number of sperm having access to each egg.
 - e. it gives the developing organism a greater degree of protection during the early phases of development.

3. Which statement about human oocytes is *true*?
 - a. By birth, the human female infant has produced a lifetime supply of oocytes.
 - b. At the onset of puberty, ovarian follicles produce new oocytes in response to hormonal stimulation.
 - c. At the onset of menopause, a woman stops producing oocytes.
 - d. Oocytes are produced by a woman throughout adolescence.
 - e. Oocytes produced by a woman are stored in the oviducts.
4. Spermatogenesis and oogenesis differ in that
 - a. spermatogenesis produces gametes with greater stores of raw materials than those produced by oogenesis.
 - b. spermatocytes remain in prophase of the first meiotic division longer than oocytes.
 - c. oogenesis produces four equally functional haploid cells per meiotic event and spermatogenesis does not.
 - d. spermatogenesis produces many gametes with meager energy reserves, whereas oogenesis produces relatively few, well-provisioned gametes.
 - e. spermatogenesis begins before birth in humans, whereas oogenesis does not start until the onset of puberty.
5. Semen contains all of the following except
 - a. fructose.
 - b. mucus.
 - c. clotting enzymes.
 - d. substances to lower the pH of the uterine environment.
 - e. an active clot-dissolving enzyme.
6. During oogenesis in mammals, the second meiotic division occurs
 - a. in the formation of the primary oocyte.
 - b. in the formation of the secondary oocyte.
 - c. before ovulation.
 - d. after fertilization.
 - e. after implantation.
7. One of the major differences between the sexual responses of men and women is
 - a. the increase in blood pressure in men.
 - b. the increase in heart rate in women.
 - c. the presence of a refractory period in women.
 - d. the presence of a refractory period in men after orgasm.
 - e. the increase in muscle tension in men.
8. Which of the following statements about the ovarian and uterine cycles is *false*?
 - a. Falling estrogen and progesterone levels induce menstruation.
 - b. A sudden rise in LH induces ovulation.
 - c. Estrogen levels rise in the first half of the ovarian cycle and progesterone levels rise in the second half.
 - d. If fertilization occurs, the corpus luteum secretes hCG.
 - e. Estrogen is produced by follicle cells
9. Contractions of muscles in the uterine wall and milk let-down are stimulated by
 - a. progesterone.
 - b. estrogen.
 - c. prolactin.
 - d. oxytocin.
 - e. human chorionic gonadotropin.
10. Which of the following methods of contraception is *most likely* to fail?
 - a. Rhythm method
 - b. Birth control pills
 - c. Diaphragm
 - d. Vasectomy
 - e. Condom

FOR DISCUSSION

1. In the deep ocean, there are species of fish in which the male is much smaller than the female and actually lives attached to her body. In terms of the selective pressures that operate on sexual and asexual reproduction and in terms of the deep-sea environment, what factors do you think resulted in the evolution of this extreme sexual dimorphism?
2. What are two main differences between the immediate products of the first and second meiotic divisions in spermatogenesis and oogenesis? Why do these differences exist?
3. At the beginning of each ovarian cycle in humans, 6 to 12 follicles begin to develop in response to rising levels of FSH, but after a week, only one follicle continues to develop, and the others wither away. Given that follicles produce estrogen, that estrogen stimulates follicle cells to produce FSH receptors, and that estrogen exerts negative feedback on FSH production in the pituitary, can you explain how a single follicle is “selected” to grow?
4. Compare the actions of LH and FSH in the ovaries and testes.
5. Ovarian and uterine events during the month following ovulation differ depending on whether fertilization occurs. Describe the differences and explain their hormonal controls.

ADDITIONAL INVESTIGATION

No male contraceptive methods exist other than vasectomy or the condom. How would you go about developing a pharmacological method to block sperm production that could lead to a

male pill without affecting the maintenance of male secondary sexual characteristics or male sexual behavior?

44

Animal Development

Go with the flow

Place your hand over your heart. Now place it over your liver. Next over your appendix. Surely you put your hand first on the left side of your chest, then on your right side just under your ribs, and finally on the right side of your lower abdomen. But in Chapter 31 you learned that vertebrates (including you) are bilaterally symmetrical (left arm/right arm, left kidney/right kidney, and so on). Clearly, however, our bilateral symmetry is not absolute.

Some of our internal organs—including the heart, liver, appendix, stomach, and the lobes of the lungs—are oriented differently with respect to the left and right sides of the body. How does a developing embryo know which side is left and which is right?

Clues to answering this question came from the fact that in about 1 out of every 7,000 people, the arrangement of the internal organs is reversed, a condition known as *situs inversus*, Latin for “location inverted.” This developmental difference arises when the very early embryo goes from being a single layer of cells to multiple layers of cells.

As you will learn in this chapter, to get from a single layer of cells to the next stage with two layers of cells, a pore or slit forms as cells in one area of the embryo migrate inward from the surface. Other cells from the surface migrate toward and through this opening to take up positions underneath. The place where the inward movement of cells starts is called the node. Cells of the node have motile cilia that sweep extracellular fluid through the opening.

Cells bordering the node also have one nonmotile cilium each—a primary cilium. When the primary cilia are bent by the flow of extracellular fluid, they initiate signaling cascades that determine the pattern of internal organ development. Since the fluid driven by the motile cilia tends to flow from right to left, the signaling cascades are not expressed symmetrically, and this initiates the left–right organization of organ development.

Among individuals carrying a mutation that eliminates motility of the nodal cilia, half have the normal orientation of the internal organs and half have *situs inversus*. Most people with this condition lead normal, healthy lives. They may not even know about it

Go with the Flow The internal organs of humans are not all symmetrical, and some individuals are born with the mirror-image pattern of what is seen in most people—a condition called *situs inversus*. The left–right asymmetry of the internal organs is initiated by asymmetrical stimulation of primary cilia at a very early stage in development.

When Sperm Meet Egg Development begins with the fertilization of an egg by a sperm. Once one sperm fuses with the egg, all other sperm are blocked. An animal egg typically is much larger than the sperm; the egg cytoplasm is loaded with informational molecules and nutrients that will direct development and nourish the growing embryo.

unless a routine physical exam reveals that the organs are not where they should be.

As frequently happens in biology, we just pushed the question back one more step. Why do the nodal cilia beat in such a way that the extracellular fluid flows from right to left? The root cause of this asymmetry likely originates in some of the early cell divisions of the fertilized egg. The fertilized egg goes through an initial series of cell divisions that subdivide the egg cytoplasm into a mass of undifferentiated cells. Although this mass of cells shows no hints of the eventual body plan, an uneven distribution of molecules from the cytoplasm of the fertilized egg can provide information that directs the fates of cells and sets up the body plan.

IN THIS CHAPTER we will see how a single cell becomes a multicellular animal through orderly cell movements that create multiple layers and set up cell–cell interactions. The regional and temporal differences in gene expression that control cell differentiation, described in Chapters 19 and 20, lead to the emergence of the body plan of the animal. We will discuss these early developmental steps in four organisms that have been studied extensively: sea urchins, frogs, chickens, and humans.

CHAPTER OUTLINE

- 44.1** How Does Fertilization Activate Development?
- 44.2** How Does Gastrulation Generate Multiple Tissue Layers?
- 44.3** How Do Organs and Organ Systems Develop?
- 44.4** How is the Growing Embryo Sustained?
- 44.5** What Are the Stages of Human Development?

44.1 How Does Fertilization Activate Development?

Fertilization is the joining of sperm and egg. You might therefore think of it as the event that begins development. Keep two things in mind, however. First, in animals that reproduce asexually, development proceeds without fertilization. And second, in animals where fertilization does occur, it is preceded by critical events in the maturing egg that will influence subsequent development. Thus, in studying fertilization we are really asking how it activates or restarts multicellular development in sexually reproducing animals.

Fertilization does far more than just restore a full diploid complement of maternal and paternal genes. The fusion of sperm and egg plasma membranes accomplishes several things:

- It sets up blocks to the entry of additional sperm.
- It stimulates ion fluxes across the egg membrane.
- It changes the egg's pH.
- It increases egg metabolism and stimulates protein synthesis.
- It initiates the rapid series of cell divisions that produce a multicellular embryo.

Section 43.2 described the mechanisms of fertilization. Here we take a closer look at the cellular and molecular interactions of sperm and egg that initiate the first steps of development.

The sperm and the egg make different contributions to the zygote

In most species, eggs are much larger than sperm. Egg cytoplasm is well stocked with organelles, nutrients, and a variety of molecules, including transcription factors and mRNAs. The sperm is little more than a DNA delivery vehicle. Nearly everything the embryo needs during its early stages of development comes from the mother. In addition to providing its haploid nucleus, the sperm makes another important contribution to the zygote in most species—a centriole.

The centriole becomes the centrosome of the zygote, which organizes the mitotic spindles for subsequent cell divisions (see Figure 11.10). The centriole is also the origin of the primary cilia of cells, which are important in cell signaling, as we saw in the opening story about *situs inversus*.

Cytoplasmic factors in the egg play important roles in setting up the signaling cascades that orchestrate the major events of development: *determination, differentiation, and morphogenesis*.

Rearrangements of egg cytoplasm set the stage for determination

The unique attributes of amphibian eggs make them ideal models for illustrating how rearrangements of egg cytoplasm set the stage for determination. The molecules in the cytoplasm of the amphibian egg are not homogeneously distributed. The entry of the sperm into the egg stimulates rearrangements of the egg cytoplasm that introduce additional organization to the egg cytoplasm. This rearrangement establishes the polarity of the zygote, and when cell divisions begin, the informational molecules that will guide development are not divided equally among daughter cells.

Rearrangement of egg cytoplasm following fertilization is easily observed in some frog species because of pigments in the cytoplasm. The nutrients in an unfertilized frog egg are dense yolk granules that are concentrated by gravity in the lower half of the egg, called the **vegetal hemisphere**. The haploid nucleus of the egg is located at the opposite end, in the **animal hemisphere**. The outermost (*cortical*) cytoplasm of the animal hemisphere is heavily pigmented, and the underlying cytoplasm has more diffuse pigmentation. The vegetal hemisphere is not pigmented. Because of these differences, it is easy to observe how the cytoplasm is rearranged when a frog egg is fertilized.

The frog egg is radially symmetrical. You can turn it on its vegetal–animal pole axis, and all sides are the same. Sperm-binding sites are localized on the surface of the animal hemisphere, so that is where the sperm enters the egg. When a sperm enters the egg, bilateral symmetry is imposed by creating an anterior–posterior axis. Cortical cytoplasm rotates toward the site of sperm entry. This rotation brings different regions of cytoplasm into contact with each other on opposite sides of the egg, producing a band of diffusely pigmented cytoplasm on the side opposite the site of sperm entry. This band, called the **gray crescent**, marks the location of important developmental events in some species of amphibians (**Figure 44.1**).

The one non-nuclear organelle that the sperm contributes to the egg—the centriole—initiates the cytoplasmic reorganization revealed by the appearance of the gray crescent. The centriole organizes the microtubules in the vegetal hemisphere cytoplasm

44.1 The Gray Crescent Rearrangement of the cytoplasm of frog eggs after fertilization creates the gray crescent.

into a parallel array that guides the movement of the cortical cytoplasm. These microtubules also appear to be directly responsible for movement of specific organelles and proteins, because these organelles and proteins move from the vegetal

44.2 Cytoplasmic Factors Set Up Signaling Cascades

Cytoplasmic movement changes the distributions of critical developmental signals. In the frog zygote, the interaction of the protein kinase GSK-3, its inhibitor, and the protein β -catenin are crucial in specifying the dorsal–ventral axis of the embryo.

hemisphere to the gray crescent region even faster than the cortical cytoplasm rotates.

The movement of cytoplasm, proteins, and organelles changes the distribution of critical developmental signals. A key transcription factor in early development is β -catenin, which is produced from maternal mRNA (mRNA produced and stored in the egg while it was maturing in the ovary). Beta-catenin is found throughout the egg cytoplasm. Also present throughout the egg cytoplasm is a protein kinase called glycogen synthase kinase-3 (GSK-3), which phosphorylates and thereby targets β -catenin for degradation. An inhibitor of GSK-3 is segregated in the vegetal cortex of the egg. After sperm entry, this inhibitor is moved along microtubules to the gray crescent, where it prevents the degradation of β -catenin. As a result, the concentration of β -catenin is higher on the dorsal than on the ventral side of the developing embryo (**Figure 44.2**).

Beta-catenin plays a major role in the cell–cell signaling cascade that begins the process of cell determination and the formation of the embryo. But before cell–cell signaling can occur, multiple cells must be in place. Let's turn to the early series of cell divisions that transform the zygote into a multicellular embryo.

Cleavage repackages the cytoplasm

Transformation of the diploid zygote into a mass of cells occurs through a rapid series of cell divisions called **cleavage**. Because the cytoplasm of the zygote is not homogeneous, these first cell divisions result in the differential distribution of nutrients and cytoplasmic determinants in the early embryo.

In most animals, cleavage proceeds with rapid DNA replication and mitosis but with no cell growth and little gene expression. The embryo becomes a solid ball of smaller and smaller cells. Eventually, this ball forms a central fluid-filled cavity called a **blastocoel**, at which point the embryo is called a **blastula**. Its individual cells are called **blastomeres**. The pattern of cleavage in different species influences the form of their blastulas.

- **Complete cleavage** occurs in most eggs that have little **yolk** (stored nutrients). In this pattern, early cleavage furrows divide the egg completely and the blastomeres are of similar size. The frog egg undergoes complete cleavage, but because its vegetal pole contains more yolk, the division of the cytoplasm is unequal and the blastomeres in the animal hemisphere are smaller than those in the vegetal hemisphere (**Figure 44.3A**).

(A) Complete cleavage (frog)

Vegetal cells have incorporated yolk and are thus larger than the animal cells in the 16-cell embryo.

The planes of the second cleavage are displaced only slightly by yolk in the cytoplasm.

The embryo forms as a blastodisc that sits on top of the yolk mass.

(B) Incomplete cleavage (zebrafish)

In birds and fishes, cleavage furrows do not penetrate the large yolk mass.

(C) Superficial cleavage (*Drosophila*)

1 Mitosis (nuclear division) occurs without cell division.

3 The nuclei migrate to the inner edge of the plasma membrane.

2 A syncytium—a single cell with many nuclei—is produced.

4 Cellularization occurs, creating a blastoderm

44.3 Some Patterns of Cleavage Differences in patterns of early embryonic development reflect differences in the way the egg cytoplasm is organized. (A) The frog is a model organism representing complete cleavage in these scanning electron micrographs. (B) SEMs of zebrafish embryos illustrate incomplete cleavage, in which the large yolk mass limits the planes of cleavage. (C) Nuclear staining reveals the syncytial nuclei characteristic of the early embryo of a fruit fly. These nuclei migrate to the periphery. Cleavage furrows then move inward to separate the nuclei into individual cells, forming the blastoderm.

- **Incomplete cleavage** occurs in many species in which the egg contains a lot of yolk and the cleavage furrows do not penetrate it all. **Discoidal cleavage** is a type of incomplete cleavage common in fishes, reptiles, and birds, the eggs of which contain a dense yolk mass. The embryo forms as a disc of cells, called a **blastodisc**, that sits on top of the yolk mass (**Figure 44.3B**).
- **Superficial cleavage** is a variation of incomplete cleavage that occurs in insects such as the fruit fly (*Drosophila*). Early in development, cycles of mitosis occur without cell division, producing a **syncytium**—a single cell with many nuclei (**Figure 44.3C**). The nuclei eventually migrate to the periphery of the egg, after which the plasma membrane of the egg grows inward, partitioning the nuclei into individual cells surrounding a core of yolk.

The positions of the mitotic spindles during cleavage are not random but are defined by cytoplasmic factors produced from the maternal genome and stored in the egg (see Section 19.4). The orientation of the mitotic spindles can determine the planes of cleavage and the arrangement of the blastomeres.

In complete cleavage, if the mitotic spindles of successive cell divisions form parallel or perpendicular to the animal–vegetal axis of the zygote, a pattern of **radial cleavage** occurs as seen in the frog: the first two cell divisions are parallel to the animal–vegetal axis and the third is perpendicular to it (see Figure 44.3A). **Spiral cleavage** results when the mitotic spindles are at oblique angles to the animal–vegetal axis. In spiral cleavage, each new cell layer is shifted to the left or right, depending on the orientation of the mitotic spindles. Most mollusks have spiral cleavage, reflected in some species by a coiling shell pattern (as seen in snails).

(B)

8-cell stage

16-cell stage

32-cell stage

44.4 Becoming a Blastocyst (A) Mammals have rotational cleavage, in which the plane of the first cleavage is parallel to the animal–vegetal (A–V) axis, but the second cell division involves two planes (beige) at right angles to each other. (B) Scanning electron micrographs show that asynchronous cell division results in an asymmetrical blastocyst at about the 32-cell stage. (C) Seen in cross section under a light microscope, the mammalian blastocyst consists of an inner cell mass adjacent to a fluid-filled blastocoel and surrounded by trophoblast cells.

(C) Blastocyst (cross section) Trophoblast (outer cells)

The inner cell mass will form the embryo.

Early cell divisions in mammals are unique

Several features of early cell divisions in placental mammals (eutherians) are so different from those seen in other animal groups that some biologists think it is inappropriate to call it cleavage. But whether you call it cleavage or not, it is still the sequence of early cell divisions that produces a body of undifferentiated cells that will become the embryo. This process in mammals is very slow. Cell divisions are 12 to 24 hours apart, compared with tens of minutes to a few hours in non-mammalian species. Also, the cell divisions of mammalian blastomeres are not in synchrony with each other. Because the blastomeres do not undergo mitosis at the same time, the number of cells in the embryo does not increase in the regular (2, 4, 8, 16, 32, etc.) progression typical of other species.

The pattern of mammalian cleavage is **rotational**: the first cell division is parallel to the animal–vegetal axis, yielding two blastomeres. In the second cell division, those two blastomeres divide at right angles to one other: one divides parallel to the animal–vegetal axis, while the other divides perpendicular to it (**Figure 44.4A**).

Another unique feature of the slow, rotational mammalian cleavage is that gene products expressed during cleavage play roles in cleavage. In animals such as sea urchins and frogs, gene transcription does not occur in the blastomeres, and cleavage is therefore directed exclusively by molecules that were present in the egg before fertilization.

As in other animals that have complete cleavage, the early cell divisions in a mammalian zygote produce a loosely associated ball of cells. After the 8-cell stage, however, the behavior of the mammalian blastomeres changes. They change shape to maximize their surface contact with one another, form tight junctions, and become a compact mass of cells (**Figure 44.4B**).

At the transition from the 16- to the 32-cell stage (the fourth division), the cells separate into two groups. The **inner cell mass** will become the embryo, while the surrounding outer cells become an encompassing sac called the **trophoblast**. Trophoblast cells secrete fluid, creating a cavity—the **blastocoel**—with the in-

ner cell mass at one end (**Figure 44.4C**). At this stage, the mammalian embryo is called a **blastocyst**, distinguishing it from the blastulas of other animal groups.

Why is mammalian cleavage so different? A key factor is that mammalian eggs contain no yolk and must derive all nutrients from the mother. Mammals are *viviparous*: the embryo develops within the uterus of the mother. To support the developing em-

44.5 A Human Blastocyst at Implantation Adhesion molecules and proteolytic enzymes secreted by trophoblast cells allow the blastocyst to burrow into the endometrium. Once the blastocyst is implanted in the wall of the uterus, the trophoblast cells send out numerous projections—the chorionic villi—which increase the embryo's area of contact with the mother's bloodstream.

bryo, a connection develops between the circulatory systems of the embryo and the mother. As we will see later in this chapter, the structures that provide this connection are the placenta and the umbilical cord. Thus, the mammalian blastocyst must produce both the embryo (from the inner cell mass) and its support structures (from the trophoblast).

Fertilization in mammals occurs in the upper reaches of the mother's oviduct, and cleavage occurs as the zygote travels down the oviduct to the uterus. When the blastocyst arrives in the uterus, the trophoblast adheres to the lining of the uterus (the *endometrium*), beginning the process of **implantation**. In humans, implantation begins about 6 days after fertilization and is aided by adhesion molecules and enzymes secreted by the trophoblast (**Figure 44.5**).

As the blastocyst moves down the oviduct to the uterus, it must not embed itself in the oviduct (Fallopian tube) wall, or the result will be an *ectopic*, or *tubal*, pregnancy—a very dangerous condition. Early implantation is prevented by the zona pellucida, which surrounded the egg and remains around the cleaving ball of cells (see Section 43.2). At about the time the blastocyst reaches the uterus, it hatches from the zona pellucida, and implantation can occur.

Specific blastomeres generate specific tissues and organs

Cleavage results in a repackaging of the egg cytoplasm into a large number of small cells surrounding the fluid-filled blastocoel. Except in mammals, little cell differentiation and little if any gene expression occur during cleavage. Nevertheless, cells in different regions of the blastula possess different complements of the nutrients and cytoplasmic determinants that were present in the egg.

The blastocoel prevents cells from different regions of the blastula from coming into contact and interacting, but that will soon change. During the next stage of development, the cells of the blastula will move around and come into new associations with one another, communicate instructions to one another, and begin to differentiate. In many animals, these movements of the blastomeres are so regular and well orchestrated that it is possible to label a specific blastomere with a dye and identify the tissues and organs that form from its progeny. Such labeling experiments produce **fate maps** of the blastula (**Figure 44.6**).

Blastomeres become **determined**—committed to specific fates—at different times in different species. In some species,

44.6 Fate Map of a Frog Blastula Colors indicate the portions of the blastula that will form the three germ layers and subsequently the frog's tissues and organs.

such as roundworms, the fates of blastomeres are restricted as early as the two-cell stage. If one of these blastomeres is experimentally removed, a particular portion of the embryo will not form. This type of development has been called **mosaic development** because each blastomere seems to contribute a specific set of “tiles” to the final “mosaic” that is the adult animal.

In contrast to mosaic development, the loss of some cells during cleavage in **regulative development** does not affect the developing embryo, because the remaining cells compensate for the loss. Regulative development is typical of many vertebrate species, including humans. The pluripotent cells of the mammalian blastocyst (the inner cell mass) are known as *embryonic stem cells* and are the subject of much research, particularly because of their therapeutic potential (see Section 19.2).

If some blastomeres can change their fate to compensate for the loss of other cells during cleavage and blastula formation, can those cells form an entire embryo? To a certain extent, yes. During cleavage or early blastula formation in mammals, for example, if the blastomeres are physically separated into two groups, both groups can produce complete embryos. Since the two embryos come from the same zygote, they will be *monozygotic twins*—genetically identical.

Non-identical twins occur when two separate eggs are fertilized by two separate sperm. Thus, while identical twins are always of the same sex, non-identical twins have a 50 percent chance of being the same sex. In about 1 out of 50,000 human pregnancies, genetic or environmental factors cause the inner cell mass to split partially. The result is twins that are *conjoined* at some point on their bodies, usually sharing some of their organs and limbs.

44.1 RECAP

The egg is stocked with nutrients and informational molecules that power and direct the early stages of development. Fertilization activates the egg and stimulates rearrangement of the cytoplasm, setting up the body axes and positional information that initiate signaling cascades, which control determination and differentiation.

- Explain how β -catenin becomes concentrated in only certain blastomeres. **See p. 925 and Figure 44.2**
- In general terms, describe the difference between complete and incomplete cleavage. **See pp. 925–926 and Figure 44.3**
- What does a fate map tell us? How are fate maps constructed? **See pp. 927–928 and Figure 44.6**

Of the next stage of development—gastrulation—the developmental biologist Louis Wolpert once said, “It is not birth, marriage, or death, but gastrulation which is the most important time in your life.” During gastrulation, cell movements create new cell-to-cell contacts, which in turn sets up signaling cascades. Signaling cascades initiate the differentiation of cells and tissues and set the stage for the emergence of the body plan.

44.2 How Does Gastrulation Generate Multiple Tissue Layers?

The blastula is typically a fluid-filled ball of cells. How does this simple ball of cells become an embryo made up of multiple tissue layers with head and tail ends and dorsal and ventral sides? **Gastrulation** is the process whereby the blastula is transformed by massive movements of cells into an embryo with multiple tissue layers and distinct body axes. The resulting spatial relationships between tissues make possible the inductive interactions between cells that trigger differentiation and organ formation (see Figure 19.10).

During gastrulation, three **germ layers** (also called *cell layers* or *tissue layers*) form (see Figure 44.6):

- The **endoderm** is the innermost germ layer, created as some blastomeres move to the inside of the embryo. The endoderm gives rise to the lining of the digestive tract, respiratory tract, pancreas, and liver.
- The **ectoderm** is the outer germ layer, formed from those cells remaining on the outside of the embryo. The ectoderm gives rise to the nervous system, including the eyes and ears; and to the epidermal layer of the skin and structures derived from skin, such as hair, feathers, nails or claws, sweat glands, oil glands, and even teeth and other tissues of the mouth.
- The **mesoderm** is the middle layer and is made up of cells that migrate between the endoderm and the ectoderm. The mesoderm contributes tissues to many organs, including the heart, blood vessels, muscles, and bones.

Some of the most interesting and important challenges in animal development have dealt with two related questions: what directs the cell movements of gastrulation, and what is responsible for the resulting patterns of cell differentiation and organ formation? Scientists have made significant progress in answering both these questions at the molecular level. In the following discussion, we will begin with sea urchin gastrulation because it is the simplest to conceptualize in spatial terms. We will then describe the more complex pattern of gastrulation in frogs, which in turn will help elucidate the still more complex patterns in reptiles, birds, and mammals.

Invagination of the vegetal pole characterizes gastrulation in the sea urchin

The sea urchin blastula is a hollow ball of cells only one cell thick. The end of the blastula stage is marked by slowing of the rate of mitosis; the beginning of gastrulation is marked by a flattening of the vegetal hemisphere (**Figure 44.7**). Some cells at the vegetal pole bulge into the blastocoel, break away from neighboring cells, and migrate into the cavity. These cells become **mesenchyme**—cells of the middle germ layer, the mesoderm. Mesenchymal cells are not organized in tightly packed sheets or tubes like epithelial cells are; they act as independent units, migrating into and among the other tissue layers.

The flattening at the vegetal pole results from changes in the shape of individual blastomeres. These cells, which are origi-

44.7 Gastrulation in Sea Urchins During gastrulation, cells move to new positions and form the three germ layers from which differentiated tissues develop.

—yourBioPortal.com—

GO TO Animated Tutorial 44.1 • Gastrulation

nally rather cuboidal, become wedge-shaped, with smaller outer edges and larger inner edges. As a result, the vegetal pole bulges inward, or *invaginates*, as if someone were poking a finger into a hollow ball (see Figure 44.7). The invaginating cells become endoderm and form the primitive gut, called the **archenteron**. At the tip of the archenteron, more cells enter the blastocoel to form more mesoderm.

Changes in cell shapes cause the initial invagination of the archenteron, but eventually it is pulled by the mesenchyme cells. These cells, attached to the tip of the archenteron, send out extensions called filopodia that adhere to the overlying ectoderm. When the filopodia contract, they pull the archenteron toward the ectoderm at the opposite end of the embryo from where the invagination began. The mouth of the animal forms where the archenteron makes contact with this overlying ectoderm. The opening created by the invagination of the vegetal pole is called the **blastopore**; it will become the anus of the animal.

What mechanisms control the various cell movements of sea urchin gastrulation? The immediate answer is that specific properties of particular blastomeres change. For example, some vegetal cells change shape and bulge into the blastocoel, and these cells become mesenchyme. Once they lose contact with their neighboring cells on the surface of the blastula, they send out filopodia that then move along an extracellular matrix of proteins laid down by the cells lining the blastocoel.

A deeper understanding of gastrulation requires that we discover the molecular mechanisms whereby different blastomeres develop different properties. Cleavage systematically divides up the cytoplasm of the egg. The sea urchin blastula at the 64-cell stage is radially symmetrical, but it has *polarity*, as described in Section 19.4. It consists of tiers of cells. As in the frog blastula, the top is the animal pole and the bottom the vegetal pole.

If different tiers of blastula cells are separated, they show different developmental potentials; only cells from the vegetal pole are capable of initiating the development of a complete larva

(see Figure 19.8). It has been proposed that these differences are due to uneven distribution of various transcriptional regulatory proteins in the egg cytoplasm. As cleavage progresses, these proteins end up in different groups of cells. Therefore, specific sets of genes are activated in different cells, determining their different developmental capacities.

Let's turn now to gastrulation in the frog, in which several key signaling molecules have been identified.

Gastrulation in the frog begins at the gray crescent

Amphibian blastulas have considerable yolk and are more than one cell thick; therefore, gastrulation is more complex in amphibians than in sea urchins. Variation is considerable among different species of amphibians, but in this brief account we will use results from studies done on different species to produce a generalized picture of amphibian development.

Amphibian gastrulation begins when certain cells in the gray crescent region change their shapes and cell adhesion properties. These cells bulge inward toward the blastocoel while they remain attached to the outer surface of the blastula by slender necks. Because of their shape, these cells are called *bottle cells*.

Bottle cells mark the spot where the **dorsal lip** of the blastopore will form (Figure 44.8). As the bottle cells move inward, the dorsal lip is created, and a sheet of cells moves over it into the blastocoel. This process is called **involution**. One group of involuting cells is the prospective endoderm; these cells form the primitive gut, or archenteron. Another group will move between the endoderm and the outermost cells to form the mesoderm. These rearrangements are due to changes in cell properties called **convergent extension**. The cells elongate in the direction of movement, but they also intercalate (move in between each other). If they just elongated, the migrating group of cells would become much narrower; by intercalating, they maintain the width of the migrating cell group.

As gastrulation proceeds, cells from the animal hemisphere flatten and move toward the site of involution in a process called **epiboly**. The blastopore lip widens and eventually forms a com-

44.8 Gastrulation in the Frog Embryo The colors in this diagram are matched to those in Figure 44.6, the frog fate map.

plete circle surrounding a “plug” of yolk-rich cells. As cells continue to move inward through the blastopore, the archenteron grows, gradually displacing the blastocoel.

As gastrulation comes to an end, the amphibian embryo consists of three germ layers: ectoderm on the outside, endoderm on the inside, and mesoderm in between. The embryo also has

a dorsal–ventral and anterior–posterior organization. Most importantly, the fates of specific regions of the endoderm, mesoderm, and ectoderm have been determined. The beautiful experiments revealing how determination takes place in the amphibian embryo are an old but exciting story.

The dorsal lip of the blastopore organizes embryo formation

In the early 1900s, the German biologist Hans Spemann was studying the development of salamander eggs. He was interested in finding out whether the nuclei of blastomeres remain capable of directing the development of complete embryos. With great patience and dexterity, he formed loops from single hairs taken from a baby (in fact, his daughter) and tied them around fertilized eggs along the plane of the first cell division, effectively dividing the eggs in half, with the nucleus restricted to one side. That side went through cell divisions and developed into a salamander; the other half simply degenerated. Up until the 16-cell stage, if one nucleus escaped to the other side of the constriction, twin salamanders could develop. Thus, each of the nuclei of the blastula (at least up to the 16-cell stage) was capable of directing and supporting development of the whole organism.

But, as often happens in science, Spemann’s bisection experiments revealed a new phenomenon. Sometimes the half of the blastula receiving an escaped nucleus did not develop. When his loops bisected the gray crescent, both halves of the zygote developed into a complete embryo. When he tied the loops so the gray crescent was on only one side of the constriction, however, only that half of the zygote developed into a complete embryo (**Figure 44.9**). The half lacking gray crescent material underwent cell division, but even if it contained a nucleus, it became a clump of undifferentiated cells that Spemann called a “belly piece.” Spemann hypothesized that cytoplasmic factors unequally distributed in the fertilized egg were necessary for gastrulation and the development of a normal salamander.

To further test the hypothesis that cells receiving different complements of cytoplasmic factors had different developmental fates, Spemann transplanted pieces of early gastrulas to various locations on other gastrulas. Guided by fate maps (see **Figure 44.6**), he was able to take a piece of ectoderm he knew would develop into skin and transplant it to a region that normally becomes part of the nervous system, and vice versa.

When he performed these transplants in early gastrulas—when the blastopore was just beginning to form—the transplanted pieces always developed into tissues that were appropriate for the location where they were placed. Transplanted cells destined to become epidermis in their original location developed into nervous system tissue, and transplanted cells destined to become nervous system tissue in their original location developed into host epidermis. Thus, Spemann learned that the fates of the transplanted cells had not been determined before the transplantation (see **Figure 19.2**).

In late gastrulas, however, the same experiment yielded opposite results. Transplanted cells destined to become epidermis in their original location produced patches of skin cells in the host

44.9 Gastrulation and the Gray Crescent Spemann's research revealed that gastrulation and subsequent normal development in salamanders depends on cytoplasmic determinants localized in the gray crescent.

nervous system, and the transplanted cells from regions that would develop into nervous system tissue produced neural tissue in the skin of the recipient. At some point during gastrulation, the fates of the embryonic cells had become determined.

Spemann's next experiment, done with his student Hilde Mangold, produced momentous results: they transplanted the dorsal lip of the blastopore (Figure 44.10). When this small piece of tissue was transplanted into the presumptive belly area of another gastrula, it stimulated a second site of gastrulation—and a second complete embryo formed belly-to-belly with the original embryo. Because the dorsal lip of the blastopore was apparently capable of inducing the host tissue to form an entire embryo, Spemann and Mangold dubbed the dorsal lip tissue the **primary embryonic organizer**, or simply the **organizer**. For more than 80 years, the organizer has been an active area of research.

Reveal the Process of Determination

Transcription factors underlie the organizer's actions

With the advent of modern molecular methods, the primary embryonic organizer has been studied intensively to discover the molecular mechanisms involved

INVESTIGATING LIFE

44.10 The Dorsal Lip Induces Embryonic Organization

In a classic experiment, Hans Spemann and Hilde Mangold transplanted the dorsal blastopore lip mesoderm of an early gastrula stage salamander embryo. The results showed that the cells of this embryonic region, which they dubbed "the organizer," could direct the formation of an entire embryo.

HYPOTHESIS Cytoplasmic factors in the early dorsal blastopore lip organize cell differentiation in amphibian embryos.

METHOD

1. Excise a patch of mesoderm tissue from above the dorsal blastopore lip of an early gastrula stage salamander embryo (the donor).
2. Transplant the donor tissue onto a recipient embryo at the same stage. The donor tissue is transplanted onto a region of ectoderm that should become epidermis (skin).

RESULTS

CONCLUSION The cells of the dorsal blastopore lip can induce other cells to change their developmental fates.

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

in its action. The distribution of the transcription factor β -catenin in the late blastula corresponds to the location of the organizer in the early gastrula, so β -catenin is a candidate for the initiator of organizer activity. To prove that a protein is an inductive signal, it has to be shown that it is both *necessary* and *sufficient* for the proposed effect. In other words, the effect should not occur if the candidate protein is not present (necessity), and the candidate protein should be capable of inducing the effect where it would otherwise not occur (sufficiency).

The criteria of necessity and sufficiency have been satisfied for β -catenin. If β -catenin mRNA transcripts are depleted by injections of antisense RNA into the egg (see Section 18.4), gastrulation does not occur. If β -catenin is experimentally overexpressed in another region of the blastula, it can induce a second axis of embryo formation, as the transplanted dorsal lip did in the Spemann–Mangold experiments. Thus, β -catenin appears to be both necessary and sufficient for the formation of the primary embryonic organizer—but it is only one component of a complex signaling process.

How the presence of β -catenin creates the organizer, and how the organizer then induces the beginnings of the body plan, involves a complex series of interactions between transcription factors and growth factors that control gene expression. What follows is only a portion of this complex and still emerging story. What you should take from this description is not the names of the genes and gene products involved. Rather, we hope you will gain a basic appreciation for how signaling molecules interact to produce different combinations of signals that convey positional and temporal information. This information guides cells into different paths of determination and differentiation.

Studies of early gastrulas revealed that primary embryonic organizer activity is generated by the interaction of β -catenin with signals coming from the vegetal cells. Together, they activate the expression of the transcription factor **Goosecoid**. Expression of the *goosecoid* gene depends on two signaling pathways.

The first of these pathways involves a *goosecoid*-promoting transcription factor called Siamois. The *siamois* gene is normally repressed by a ubiquitous transcription factor called Tcf-3, but in cells in which β -catenin is present, an interaction between Tcf-3 and β -catenin induces *siamois* expression (Figure 44.11). But Siamois protein alone is not sufficient for *goosecoid* expression.

The second pathway involves mRNAs from the original egg cytoplasm for a family of proteins called transforming growth factor- β (TGF- β). TGF- β interacts with the Siamois protein to control *goosecoid* transcription. Thus, you can see that it is a complex combination of factors that determines which cells become the primary organizer.

The organizer changes its activity as it migrates from the dorsal lip

Organizer cells begin the process of formation of the dorsal lip of the blastopore. Specifically, these cells are at the center of the dorsal lip and involute, moving forward on the midline (i.e., the middle of the anterior–posterior axis). The first organizer cells to enter the embryo migrate anteriorly to become the head endoderm and head mesoderm. Here, they induce neighboring

44.11 Molecular Mechanisms of the Organizer In amphibians, the organizing potential of the gray crescent depends on the activity of the *goosecoid* gene, which in turn is activated by signaling pathways set up in the vegetal cells below the gray crescent.

cells to participate in making structures of the head. Later organizer cells that involute into the embryo will induce structures of the trunk, and the last of the organizer cells to move inward from the dorsal lip will induce structures of the tail. How does the nature of the organizer cells change to enable them to induce head, trunk, or tail structures?

Inductive tissue interactions can suppress as well as activate. As we learned above, the early organizer cells express the transcription factor Goosecoid, which activates genes encoding soluble signals. As these cells move forward in the blastocoel, they come into contact with new populations of cells that produce a number of different growth factors. For head structures to form, certain of these growth factors have to be suppressed. The anteriormost organizer cells, under the influence of Goosecoid, produce and release antagonists to those growth factors.

The induction of trunk structures requires suppression of a different set of growth factors. In organizer cells that involute later than the head organizers, Goosecoid is no longer the dominant transcription factor, and these cells express different growth factor antagonists. The induction of tail structures requires still different activities of the organizer cells that involute last. Thus, the organizer cells express appropriate sets of growth factor antagonists at the right times to achieve different patterns of differentiation on the anterior–posterior axis.

The initiation of the development of the nervous system also involves a suppressive tissue interaction. For a long time it was thought that the involuting organizer cells actively induced the

INVESTIGATING LIFE

44.12 Differentiation Can Be Due to Inhibition of Transcription Factors

When organizer cells involute to underlie dorsal ectoderm along the embryo midline, that overlying ectoderm becomes neural tissue rather than skin (epidermis). But do the organizer cells cause dorsal ectoderm to become neural tissue, or do they *prevent* this ectoderm from becoming skin?

HYPOTHESIS The default state of amphibian dorsal ectoderm is neural; it is induced by underlying mesoderm to become epidermis.

METHOD

1. Excise the animal caps of late-stage frog blastulas and disperse the cells in culture medium so there is no cell-to-cell contact. From the culture, extract molecules of BMP4 (secreted by mesoderm cells) and molecules of an inhibitor of BMP4.

2. Prepare four separate cultures of embryonic ectodermal cells. Incubate with no additions (control); with BMP4 from step 1; with BMP4 inhibitor from step 1; and with both molecules.

3. After incubation, extract mRNAs from the ectodermal cells and analyze for the presence of mRNAs for marker proteins NCAM (neural cell adhesion molecule, a neural protein) and/or keratin (an epidermal protein).

RESULTS

The control ectoderm (no inductive factors added) expresses the neural marker. In the presence of mesodermal BMP4, ectoderm expresses the epidermal marker. If BMP4 is inhibited, ectoderm expresses the neural marker.

This control message is from a gene expressed in all cells and verifies that each sample contains similar amounts of mRNA.

CONCLUSION

The default state of amphibian dorsal ectoderm is neural. BMP4 protein from mesoderm can induce ectoderm cells to differentiate into epidermis. Thus the organizer cells must secrete an inhibitor of BMP4.

overlying ectoderm to form neural tissue rather than becoming epidermis. We now know, however, that epidermis is not the default state of the dorsal ectoderm. Rather, the underlying mesoderm secretes factors called BMP proteins that induce the ectoderm to become epidermis. The role of the involuting organizer cells is to block that induction, allowing the overlying ectodermal cells to follow what is really their default pathway—differentiation into neural tissue (**Figure 44.12**).

Reptilian and avian gastrulation is an adaptation to yolk eggs

The eggs of reptiles and birds contain a mass of yolk, and the blastulas of these groups develop as a disc of cells on top of the yolk (see **Figure 44.3B**). We will use the chicken egg to show how gastrulation proceeds in a flat disc of cells rather than in a ball of cells.

Cleavage in the chick results in a flat, circular layer of cells called a blastodisc (**Figure 44.13**). Between the blastodisc and the yolk mass is a fluid-filled space. Some cells from the blastodisc break free and move into this space. These cells come together to form a continuous layer called the **hypoblast**, which will later contribute to *extraembryonic membranes* that will support and nourish the developing embryo. The overlying cells make up the **epiblast**, from which the embryo proper will form. Thus, the avian blastula is a flattened structure consisting of an upper epiblast and a lower hypoblast, which are joined at the margins of the blastodisc. The blastocoel is the fluid-filled space between the epiblast and hypoblast.

Gastrulation begins with a thickening in the posterior region of the epiblast, caused by the movement of cells toward the midline and then forward along the midline (see **Figure 44.13**). The result is a midline ridge called the *primitive streak*. A depression called the *primitive groove* forms along the length of the primitive streak. The primitive groove functions as the blastopore, and cells migrate through it into the blastocoel to become endoderm and mesoderm.

In the chick embryo, no archenteron forms, but the endoderm and mesoderm migrate forward to form the gut and other structures. At the anterior end of the primitive groove is a thickening called **Hensen's node**, which in birds, reptiles, and mammals is the equivalent of the dorsal lip of the amphibian blastopore. Many signaling molecules that have been identified in the frog organizer are also expressed in Hensen's node. Some cells that pass over

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

Chick embryo viewed from above

Hensen's node become the notochord and organize the chick embryo in a manner similar to that of the frog embryo. And, as we learned at the start of this chapter, the asymmetrical flow of extracellular fluid over this node stimulates the primary cilia of nodal cells, creating asymmetrical signaling cascades that determine the left–right asymmetry of the internal organs.

Placental mammals retain the avian–reptilian gastrulation pattern but lack yolk

Mammalian embryos (with the exception of monotremes) derive their nourishment from the maternal circulation, and therefore mammalian eggs do not have large amounts of yolk to constrain their patterns of cleavage and early development. Nevertheless, mammals and birds evolved from reptilian ancestors, so it is not surprising that they share certain patterns of early development. Earlier we described the development of the mammalian inner cell mass (the equivalent of the avian epiblast) and the outer trophoblast.

As in avian development, in placental mammals the inner cell mass splits into an upper layer called the epiblast and a lower layer called the hypoblast. The embryo forms from the epiblast, while the hypoblast contributes to the extraembryonic membranes that will encase the developing embryo and help form the placenta (see Figure 44.5). The epiblast also contributes to the extraembryonic membranes; specifically, it splits off an upper layer of cells that will form the amnion. The amnion will grow to surround the developing embryo as a membranous sac filled with amniotic fluid. Gastrulation occurs in the mammalian epiblast just as it does in the avian epiblast. A primitive groove forms, and epiblast cells migrate through the groove to become layers of endoderm and mesoderm.

44.13 Gastrulation in Birds Because their eggs contain a large yolk mass, bird and reptile embryos have a flattened blastodisc and display a pattern of gastrulation very different from that of amphibians.

44.2 RECAP

The cell movements of gastrulation convert the blastula into an embryo with three tissue layers. New contacts between cells set up inductive signaling interactions that determine cell fates. Dorsal lip tissue is the source of organizer cells that induce development of preliminary head, trunk, and tail structures.

- Describe and compare the cell movements that occur during gastrulation in a sea urchin, a frog, and a bird. **See Figures 44.7, 44.8, and 44.13**
- Explain the molecular basis for the inductive capabilities of the organizer. **See pp. 931–932 and Figures 44.11 and 44.12**

We have described how the fertilized egg develops into an embryo with three germ layers and how cellular signals trigger different patterns of differentiation. In the next section we will describe how organs and organ systems develop.

44.3 How Do Organs and Organ Systems Develop?

Gastrulation produces an embryo with three germ layers that are positioned to influence one another through inductive tissue interactions. During the next phase of development, called **organogenesis**, many organs and organ systems develop simultaneously and in coordination with one another. An early process of organogenesis in chordates that is directly related to gastrulation is neurulation. **Neurulation** is the initiation of the nervous system. We will examine neurulation in the amphibian embryo, but it occurs in a similar fashion in reptiles, birds, and mammals.

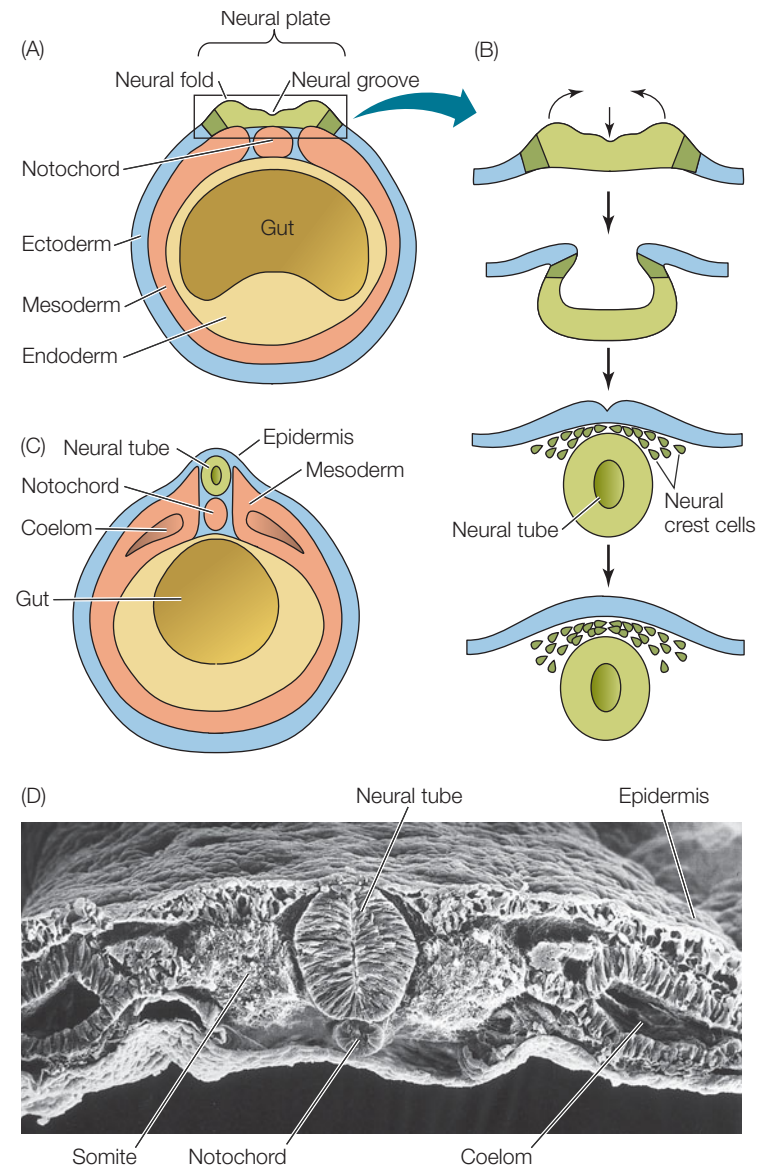

The stage is set by the dorsal lip of the blastopore

As we learned in the previous section, one group of cells that passes over the dorsal lip of the blastopore moves anteriorly and becomes the endodermal lining of the digestive tract. The other group of cells that involutes over the dorsal lip becomes *chordamesoderm*, so named because it forms a rod of mesoderm—the **notochord**—that extends down the center of the embryo. These cells also have important organizer functions (see Figure 44.8). The notochord gives structural support to the developing embryo and is eventually replaced by the vertebral column. The organizing capacity of the chordamesoderm enables the overlying ectoderm to become neural ectoderm (see Figure 44.12). It does this by expressing signaling molecules (one appropriately called *Noggin* and another one called *Chordin*) that initiate differentiation of the different divisions of the nervous system.

Neurulation involves the formation of an internal neural tube from an external sheet of cells. The first signs of neurulation are flattening and thickening of the ectoderm overlying the notochord; this thickened area forms the **neural plate** (Figure 44.14A). The edges of the neural plate that run in an anterior–posterior direction continue to thicken to form ridges or folds. Between these neural folds, a groove forms and deepens as the folds roll over it to converge on the midline. The folds fuse, forming a cylinder, the **neural tube**, and a continuous overlying layer of epidermal ectoderm (Figure 44.14B–D).

Cells from the most lateral portions of the neural plate do not become part of the neural tube, but disassociate from it and come to lie between the neural tube and the overlying epidermis. These **neural crest cells** migrate outward to lead the development of the connections between the central nervous system (brain and spinal cord) and the rest of the body.

The neural tube develops bulges at the anterior end, which become the major divisions of the brain; the rest of the tube becomes the spinal cord. In humans, failure of the neural folds to fuse in this posterior region results in a birth defect known as *spina bifida*. If the folds fail to fuse at the anterior end, an infant can develop without a forebrain—a condition called *anencephaly*. Although several genetic factors can cause these defects, other factors are environmental, including maternal diet. The incidence of neural tube defects in the United States in the early 1900s was as high as 1 in 300 live births; today it is less than 1

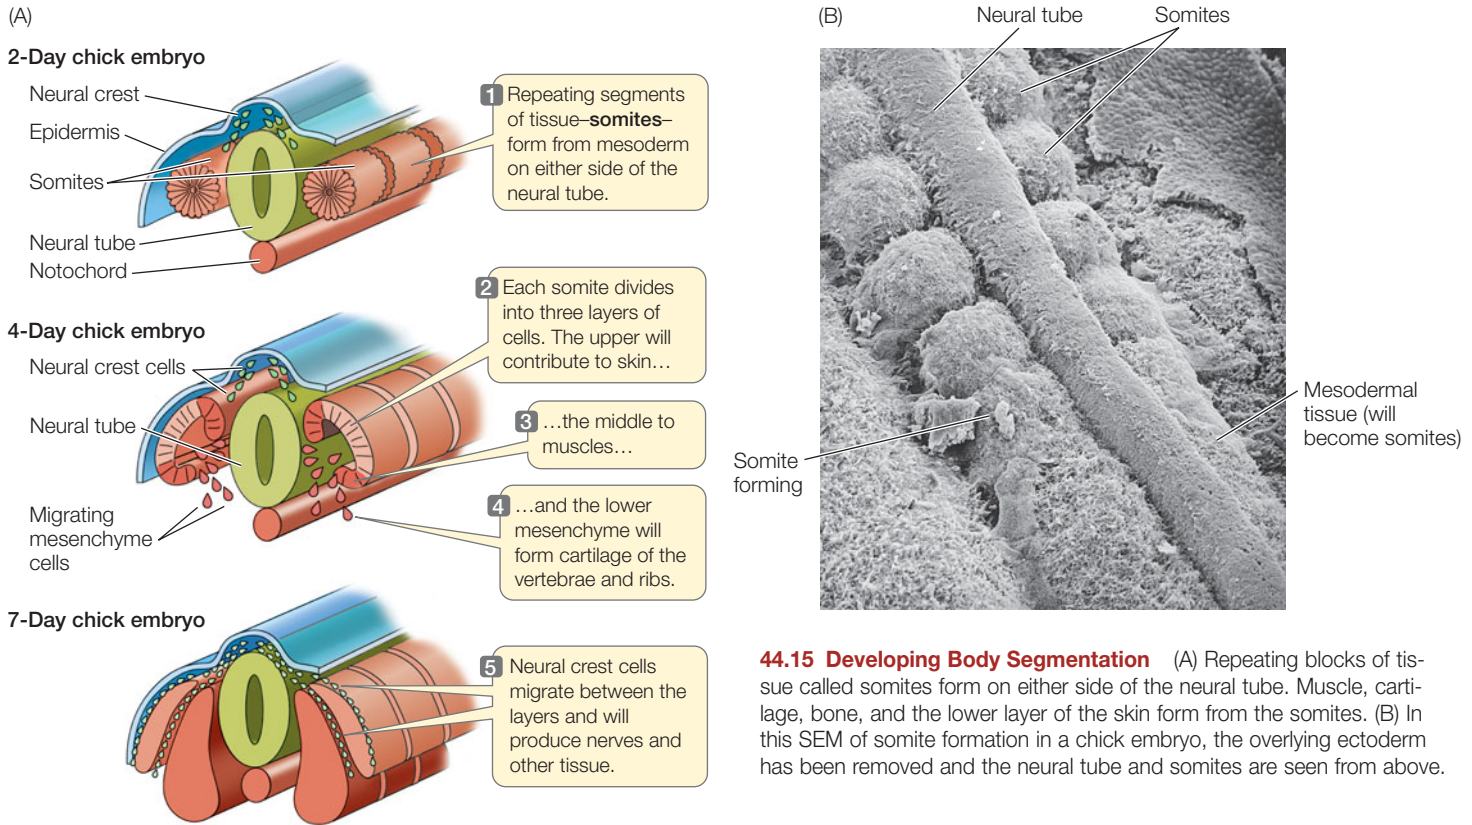

44.14 Neurulation in a Vertebrate (A) At the start of neurulation, the ectoderm of the neural plate (green) is flat. (B) The neural plate invaginates and folds, forming a tube. (C,D) The completely formed neural tube seen in (C) diagrammatic form and (D) in a scanning electron micrograph of a chick embryo.

in 1,000. A major factor in this improvement has been the inclusion of folic acid (a B vitamin, also known as folate) in the mother's diet. It is essential for pregnant women to ingest sufficient folic acid.

Body segmentation develops during neurulation

The vertebrate body plan, like that of arthropods, consists of repeating segments that are modified during development. These segments are most evident as the repeating patterns of vertebrae, ribs, nerves, and muscles along the anterior–posterior axis.

As the neural tube forms, mesodermal tissues gather along the sides of the notochord to form separate, segmented blocks

44.15 Developing Body Segmentation (A) Repeating blocks of tissue called somites form on either side of the neural tube. Muscle, cartilage, bone, and the lower layer of the skin form from the somites. (B) In this SEM of somite formation in a chick embryo, the overlying ectoderm has been removed and the neural tube and somites are seen from above.

of cells called **somites** (Figure 44.15). The somites produce cells that will become the vertebrae, ribs, muscles of the trunk and limbs, and the lower layer of the skin.

Nerves that connect the brain and spinal cord with tissues and organs throughout the body are also arranged segmentally. The somites help guide the organization of these peripheral nerves, but the nerves are not of mesodermal origin. As we saw above, when the neural tube fuses, the neural crest cells break loose and migrate inward between the epidermis and the somites and through the somites. These neural crest cells have diverse fates, including the development of peripheral nerves.

As development progresses, the different segments of the body change. Regions of the spinal cord differ, regions of the vertebral column differ in that some vertebrae grow ribs of various sizes and others do not, forelegs arise in the anterior part of the embryo, and hind legs arise in the posterior region.

Hox genes control development along the anterior–posterior axis

How is mesoderm in the anterior part of a mouse embryo programmed to produce forelegs rather than hind legs? In Section 19.5, we saw how homeotic genes control body segmentation in *Drosophila*. We also learned that all homeotic genes contain a DNA sequence called the *homeobox*. Some of the genes directing gastrulation in the frog are homeobox genes—for example, *gooseoid* and *siamois*. In vertebrates, the homeotic genes that control differentiation along the anterior–posterior body axis are called **Hox genes**.

In mammals, four Hox gene complexes reside on different chromosomes in clusters of about 10 genes each. Remarkably, the temporal and spatial expression of these genes follows the same pattern as their linear order on their chromosome. That is, the Hox genes closest to the 3' end of each gene complex are expressed first and in the anterior of the embryo. The Hox genes at the 5' end of the gene complex are expressed later and in a more posterior part of the embryo. As a result, different segments of the embryo receive different combinations of Hox gene products, which serve as transcription factors (Figure 44.16; see also Figure 20.2).

Whereas Hox genes give cells information about their position on the anterior–posterior body axis, other genes provide information about their dorsal–ventral position. Tissues in each segment of the body differentiate according to their dorsal–ventral location. The notochord provides many of these signals. One example of a dorsal–ventral difference is seen in the spinal cord; sensory nerve connections develop in the dorsal region, and motor nerve connections in the ventral region. The protein Sonic hedgehog (named for a video-game character), which is expressed in the mammalian notochord, induces cells in the overlying neural tube (i.e., the ventralmost cells of the neural tube) to become motor neurons.

After the development of body segmentation, the formation of organs and organ systems progresses rapidly. The development of an organ involves extensive inductive interactions of the kind we saw in the example of the vertebrate eye (see Figure 19.10). These inductive interactions are a current focus of study for developmental biologists.

44.16 Hox Genes Control Body Segmentation Hox genes are expressed along the anterior-posterior axis of the embryo in the same order as their arrangement between the 3' and 5' ends of the gene complex. As a result of gene duplication during evolution, vertebrates have four copies of the Hox gene complex shown.

44.3 RECAP

Gastrulation sets up tissue interactions that initiate organogenesis. Neurulation is initiated by organizer mesoderm that forms the notochord.

- Describe the formation of the neural tube in vertebrates. **See p. 935 and Figure 44.14**
- How do somites relate to segmentation of the body axis? **See pp. 935–936 and Figure 44.15**
- Using information from this chapter and from Chapters 19 and 20, explain what Hox genes are and how they instruct patterns of differentiation along the body axis. **See Figures 19.19, 20.1, and 44.16**

You may be aware that in mammals the circulatory systems of the fetus and mother are separate and that nourishment reaches the fetus through the placenta and the umbilical cord. In the next section we will examine the developmental events that result in the creation of the placenta.

44.4 How is the Growing Embryo Sustained?

There is more to a developing reptile, bird, or mammal than the embryo itself. As mentioned earlier, the embryos of these vertebrates are surrounded by several **extraembryonic membranes**, which originate from the embryo but are not part of it. Extraembryonic membranes function in nutrition, gas exchange, and waste removal. In mammals, they interact with tissues of the mother to form the placenta.

Extraembryonic membranes form with contributions from all germ layers

The chicken provides a good example of how extraembryonic membranes form from the germ layers created during gastrulation. In the chick, four membranes form—the *yolk sac*, the *allantoic membrane*, the *amnion*, and the *chorion*. The **yolk sac** is the first to form, and it does so by extension of the hypoblast layer along with some adjacent mesoderm. The yolk sac grows to enclose the entire body of yolk in the egg (**Figure 44.17**). It constricts at the top to create a tube that is continuous with the gut of the embryo. However, yolk does not pass through this tube. Yolk is digested by the cells of the yolk sac, and the nu-

44.17 The Extraembryonic Membranes In birds, reptiles, and mammals, the embryo constructs four extraembryonic membranes. The yolk sac encloses the yolk, and the amnion and chorion enclose the embryo. Fluids secreted by the amnion fill the amniotic cavity, providing an aqueous environment for the embryo. The chorion, along with the allantoic membrane, mediates gas exchange between the embryo and its environment. The allantois stores the embryo's waste products.

GO TO Web Activity 44.1 • Extraembryonic Membranes

44.18 The Mammalian Placenta In humans and most other mammals, nutrients and wastes are exchanged between maternal and fetal blood in the placenta, which forms from the chorion and tissues of the uterine wall. The embryo is attached to the placenta by the umbilical cord. Embryonic blood vessels invade the placental tissue to form fingerlike chorionic villi. Maternal blood flows into the spaces surrounding the villi, and placental blood flows through the villi so nutrients and respiratory gases can be exchanged between the maternal and fetal blood.

rients are transported to the embryo through blood vessels that form from mesoderm and line the outer surface of the yolk sac. The **allantoic membrane** is also an outgrowth of the extraembryonic endoderm plus adjacent mesoderm. It forms the *allantois*, a sac for storage of metabolic wastes.

Ectoderm and mesoderm combine and extend beyond the limits of the embryo to form the other extraembryonic membranes. Two layers of cells extend all along the inside of the eggshell, both over the embryo and below the yolk sac. Where they meet, they fuse, forming two membranes, the inner **amnion** and the outer **chorion**. The amnion surrounds the embryo, forming the amniotic cavity. The amnion secretes fluid into the cavity, providing a protective environment for the embryo. The outer membrane, the chorion, forms a continuous membrane just under the eggshell (see Figure 44.17). It limits water loss from the egg and also works with the enlarged allantoic membrane to exchange respiratory gases between the embryo and the outside world.

Extraembryonic membranes in mammals form the placenta

In placental mammals, the first extraembryonic membrane to form is the trophoblast, which is already apparent by the fifth cell division (see Figure 44.4). When the blastocyst reaches the uterus and hatches from its encapsulating zona pellucida, the trophoblast cells interact directly with the endometrium. Adhesion molecules expressed on the surfaces of these cells attach them to the uterine wall. By secreting proteolytic enzymes, the trophoblast burrows into the endometrium, beginning the process of implantation (see Figure 44.5). Eventually, the entire trophoblast is within the wall of the uterus. The trophoblast cells then send out numerous projections, or villi, to increase the surface area of contact with maternal blood.

Meanwhile, the hypoblast cells proliferate to form what in the bird would be the yolk sac. But there is no yolk in eggs of placental mammals, so the yolk sac contributes mesodermal tissues that interact with trophoblast tissues to form the chorion. The chorion, along with tissues of the uterine wall, produces the **placenta**, the organ that exchanges nutrients, respiratory

gases, and metabolic wastes between the mother and the embryo (**Figure 44.18**).

At the same time the yolk sac is forming from the hypoblast, the epiblast produces the amnion, which grows to enclose the entire embryo in a fluid-filled amniotic cavity. The rupturing of the amnion and chorion and the loss of the **amniotic fluid** (a process called “water breaking”) herald the onset of labor in humans.

An allantois also develops in mammals, but its importance depends on how well nitrogenous wastes can be transferred across the placenta. In humans the allantois is minor; in pigs it is important. In humans and other mammals, allantoic tissues contribute to the formation of the umbilical cord, by which the embryo is attached to the chorionic placenta. It is through the blood vessels of the umbilical cord that nutrients and oxygen from the mother reach the developing fetus, and wastes, including carbon dioxide and urea, are removed (see Figure 44.18).

44.4 RECAP

The extraembryonic membranes of reptiles, birds, and mammals sustain the growing embryo. In reptiles and birds, these membranes surround the embryo within the shelled egg. In mammals the extraembryonic membranes form the placenta, an organ that exchanges nutrients, respiratory gases, and metabolic wastes between the mother and the embryo.

- Describe each of the four extraembryonic membranes and their functions in the developing chick egg. **See pp. 937–938 and Figure 44.17**
- Explain the role of the trophoblast in the early development of a mammalian embryo. **See p. 938**

44.5 What Are the Stages of Human Development?

In humans, **gestation**, or pregnancy, lasts about 266 days, or 9 months. In smaller mammals gestation is shorter—for example, 21 days in mice—and in larger mammals it is longer—for example, 330 days in horses and 600 days in elephants. The events of human gestation can be divided into three periods of roughly 3 months each, called *trimesters*.

Organ development begins in the first trimester

Implantation of the human blastocyst begins about 6 days after fertilization. After implantation, gastrulation occurs, tissues differentiate, the placenta forms, and organs begin to develop. The heart begins to beat during week 4, and limbs are formed by week 8 (**Figure 44.19 A,B**). By the end of the first trimester, most organs have started to form. The embryo is about 8 centimeters long and weighs about 40 grams (less than 2 ounces); it would fit neatly in a teaspoon. At about this point in time, the human embryo is medically and legally referred to as a **fetus**. (This distinction is not made for other mammals; developing mice, for example, remain embryos until they are born.)

The first trimester is a time of rapid cell division and tissue differentiation. Signal transduction cascades and the resulting branching sequences of developmental processes are in their early stages. Therefore, the first trimester is the period during which the embryo is most sensitive to damage from ra-

diation, drugs, chemicals, and pathogens that can cause birth defects. An embryo can be damaged before the mother even knows she is pregnant. A classic and tragic case is that of thalidomide, a drug widely prescribed in Europe in the late 1950s to treat nausea. Women who took this drug in the fourth and fifth weeks of pregnancy, when the embryo's limbs are beginning to form, gave birth to children with missing or severely malformed arms and legs.

Organ systems grow and mature during the second and third trimesters

During the second trimester the fetus grows rapidly to a weight of about 600 grams. The limbs of the fetus elongate, and the fingers, toes, and facial features become well formed (**Figure 44.19C**). Eyebrows and fingernails grow and the fetus's nervous system develops rapidly. Fetal movements are first felt by the mother early in the second trimester, and they become progressively stronger and more coordinated.

The fetus grows rapidly during the third trimester (**Figure 44.19D**). As the trimester approaches its end, internal organs mature. The digestive system begins to function, the liver stores glycogen, the kidneys produce urine, and the brain undergoes cycles of sleep and waking. A human infant is born as soon as the last of its critical organs—the lungs—mature.

Although the first-trimester embryo is the most susceptible to adverse effects of drugs, chemicals, and diseases, the potential for serious effects from exposure to environmental factors

(A) 4 weeks

44.19 Stages of Human Development

(A) At 4 weeks of gestation, most of the embryo's organ systems have been formed and the heart is beating. (B) The body structures of this 8-week-old embryo are forming rapidly, and it is visibly a male. The umbilical cord attaches the embryo to the placenta (upper left). (C) At 4 months, the fetus has fully formed limbs with fingers and toes, and moves freely within the amniotic cavity. (D) This fetus is well along in its ninth month. Soon its lungs will be mature enough to trigger the onset of contractions and birth.

exists throughout pregnancy and continues after birth. Severe protein malnutrition, alcohol, and cigarette smoke are examples of factors that can cause low birth weight, mental retardation, and other developmental complications.

Developmental changes continue throughout life

Development does not end with birth. Obviously, growth continues until adult size is reached, and even when growth stops, organs of the body continue to repair and renew themselves through cycles of cell replacement by the progeny of undifferentiated stem cells. In humans especially, enormous developmental changes occur in the brain in the years between birth and adolescence. Especially in the early years, there is a great deal of plasticity in the organization of the nervous system as the connections between neurons develop.

For example, a child born with misaligned eyes (a condition known as *strabismus*) will use mostly one eye. The connections to the brain from that eye will become strong while connections from the other eye remain weak, and the child will develop with reduced visual acuity and depth perception. If eye

alignment is corrected in the first 3 years of life, the connections between the eyes and the brain can improve and the child is likely to develop normal vision. After the age of 3, correcting the connections between the eyes and the brain is less likely to result in improvement, and visual impairments may persist. Thus plasticity in human visual system development declines during early childhood. However, recent data indicate that it is not lost entirely and may be reactivated even in adulthood.

44.5 RECAP

Human gestation lasts 9 months and can be divided into 3 trimesters. At the end of the first trimester, the fetus is very small but most of its organs have begun to form. In the second trimester, limbs elongate and the fetus moves. By the end of the third trimester, most organs have begun to function.

- Why is a first-trimester embryo particularly sensitive to environmental risks? [See p. 939](#)

CHAPTER SUMMARY

44.1 How Does Fertilization Activate Development?

- The sperm and the egg contribute differentially to the zygote. The sperm contributes a haploid nucleus and, in most species, a centriole. The egg contributes a haploid nucleus, nutrients, ribosomes, mitochondria, mRNAs, and proteins.
- In amphibians, the cytoplasmic contents of the egg are not distributed homogeneously, and they are rearranged after fertilization to set up the major axes of the future embryo. The nutrient molecules are generally found in the **vegetal hemisphere**, whereas the nucleus is found in the **animal hemisphere**. [Review Figures 44.1 and 44.2](#)
- **Cleavage** is a period of rapid cell division. Except in mammals, little if any gene expression occurs during cleavage. Cleavage can be complete or incomplete, and the pattern of cell divisions depends on the orientation of the mitotic spindles. The result of cleavage is a ball or mass of cells called a **blastula**. [Review Figure 44.3](#)
- Early cell divisions in mammals are unique in being slow and allowing for gene expression early in the process. These cell divisions produce a **blastocyst** composed of an **inner cell mass** that becomes the embryo and an outer cell mass that becomes the **trophoblast**. At the time of **implantation**, the trophoblast secretes molecules that help the blastocyst implant in the uterine wall. [Review Figures 44.4 and 44.5](#)
- A **fate map** can be created by labeling specific **blastomeres** and observing what tissues and organs are formed by their progeny. [Review Figure 44.6](#)
- Some species undergo **mosaic development**, in which the fate of each cell is determined during early divisions. Other species, including vertebrates, undergo **regulative development**, in which remaining cells can compensate for cells lost in early cleavages.

44.2 How Does Gastrulation Generate Multiple Tissue Layers?

- **Gastrulation** involves massive cell movements that produce three **germ layers** and place cells from various regions of the blastula into new associations with one another. [Review Figure 44.7, ANIMATED TUTORIAL 44.1](#)
- The initial step of sea urchin and amphibian gastrulation is inward movement of certain blastomeres. The site of inward movement becomes the **blastopore**. Cells that move into the blastula become the **endoderm** and **mesoderm**; cells remaining on the outside become the **ectoderm**. Cytoplasmic factors in the vegetal pole cells are essential to initiate development. [Review Figures 44.7 and 44.8](#)
- The **dorsal lip** of the amphibian blastopore is a critical site for cell determination. It has been called the **primary embryonic organizer** because it induces determination in cells that pass over it during gastrulation. [Review Figures 44.8, 44.9, and 44.10, ANIMATED TUTORIAL 44.2](#)
- The protein β -catenin activates a signaling cascade that induces the primary embryonic organizer and sets up the anterior–posterior body axis. [Review Figures 44.2, and 44.11](#)
- Gastrulation in reptiles and birds differs from that in sea urchins and frogs because the large amount of yolk in reptile and bird eggs causes the blastula to form a flattened disc of cells. [Review Figure 44.13](#)
- Although their eggs have no yolk, placental mammals have a pattern of gastrulation similar to that of reptiles and birds.

44.3 How Do Organs and Organ Systems Develop?

- Gastrulation is followed by **organogenesis**, the process whereby tissues interact to form organs and organ systems.

- In the formation of the vertebrate nervous system, one group of cells that migrates over the blastopore lip is determined to become the **notochord**. The notochord organizes the overlying ectoderm to thicken, form parallel ridges, and fold in on itself to form a **neural tube** below the epidermal ectoderm. The nervous system develops from this neural tube. **Review Figure 44.14**
- The notochord and **neural crest cells** participate in the segmental organization of mesoderm into structures called **somites** along the body axis. Rudimentary organs and organ systems form during these stages. **Review Figure 44.15**
- In vertebrates, **Hox genes** determine the pattern of anterior–posterior differentiation along the body axis in mammals. Other genes, such as *sonic hedgehog*, contribute to dorsal–ventral differentiation. **Review Figure 44.16**

44.4 How is the Growing Embryo Sustained?

- The embryos of reptiles, birds, and mammals are protected and nurtured by four **extraembryonic membranes**. In birds and rep-

tiles, the **yolk sac** surrounds the yolk and provides nutrients to the embryo, the **chorion** lines the eggshell and participates in gas exchange, the **amnion** surrounds the embryo and encloses it in an aqueous environment, and the **allantois** stores metabolic wastes. **Review Figure 44.17, WEB ACTIVITY 44.1**

- In mammals, the chorion and the trophoblast cells interact with the maternal uterus to form a **placenta**, which provides the embryo with nutrients and gas exchange. The amnion encloses the embryo in an aqueous environment. **Review Figure 44.18**

44.5 What Are the Stages of Human Development?

- Human pregnancy, or **gestation**, can be divided into three trimesters. The embryo forms in the first trimester; during this time, it is most vulnerable to environmental factors that can lead to birth defects. During the second and third trimesters the **fetus** grows, the limbs elongate, and the organ systems mature.
- Development continues throughout childhood and throughout life.

SELF-QUIZ

- Fertilization involves all of the following *except*
 - equal contributions of cell organelles from sperm and egg.
 - joining of sperm and egg haploid nuclei.
 - induction of rearrangements of the egg cytoplasm.
 - sperm binding to specific sites on the egg surface.
 - metabolic activation of the egg.
- Which of the following does *not* occur during cleavage in frogs?
 - A high rate of mitosis
 - Reduction in the size of cells
 - Expression of genes critical for blastula formation
 - Orientation of cleavage planes at right angles
 - Unequal division of cytoplasmic determinants
- How does cleavage in mammals differ from cleavage in frogs?
 - Slower rate of cell division
 - Formation of tight junctions
 - Expression of the embryo's genome
 - Early separation of cells that will not contribute to the embryo
 - All of the above
- Which statement about gastrulation is *true*?
 - In frogs, gastrulation begins in the vegetal hemisphere.
 - In sea urchins, gastrulation produces the notochord.
 - In birds, cells from the surface of the blastodisc move down through the primitive groove to form the hypoblast.
 - In mammals, gastrulation occurs in the hypoblast.
 - In sea urchins, gastrulation produces only two germ layers.
- Which of the following was a conclusion from the experiments of Spemann and Mangold?
 - Cytoplasmic determinants of development are homogeneously distributed in the amphibian zygote.
 - In the late blastula, certain regions of cells are determined to form skin or nervous tissue.
 - The dorsal lip of the blastopore can be isolated and will form a complete embryo.
 - The dorsal lip of the blastopore can initiate gastrulation.
 - The dorsal lip of the blastopore gives rise to the neural tube.
- Which of the following is true of human development?
 - Most organs begin to form during the second trimester.
 - Gastrulation takes place in the oviducts.
 - Genetic diseases can be detected by sampling cells from the chorion.
 - Implantation occurs through interactions of the zona pellucida with the uterine lining.
 - Exposure to drugs and chemicals is most likely to cause birth defects when it occurs in the third trimester.
- Which of the following characterizes neurulation?
 - The notochord forms a neural tube.
 - The neural tube is formed from ectoderm.
 - A neural tube forms around the notochord.
 - The neural tube forms somites.
 - In birds, the neural tube forms from the primitive groove.
- Which statement about trophoblast cells is *true*?
 - They are capable of producing monozygotic twins.
 - They are derived from the hypoblast of the blastocyst.
 - They are endodermal cells.
 - They secrete proteolytic enzymes.
 - They prevent the zona pellucida from attaching to the oviduct.
- Which of the following is part of the embryonic contribution to placenta formation?
 - Amnion
 - Chorion
 - Ectoderm
 - Allantois
 - Zona pellucida
- When is the developing human most susceptible to the occurrence of birth defects from radiation or chemical insults?
 - At the time of birth
 - During the third trimester
 - During the first trimester
 - When it is a zygote
 - During the final stages of organ formation

FOR DISCUSSION

1. If you found a protein that was localized to a small group of cells in the frog blastula, how would you determine whether that protein played a role in development? Address the issues of sufficiency and necessity.
2. During gastrulation in birds, the *sonic hedgehog* gene is expressed only on the left side of Hensen's node. What might be the cause of this expression pattern, and what is its significance?
3. Much of the early work of describing animal development was done on sea urchins, amphibians, and chickens. Most of the recent work on the molecular mechanisms of animal development has been done on nematodes, fruit flies, zebrafish, and mice. Why do you think there has been a shift in the animal models used by developmental biologists?
4. If all the mitochondria and mitochondrial DNA in the embryo come from the egg, what implications does this have for using mitochondrial DNA for molecular evolutionary studies?
5. There is currently much controversy over therapeutic cloning as a way of obtaining embryonic stem cells to treat diseases. Given that human development is regulative—in other words, twinning can occur if an early blastocyst is divided into two cell masses—can you think of a way to guarantee a source of isogenic (i.e., identically matching a person's own body) stem cells for an individual without resorting to therapeutic cloning? Assume isolated cells can be preserved indefinitely in a frozen state.

ADDITIONAL INVESTIGATION

It is hypothesized that the differential development of the different body segments is due to the differential expression of Hox genes along the anterior-posterior body axis. For example,

in mammals, ribs develop in anterior body trunk segments but not in posterior segments. Using the mouse as a model, how would you test this hypothesis?

Fear and survival in the brain

Charles Whitman was a normal and responsible child. He became the youngest Eagle Scout in the country. He was a fine son and husband and received commendations as a U.S. Marine. While in the service, however, he began having unexplained fits of anger and other personality disorders. He was discharged from the Marines and entered the University of Texas. Several times he visited campus doctors and complained about having violent thoughts. Then, on August 1, 1966, after killing his wife and mother, Whitman barricaded himself inside the top floor of the clock tower on campus along with several high-powered rifles. From this vantage point, he killed 14 people and wounded 38 others before being shot and killed by Austin police. In his suicide note, he requested that proceeds from his insurance be donated to a mental health foundation. He also requested

an autopsy, and that autopsy revealed a tumor pressing on his amygdala.

The *amygdala* (Latin for “almond”) is the brain’s center for the emotion and memory of fear. When the cells of this structure are activated, your heart beats faster, your breathing becomes rapid and shallow, and your hands get cold and clammy. If you encounter a threatening situation, your amygdala is activated. If you are alone at night and hear a strange noise, your amygdala is activated. If you are faced with attempting something physically dangerous, your amygdala is activated. Without an amygdala, you would never be scared—and *not* being scared could be hazardous to your health.

A rare case of brain damage left a woman without a functional amygdala. When shown pictures of faces registering different emotions, she could not pick out the ones that were threatening or scary. She could not recall ever having a frightening experience. In tests where she was administered mild electrical shocks, she developed no anticipatory fear; even though she knew that seeing a red card meant she was about to receive a shock, she never reacted to the red card. In real life, she would not have the reflex to pull away from a threat.

People with a damaged amygdala frequently have trouble engaging in normal social relationships. They cannot “read” the nature, mood, or intentions of other people by looking at their faces. The pres-

Fear Factor The fear response—muscle tension, racing heart, cold sweat—kicks in when you are faced with potential pain, even if that experience ultimately will be beneficial.

CHAPTER OUTLINE

45.1 What Cells Are Unique to the Nervous System?

45.2 How Do Neurons Generate and Transmit Electrical Signals?

45.3 How Do Neurons Communicate with Other Cells?

Source of the Fear Response Frightening situations—or even memories of such a situation—activate a brain region called the amygdala, as shown in this functional magnetic resonance image (fMRI) of the brain of a person experiencing fear.

sure on Charles Whitman's amygdala may have been a factor in the emotions that drove him to mass murder; this diagnosis remains a matter for medical speculation.

Our nervous systems enable us to experience the world around us and to react to it. But in between sensing and reacting, there is much interpretation based on memory, learning, emotions, and beliefs—all of which are based on the activities of cells in the nervous system. To understand how our eyes see, how our fingers play the piano, or how our emotions affect our behavior, we have to understand how cells in different parts of our nervous systems work and interact.

IN THIS CHAPTER we will first describe the cells that make up nervous systems—neurons and glia—and explain how neurons process and transmit information by generating and transmitting electrical signals called action potentials. We will examine the membrane properties and events underlying action potentials and the mechanisms of cell-to-cell communication where neurons come together. Finally, we will consider how changes in the properties of neurons might explain learning and memory.

45.1 What Cells Are Unique to the Nervous System?

Nervous systems are composed of two types of cells: *nerve cells*, or **neurons**, and *glial cells*, or **glia** (see Figure 40.6). Neurons are *excitable*: they can generate and transmit electrical signals, which are known as nerve impulses, or **action potentials**. Many neurons have a long extension called an **axon** that enables them to conduct action potentials over long distances. Glia do not conduct action potentials; rather, they support neurons physically, immunologically, and metabolically. A **nerve** (as distinct from a neuron) is a bundle of axons that come from many different neurons. Many axons are wrapped by glia to electrically isolate them and increase their speed of conduction of action potentials.

Nervous systems can process information because their neurons are organized into **neural networks**. These networks include three functional categories of neurons, which can be thought of as being involved with input, output, and integration:

- **Afferent neurons** carry sensory information into the nervous system. That information comes from specialized **sensory neurons** that transduce (convert) various kinds of sensory stimuli (e.g., light, heat, pressure) into action potentials.
- **Efferent neurons** carry commands to physiological and behavioral *effectors* such as muscles and glands.
- **Interneurons** integrate and store information and communicate between afferent and efferent neurons.

Neural networks can be simple, like the one that causes your leg to kick when a physician taps your knee; or they can be exceedingly complex, like the network that enables you to read and remember this chapter.

Neural networks range in complexity

Simple animals such as cnidarians (e.g., sea anemones) can process information with simple neural networks that do little more than provide direct lines of communication from sensory cells to effectors; there is little or no integration or processing of signals (**Figure 45.1A**). The cnidarian's *nerve net* is most developed around the tentacles and the oral opening, where it facilitates detection of food or danger and causes tentacles to extend or retract.

Animals that are more complex and actively move about in search for food and mates need to process and integrate larger amounts of information. Even earthworms fit this description, and their increased need for information processing is met by higher numbers of neurons organized into clusters called **ganglia**. Ganglia serving different functions may be distributed around the body, as in earthworms or squid (**Figure 45.1B,C**).

(A) Sea anemone

A **nerve net** serves simple behaviors such as contraction and relaxation.

(B) Earthworm

In the earthworm, **ganglia** in each segment coordinate movement and anterior ganglia control more complex behavior.

(C) Squid

In squid, more complex behaviors are served by collections of neurons in specialized ganglia that process and integrate information.

(D) Human

The human brain and spinal cord are the **central nervous system**...

...which communicates to the cells and organs of the body via the **peripheral nervous system**.

In animals that are bilaterally symmetrical, ganglia frequently come in pairs, one on each side of the body. Also, as animals increase in complexity, some ganglia may become enlarged or fused together at the anterior end, forming a larger, centralized integrative center, or **brain**. The small nervous systems of invertebrates can be remarkably complex. Consider the nervous systems of spiders, which have programmed within them the thousands of precise movements necessary to construct a beautiful web without prior experience or opportunities to learn the specific web architecture of their species.

45.1 Nervous Systems Vary in Size and Complexity In animal species with increasingly complex sensory and behavioral abilities, information processing is increasingly centralized in ganglia (collections of neurons) or in a brain.

In vertebrates, most cells of the nervous system are found in the brain and the **spinal cord**, the sites of most information processing, storage, and retrieval (**Figure 45.1D**). Therefore, the brain and spinal cord are called the **central nervous system (CNS)**. Information is transmitted from sensory cells to the CNS and from the CNS to effectors via neurons that extend or reside outside the brain and the spinal cord; these neurons and their supporting cells are called the **peripheral nervous system (PNS)**. Vertebrates differ greatly in their behavioral complexity and in their physiological specializations, and their nervous systems reflect this diversity. **Figure 45.2** shows the brains of four vertebrate species of similar body mass drawn to the same scale.

The human nervous system contains an estimated 10^{11} neurons. Information is passed from one neuron to another where they come into close proximity at structures called **synapses**. The neuron sending the information is the **presynaptic neuron**, and the neuron receiving the information is the **postsynaptic neuron**. A given neuron in the brain can have 1,000 or more synapses. Thus the human brain can contain 10^{14} synapses (10^{11} neurons $\times 10^3$ synapses per neuron).

Synapses are not constant but instead can be highly plastic. They can increase or decrease in number and size. They can become more or less sensitive. Therein lies the incredible ability of the human brain to process information, to learn, to do complex tasks, to remember, and to have emotions. The astronomical number of neurons and synapses is divided into thousands of distinct but interacting networks that function in parallel. Before we can understand how even one of these circuits works, however, we must understand the properties of individual neurons.

Neurons are the functional units of nervous systems

Nervous systems of different species vary enormously in structure and function, but neurons behave similarly in animals as different as squid and humans. Their plasma membranes generate action potentials and conduct these signals from one lo-

45.2 Brains Vary in Size and Complexity The brains of four vertebrate species—all of which may have a similar body mass—show immense differences. Note that the brainstem, which is involved in physiological regulation and stereotypic behavior, differs less among these species than does the cerebrum, which in higher vertebrates is responsible for complex behavior and learning.

cation on a neuron to the most distant reaches of that cell—a distance that can be more than a meter in a human and many meters in a whale. Moreover, this transmission of action potentials can be rapid—up to 100 meters/sec, which is 360 km/hr—making it possible to sense, process, and act on information very quickly.

Most neurons have four regions—a *cell body*, *dendrites*, one or more *axons*, and *axon terminals* (**Figure 45.3A**)—but the variation among different types of neurons is considerable (**Figure 45.3B**). The *cell body* contains the nucleus and most of the cell's organelles. Many projections may sprout from the cell body. Most of these projections are shrublike **dendrites** (from the Greek *dendron*, “tree”), which bring information from other neu-

45.3 Neurons (A) A generalized diagram of a neuron. (B) Neurons from different parts of the mammalian nervous system are specifically adapted to their functions.

(A) Generalized neuronal anatomy

(B) Specialized neurons

rons or sensory cells to the cell body. The degree of branching of the dendrites differs among different types of neurons.

In most neurons, one projection—the axon—is much longer than the others. Axons usually carry action potentials away from the cell body. The length of the axon also differs among different types of neurons—some axons are remarkably long, such as those that run from the spinal cord to the toes. Axons are the “telephone lines” of the nervous system. Information received by dendrites can cause the axon to generate an action potential that is conducted down the axon toward its target cell. At the target cell, the axon divides into a spray of fine nerve endings. At the tip of each of these tiny nerve endings is a swelling, called an **axon terminal**, that comes very close to the membrane of the target cell to form a synapse.

As we will discuss in Section 45.3, synapses can be either chemical or electrical. Most synapses in vertebrates are chemical synapses. At chemical synapses a space only about 25 nanometers wide (about 1/2000th of a human hair) separates the *presynaptic* and *postsynaptic membranes*. An action potential arriving at an axon terminal causes it to release chemical messenger molecules called **neurotransmitters**. The neurotransmitters diffuse across the space and bind to receptors on the plasma membrane of the postsynaptic or target cell. This binding alters the activity of the postsynaptic neuron. Some neurotransmitter–receptor combinations inhibit activity of the postsynaptic neuron, and other neurotransmitter–receptor combinations excite it. Neurons integrate information by summing excitatory and inhibitory inputs.

Glia are also important components of nervous systems

Glia are another class of nervous system cells. There are many more glia than neurons in the human brain. Like neurons, glia come in several forms and have diverse functions. They do not generate or transmit electrical signals, but they can release neurotransmitters. Some glia physically support and orient the neurons and help them make the right contacts during embryonic development. Others supply neurons with nutrients, maintain the extracellular environment, and insulate axons. Still others consume debris and foreign particles and provide immune functions for the nervous system.

In the CNS, glia called **oligodendrocytes** wrap around the axons of neurons, covering them with concentric layers of insulating plasma membrane. In the PNS, glia called **Schwann cells** perform this function (**Figure 45.4**). **Myelin** is the covering produced by oligodendrocytes and Schwann cells, and it gives many parts of the nervous system a glistening white appearance. Not all axons are myelinated, but those that are can conduct action potentials more rapidly than axons that are not myelinated.

Diseases that affect myelin can be devastating because they impair conduction of action potentials. The most common demyelinating disease is *multiple sclerosis*—meaning literally “multiple scars”—which occurs in about 1 in 700 people in the United States. Individuals with this autoimmune disease produce antibodies to proteins in the myelin in the CNS. The symptoms and damage from the disease depend on where in the CNS the antibody attacks take place. Motor impairment is common. An example of a demyelinating disease that affects the PNS is Guillain-Barre Syndrome. Environmental factors such as pesticide exposure can also damage myelin. There are no known cures for demyelinating diseases.

Glia called **astrocytes** (because they look like stars; see Figure 40.6B) contribute to the **blood–brain barrier**, which protects the brain from toxic chemicals in the blood. Blood vessels throughout the body are very permeable to many chemicals, including toxic ones, which would reach the brain if this barrier did not exist. Astrocytes help form the blood–brain barrier by surrounding the smallest, most permeable blood vessels in the brain. The barrier is not perfect, however. Since it consists of plasma membranes, it is permeable to fat-soluble substances such as anesthetics and alcohol, which explains why these substances have such rapid and marked effects on the nervous system.

The blood–brain barrier usually prevents antibodies in the general circulation from entering the CNS. To provide the CNS with immune defenses, **microglia**, which originate during development from stem cells in the bone marrow, come to reside

45.4 Wrapping Up an Axon (A) Schwann cells produce layers of myelin, a type of plasma membrane that provides electrical insulation to the axon. At the intervals between Schwann cells—the nodes of Ranvier—the axon is exposed. Action potentials travel along the axon by “jumping” from node to node. (B) A myelinated axon, seen in cross section through an electron microscope.

in the CNS and act as macrophages and mediators of inflammatory responses.

45.1 RECAP

Nervous systems consist of neurons and glia. Neurons are arranged in circuits. Sensory neurons convert information from the external or internal environment into electrical signals; interneurons integrate and process information; and efferent neurons carry commands to target tissues. Glia have a wide variety of supporting roles, including contributing to the blood–brain barrier.

- Comparing nervous systems of anemones, worms, fishes, and humans, what trends seem to reflect increasing complexity? **See pp. 945–946 and Figures 45.1 and 45.2**
- Describe the different parts of neurons and their functions. **See pp. 946–947 and Figure 45.3**
- What are some types of glia, and what are their functions? **See p. 947**

The one feature common to all nervous systems is that they process information in the form of action potentials. In the next section we will focus on how action potentials are generated and transmitted by nervous systems.

45.2 How Do Neurons Generate and Transmit Electrical Signals?

All animal cells have more potassium ions (K^+) inside and more sodium ions (Na^+) in the extracellular fluid. Both inside and outside the cell, the positive charges of these ions are balanced by negatively charged ions so that, individually, the cell interior and the extracellular fluid are both electrically neutral. However, *across the cell membrane* there is an electrical charge difference, with the inside being negative to the outside. Why is this so?

The reason is that there are *leak currents* in the cell membrane due to channels that allow only certain ions—mostly K^+ —to “leak” passively across. Because there are more potassium ions inside the cell than outside, K^+ diffuses out of the cell down a concentration gradient. But when K^+ leaks out of the cell, it leaves behind an unbalanced negative charge that tends to pull K^+ back into the cell. An equilibrium is reached when the tendency for K^+ to diffuse out is countered by the electrical charge pulling K^+ back in. The result is an electric charge difference—a **membrane potential**—across the plasma membrane, with the inside of the cell negative to the outside.

Membrane potentials exist in all cells. In neurons, the steady state membrane potential is called the **resting potential**, because neurons can also be active, generating rapid, large changes in membrane potential. These sudden large shifts are called *action potentials* (sometimes referred to as *nerve impulses*). An action potential is generated by sudden openings and rapid closings

of ion channels. Before describing the properties of ion channels and action potentials in detail, a review of some simple concepts of electricity may be useful.

Simple electrical concepts underlie neural function

Voltage (electric potential difference) is a force that causes electrically charged particles to move between two points. Voltage is to the flow of electrically charged particles as pressure is to the flow of water. If the negative and positive poles of a battery are connected by a wire, an electric current will flow through the wire because there is a voltage difference between the two poles. This flow of electric current can be used to do work, just as a current of water can be used to do work.

In wires, electric current is carried by electrons, but in solutions and across cell membranes, electric current is carried by ions. The major ions that carry electric charges across the plasma membranes of neurons are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-). Recall that ions with opposite charges attract one another and that those with like charges repel one another. How do these basic principles of bioelectricity establish the resting potential of the neural plasma membrane? And how is the flow of ions through membrane channels turned on and off to generate action potentials? We address these questions next.

Membrane potentials can be measured with electrodes

We can record electrical events in a cell using electrodes. **Figure 45.5** shows how this technique is applied across an unstimulated axon to measure the resting potential, which is usually between -60 and -70 mV. The minus sign indicates that the inside of the cell is electrically negative compared with the outside.

The resting potential provides a means for neurons to respond to a stimulus. Because of the voltage difference across the membrane, and the different ion concentrations on either side of the membrane, ions would cross the membrane if they could. For example, Na^+ ions are more abundant outside the cell than inside and the inside of the resting cell is negatively charged. Therefore, if the membrane suddenly became permeable to Na^+ , those positively charged ions would rush into the cell. Any chemical or physical stimulus that changes the permeability of the plasma membrane to ions will produce a change in the cell’s membrane potential. The most extreme change in membrane potential is the action potential, a sudden and rapid reversal in the voltage across a portion of the plasma membrane. For one or two milliseconds, positively charged ions flow into the cell, making the inside of the cell *more positive* than the outside.

Ion transporters and channels generate membrane potentials

The plasma membranes of neurons, like those of all other cells, are lipid bilayers that are impermeable to ions but contain many

TOOLS FOR INVESTIGATING LIFE

45.5 Measuring the Membrane Potential

An electrode can be made from a glass pipette with a very sharp tip filled with a solution that conducts electric charges. If one electrode is placed inside the plasma membrane of an axon and another is placed just outside the axon, the difference in voltage can be measured.

protein molecules that serve as ion transporters and channels. Ion transporters and channels are responsible for the distribution of charges across the membrane that create resting and action potentials.

Ion transporters require energy to move ions against their concentration or electrical gradients and are therefore called ion pumps. A major ion transporter in the plasma membranes of neurons (and all other cells) is the **sodium-potassium pump**, so called because it actively expels Na^+ ions from inside the cell, exchanging them for K^+ ions from outside the cell (**Figure 45.6A**). The Na^+-K^+ pump is an *antiporter* (see Section 6.3) and is also known as *sodium-potassium ATPase*, a term emphasizing that it is an enzyme complex requiring ATP to do its work. The Na^+-K^+ pump keeps the concentration of K^+ inside the cell greater than that of the extracellular fluid, and the concentration of Na^+ inside the cell less than that of the extracellular fluid. The concentration differences established by this antiporter mean that K^+ would diffuse out of the cell and Na^+ would dif-

(A) Na^+-K^+ pump (ATPase)

(B) Na^+-K^+ channels

45.6 Ion Transporters and Channels (A) The sodium-potassium pump is in an antiporter that actively moves K^+ to the inside of a neuron and Na^+ to the outside. (B) Ion channels allow specific ions to diffuse down their concentration gradients; K^+ tends to leave neurons when potassium channels are open, and Na^+ tends to enter neurons when sodium channels are open. Leak channels like the K^+ channel shown are always open and create the resting membrane potential. Gated channels like the Na^+ channels shown are opened by chemical or electrical stimulation.

TOOLS FOR INVESTIGATING LIFE

45.7 Using the Nernst Equation

The Nernst equation calculates membrane potential when only one type of ion can cross a membrane that separates solutions with different concentrations of that ion.

1. Measure concentrations of ions inside and outside a neuron.

To measure the concentration of ions in a neuron, the neuron (and its axon) must be big. Squid have giant neurons that control their escape response (see Figure 45.1C). It is possible to sample the cytoplasm of these axons, which are about 1 mm in diameter.

2. Use the Nernst equation to calculate what the membrane potential would be if it were permeable to each of the ions that are differently concentrated on the two sides of the membrane: Na⁺, K⁺, Ca²⁺, and Cl[−].

The Nernst equation predicts the membrane potential resulting from membrane permeability to a single type of ion that differs in concentration on the two sides of the membrane. The equation is written

$$E_{\text{ion}} = 2.3 \frac{RT}{zF} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

where *E* is the equilibrium (resting) membrane potential (the voltage across the membrane in mV), *R* is the universal gas constant, *T* is the absolute temperature, *z* is the charge on the ion (+1, +1, +2, or −1), and *F* is the Faraday constant. The subscripts *o* and *i* indicate the ion concentrations outside and inside the cell, respectively.

At this point you could just “plug and play,” but do you understand this equation?

A concentration difference of ions across a membrane creates a *chemical* force that pushes the ions across the membrane; however, the resulting unbalanced *electrical charges* will pull the ions back the other way. At *equilibrium*, the work done moving ions in each direction will be the same.

The *chemical* energy pushing the ions will equal 2.3 *RT* log $\frac{[\text{ion}]_o}{[\text{ion}]_i}$.
 The *electrical* energy pulling the ions will equal *zEF*. So, at equilibrium:

$$zEF = 2.3 RT \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

Rearranging the equation to solve for *E*, we get the Nernst equation:

$$E_{\text{ion}} = 2.3 \frac{RT}{zF} \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

We can simplify the equation by picking a temperature—let’s use “room temperature,” or 20°C—and solving for 2.3 *RT*/*F*. At 20°C, 2.3 *RT*/*F* equals 58. Thus:

$$E_{\text{ion}} = 58/z \log \frac{[\text{ion}]_o}{[\text{ion}]_i}$$

3. Measuring ion concentrations in squid giant axon cytoplasm and in seawater, then solving the Nernst equation for each ion, we find:

Ion	Ion concentration (mM)		Predicted membrane potential (mV)
	in squid axon	in seawater	
K ⁺	400	20	−75
Na ⁺	50	460	+56
Ca ²⁺	0.5	10	+38
Cl [−]	50	560	−60

4. Since the measured membrane potential is −66 mV, it is clear that the resting potential of the axon is due to permeability of the membrane to more than just one type of ion.

fuse in if the ions could cross the lipid bilayer. How do these concentration gradients relate to the electric gradients we discussed above?
 Ion channels permit the diffusion of ions across membranes. These channels are water-filled pores formed by proteins that

cross the lipid bilayer and are generally *selective*—they allow some types of ions to pass through more easily than others (**Figure 45.6B**). Thus, there are potassium channels, sodium channels, chloride channels, and calcium channels, and there are different kinds of each. Ions can diffuse through these channels in

either direction. The direction and magnitude of the net movement of ions through a channel depend on the concentration gradient of that ion type across the plasma membrane, as well as on the voltage difference across that membrane. These two motive forces acting on an ion are termed its **electrochemical gradient**. Although the electrochemical gradient drives the movement of ions through channels across bilayers, movement through channels can be modified by gates that open and close channels.

Potassium channels are the most common open, or leak, channels in the plasma membranes of resting (non-stimulated) neurons. As a consequence, resting neurons are more permeable to K^+ than to any other ion. Thus, open potassium channels are largely responsible for the resting membrane potential. Because the potassium channels make the plasma membrane permeable to K^+ , and because the Na^+-K^+ pump keeps the concentration of K^+ inside the cell much higher than that outside the cell, K^+ tends to diffuse down its electrochemical gradient, out of the cell, through the channels. As these positively charged potassium ions diffuse out of the cell, they leave behind unbalanced negative charges, generating an electric potential across the membrane that tends to pull K^+ back into the cell.

The membrane potential at which the net diffusion of K^+ out of the cell ceases (that is, the point at which K^+ diffusion out due to the concentration gradient is balanced by its movement in due to the negative electric potential) is the **potassium equilibrium potential**. The value of the potassium equilibrium potential can be calculated from the concentrations of K^+ on the two sides of the membrane using the **Nernst equation** (Figure 45.7). This equation, developed in the late 1800s, illustrates that the nature of ion channels in neural membranes was hypothesized long before their specific structures and properties were described.

In the late 1940s, A. L. Hodgkin and A. F. Huxley at the University of Cambridge set out to study the electrical properties of axonal membranes. With the techniques available at that time, the necessary measurements could be made only if you had a very large axon to work with. Such an axon exists in nature, in the huge neuron that controls the escape response of squid. Hodgkin and Huxley used electrodes to measure the voltage across the plasma membrane of this large axon, as seen in Figure 45.7, and to pass electric current into it to change its resting potential. They also changed the concentrations of Na^+ and K^+ both inside and outside the squid axon and measured the resulting changes in membrane potential. On the basis of their many careful experiments, Hodgkin and Huxley developed virtually all of our basic concepts about the electrical properties of neurons, and received the Nobel prize in 1963.

We now know that, in general, the resting potential is less negative than the Nernst equation predicts because resting neurons are also slightly permeable to other ions, such as Na^+ and Cl^- . Another equation, called the Goldman equation, takes all of the ions that

can cross the membrane into account and therefore can calculate the membrane potential accurately.

Ion channels and their properties can now be studied directly

Because Hodgkin and Huxley were working long before there were laboratory techniques that could investigate ion channels, they could only hypothesize their properties. These hypotheses could not be tested until the late 1970s, when B. Sakmann and E. Neher developed a technique called **patch clamping**, for which they won the Nobel prize in 1991. Patch clamping, described in Figure 45.8, is widely used by neurobiologists, en-

TOOLS FOR INVESTIGATING LIFE

45.8 Patch Clamping

The patch clamp is a glass micropipette filled with an electrically conductive solution that has the same composition as extracellular fluids. When this pipette/electrode is positioned against the membrane of a cell and slight suction is applied, a seal forms. If a single ion channel (or a few ion channels) are within the patch of membrane bounded by the seal, the openings and closings of individual channels can be recorded by the electrode. If the pipette is retracted, it can tear the patched membrane away from the cell, and the activities of the ion channels in the patch can continue to be recorded.

abling them to record in real time the tiny electrical currents caused by the openings and closings of single ion channels.

Gated ion channels alter membrane potential

The ion channels called leak channels are always open, but other ion channels in the plasma membranes of neurons behave as if they contain “gates”; they are open under some conditions and closed under other conditions. **Voltage-gated channels** open or close in response to a change in the voltage across the plasma membrane. **Chemically gated channels** open or close depending on the presence or absence of a specific molecule that binds to the channel protein, or to a separate receptor that in turn alters the channel protein. **Mechanically gated channels** open or close in response to mechanical force applied to the plasma membrane. Gated channels play important roles in neural function.

Openings and closings of gated channels alter the resting potential. Imagine what happens, for example, if sodium channels in the plasma membrane open. Na^+ diffuses into the neuron down its electrochemical gradient. As a result, the inside of the cell becomes less negative. When the inside of a neuron becomes less negative (or more positive) in comparison to its resting condition, its plasma membrane is **depolarized** (Figure 45.9).

An opposite change in the resting potential occurs if gated K^+ channels open. When K^+ efflux from the neuron increases over the normal leak current (the movement of K^+ through the leak channels), the membrane potential becomes even more negative, and the plasma membrane is **hyperpolarized**.

The openings and closings of ion channels, which result in changes in the voltage across the plasma membrane, are the

basic mechanisms by which neurons respond to stimuli, be they electrical, chemical, or mechanical. How do such local changes in membrane potential get communicated to other parts of the cell?

A local change in membrane potential causes a flow of ions that spreads the change in membrane potential to adjacent regions of the membrane. For example, when Na^+ enters a neuron through open sodium channels at one location, those positively charged ions are attracted to adjacent areas on the inside of the membrane that are more negative, and thus there is a rapid flow of electric current (movement of ions) away from the site of the open Na^+ channels. However, this local flow of electric current decays as it spreads and therefore does not spread very far. Electric currents do not spread far in cells because cell membranes are not completely impermeable to ions. An electric current traveling along a membrane is like water flowing through a leaky hose.

Graded changes in membrane potential can integrate information

Even though the flow of electric current along plasma membranes can only extend over short distances, it can cause graded changes in membrane potentials locally. A **graded membrane**

45.9 Membranes Can Be Depolarized or Hyperpolarized The resting potential is produced by leak K^+ channels. A shift from the resting potential to a less negative membrane potential, as occurs when Na^+ enters the cell through a gated sodium channel, is called depolarization. Hyperpolarization occurs when the membrane potential becomes more negative, as when additional K^+ leaves the cell through gated K^+ channels, which occurs extensively in your brain when you fall asleep.

potential is a change from the resting potential. Such changes can be due to chemical or mechanical influences on ion channels. Graded potentials are a means of integrating inputs to a cell because the membrane can respond to those inputs with proportional amounts of depolarization or hyperpolarization.

Graded potentials can transmit signals over very short distances and play an important role at the neuromuscular junction (see Section 45.3). In the next chapter we will learn how they play important roles in sensory systems. However, axons are too long to transmit information as a continuous flow of electric current (as telephone wires do). Therefore axons code information as discrete action potentials that travel along their membranes. Graded potentials, however, play an important role in the generation of action potentials.

45.10 The Course of an Action Potential Action potentials result from rapid changes in voltage-gated Na^+ and K^+ channels.

yourBioPortal.com

GO TO Animated Tutorial 45.2 •
The Action Potential

Sudden changes in Na^+ and K^+ channels generate action potentials

Action potentials are sudden, transient, large changes in membrane potential. In unmyelinated axons they can be conducted at speeds of up to 2 meters per second, but in myelinated axons the conduction velocity can be 100 meters per second. Think of running the 100-meter dash—the world record is slightly under 10 seconds.

If we place the tips of a pair of electrodes on either side of the plasma membrane of a resting axon and measure the voltage difference, the reading might be about -60 mV, as we saw in Figure 45.5. If these electrodes are in place when an action potential travels down the axon, they register a rapid change in membrane potential, from -60 mV to about $+50$ mV. The membrane potential then rapidly returns to its resting level of -60 mV as the action potential passes (Figure 45.10).

The action potential is generated by the actions of voltage-gated Na^+ and K^+ channels in the plasma membrane of the axon. At the resting potential, most of these channels are closed (balloon 1 in Figure 45.10). Depolarization of the membrane causes them to open. For example, if a neuron is stimulated sufficiently

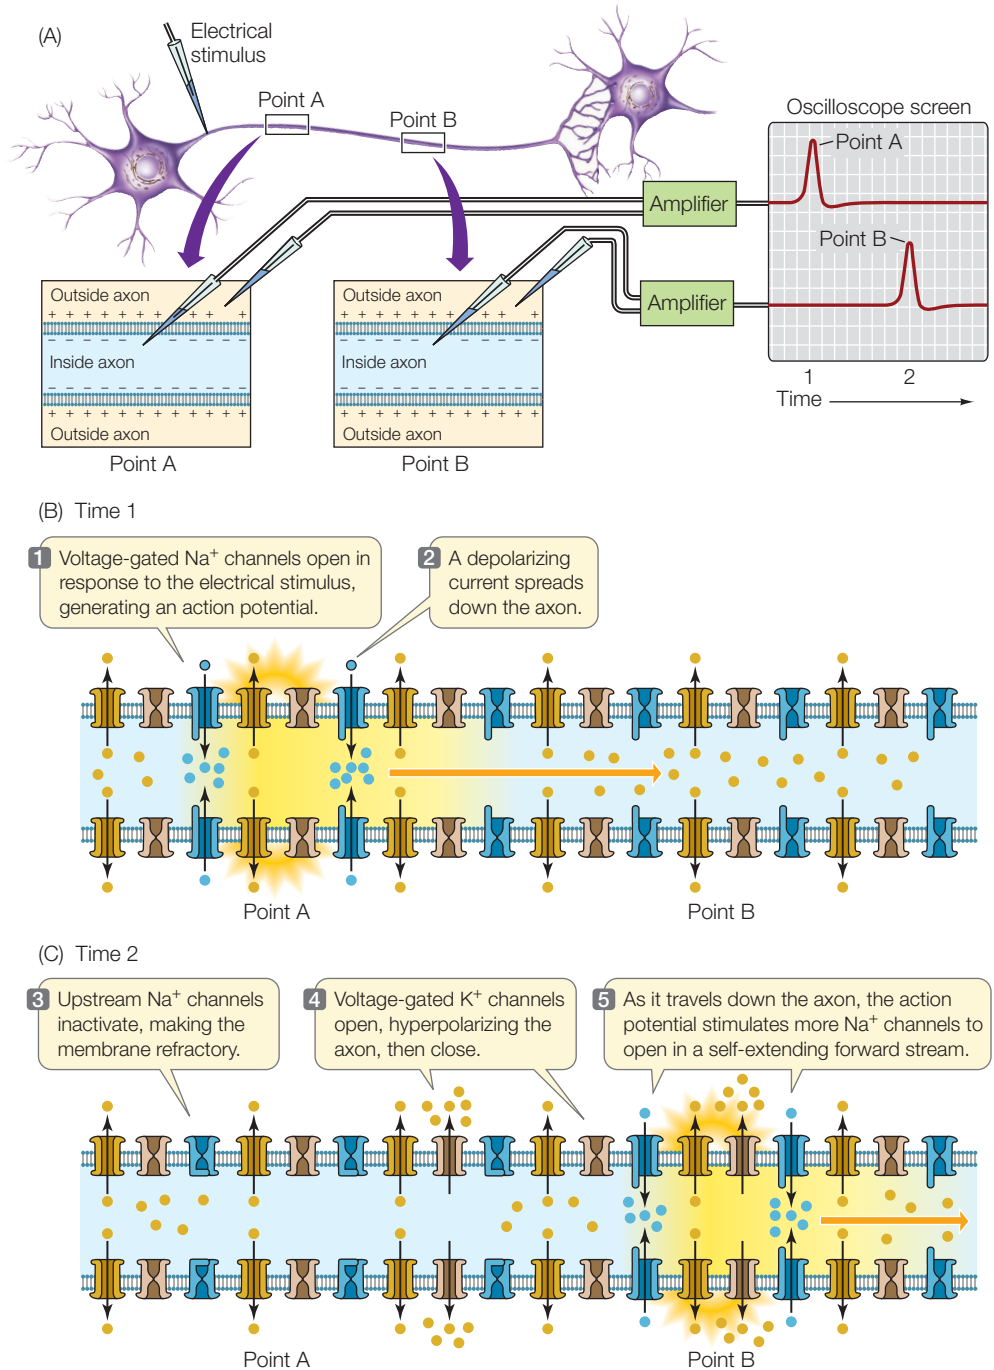

to cause the plasma membrane of its cell body to depolarize, that depolarization can spread by local current flow to the **axon hillock**, the region of the cell body at the base of the axon (see Figure 45.3). Voltage-gated Na^+ channels are concentrated in the axon hillock. When the plasma membrane in this area depolarizes, some of these voltage-gated channels open briefly—for less than a millisecond (balloon 2 in Figure 45.10). When these channels open, Na^+ rushes into the axon and depolarizes the membrane even more, causing more Na^+ channels to open—a *positive feedback* effect. When the membrane is depolarized about 5 to 10 mV above the resting potential, a **threshold** is reached; a large number of sodium channels open (balloon 3 in Figure 45.10), and the membrane potential becomes positive—an action potential. The rising phase of the action potential halts abruptly in 1 to 2 milliseconds, and the membrane potential rapidly becomes negative once again.

What causes the axon to return to resting potential? There are two contributing factors: the voltage-gated Na^+ channels close, and voltage-gated K^+ channels open (balloon 4 in Figure 45.10). The voltage-gated K^+ channels open more slowly than the Na^+ channels and stay open longer, allowing K^+ to carry excess positive charges out of the axon. As a result, the membrane potential returns to a negative value and usually becomes even more negative than the resting potential until the voltage-gated K^+ channels close (balloon 5 in Figure 45.10).

Another feature of the voltage-gated Na^+ channels is that once they open and close, they have a **refractory period** of 1 to 2 milliseconds during which they cannot open again. This property can be explained by the channels having two gates, an **activation gate** and an **inactivation gate** (see Figure 45.10). Under resting conditions, the activation gate is closed and the inactivation gate is open. Depolarization of the membrane to the threshold level causes both gates to change state, but the activation gate responds faster. As a result, the channel is open for a brief time between the opening of the activation gate and the closing of the inactivation gate. Inactivation gates remain closed for 1 to 2 milliseconds before they spontaneously open again, thus explaining why the membrane has a refractory period before it can fire another action potential. By the time the inactivation gate reopens, the activation gate is closed, and the membrane is poised to generate another action poten-

tial. Another contribution to the refractory period is the duration of the opening of the voltage-gated K^+ channels, as we saw above. The dip in the membrane potential following an action potential is called the *after-hyperpolarization* or *undershoot*.

The difference in the concentration of Na^+ across the plasma membrane and the negative resting potential constitute the “bat-

45.11 Action Potentials Travel along Axons (A) There is no loss of signal as an action potential travels along an axon. (B) When an action potential is stimulated in one region of membrane, electric current flows to adjacent areas of membrane and depolarizes them. (C) The advancing wave of depolarization causes more Na^+ channels to open, and the action potential is generated anew in the next section of membrane. Meanwhile, in the region where the action potential has just fired, the Na^+ channels are inactivated and the voltage-gated K^+ channels are still open, rendering this section of the axon refractory. Hence the action potential cannot “back up,” but moves continuously forward along the axon, regenerating itself as it goes.

tery” that drives action potentials. How rapidly does the battery run down? It might seem that a substantial number of ions would have to cross the membrane for the membrane potential to change from -60 mV to $+50$ mV and back to -60 mV again. In fact, only a vanishingly small percentage of the Na^+ concentrated outside the plasma membrane moves through the channels during the passage of an action potential. Thus the effect of a single action potential on the concentration gradients of Na^+ and K^+ is very small, and it is possible in most cases for the sodium–potassium pump to keep the “battery” charged, even when the neuron is generating many action potentials every second.

Action potentials are conducted along axons without loss of signal

Action potentials can travel over long distances with no loss of signal. If we place two pairs of electrodes at two different locations along an axon, we can record an action potential at those two locations as it travels along the axon (**Figure 45.11A**). The magnitude of the action potential does not change between the two recording sites. This constancy is possible because an action potential is an all-or-none, self-regenerating event.

- An action potential is *all-or-none* because of the interaction between the voltage-gated Na^+ channels and the membrane potential. If the membrane is depolarized slightly, some voltage-gated Na^+ channels open. Some sodium ions cross the plasma membrane and depolarize it even more, opening more voltage-gated Na^+ channels, and so on, until the membrane reaches threshold and generates an action potential. This positive feedback mechanism ensures that action potentials always rise to their maximum value.
- An action potential is *self-regenerating* because it spreads by local current flow to adjacent regions of the plasma membrane. The resulting depolarization brings those neighboring areas of membrane to threshold. So when an action potential occurs at one location on an axon, it stimulates the adjacent region of axon to generate an action potential, and so on down the length of the axon.

We can use an electrode to stimulate an axon, causing it to depolarize and to fire an action potential that is then conducted along the axon. **Figure 45.11B** shows the changes in the ion channels in the membrane that are responsible for conducting the action potential along the axon without a reduction in amplitude. Normally, an action potential is propagated in only one direction—away from the

body. It cannot reverse itself because the voltage-gated Na^+ channels in the region of the membrane it came from are still in their refractory period.

Action potentials do not travel along all axons at the same speed. They travel faster in large-diameter axons than in small-diameter axons because the resistance to current flow decreases as an axon’s diameter gets bigger. They travel faster in myelinated than in nonmyelinated axons because they can “jump” from one node to another without traversing the intervening space (**Figure 45.12**). Invertebrates mostly depend on increased axon diameter for fast conduction, but vertebrates mostly depend on myelination of axons to increase conduction velocity.

Action potentials can jump along axons

In vertebrate nervous systems, increasing the speed of action potentials by increasing the diameter of axons is not feasible because of the huge number of axons involved. Each of our eyes,

45.12 Saltatory Action Potentials Action potentials appear to jump from node to node in myelinated axons.

for example, has about a million axons connecting it to the brain. These axons conduct action potentials at about the same speed as does the squid giant axon—about 20 meters per second—yet the diameter of each is 200 times smaller than the squid axon’s diameter. Vertebrates have evolved a different way of increasing conduction velocity of axons, and that adaptation is *myelination*.

When glia wrap themselves around axons, covering them with concentric layers of myelin (see Figure 45.4), they leave regularly spaced gaps, called **nodes of Ranvier**, where the axon is not covered (see Figure 45.12). The leakage of ions across the regions of the plasma membrane that are wrapped in myelin is reduced, so electric current can spread farther along the inside of a myelinated axon than it can along a nonmyelinated axon. Additionally, voltage-gated ion channels are clustered at the nodes of Ranvier. Thus an axon can fire action potentials only at nodes, and those action potentials cannot be propagated through the adjacent patch of membrane covered with myelin. The positive charges that flow into the axon at the node do, however, flow down the inside of the axon in the form of electric current. When the current reaches the next node, the plasma membrane at that node is depolarized to threshold and fires another action potential. Action potentials therefore appear to jump from node to node along the axon.

The speed of conduction is increased in these myelin-wrapped axons because electric current flows much faster through the cytoplasm than ion channels can open and close. This form of rapid impulse propagation is called **saltatory conduction** (Latin *saltare*, “to jump”).

45.2 RECAP

Neurons have membrane potentials due to ionic concentration differences across their membranes and because leak channels make the membrane differentially permeable to ions. Changes in ion channel permeabilities cause graded changes in membrane potentials. Sudden openings and closings of gated ion channels in the membrane produce action potentials. Action potentials are rapid, all-or-none changes in membrane potential that are conducted along axons from the neuron body to the axon terminals.

- How are membrane resting potentials generated and altered? **See pp. 949–950 and Figures 45.6 and 45.9**
- How are action potentials generated? **See pp. 953–955 and Figure 45.10**
- How are action potentials transmitted along axons? **See pp. 955–956 and Figures 45.11 and 45.12**

Now that we understand how action potentials are generated and transmitted along axons, let’s address the question of what happens when the action potential gets to the axon terminals. How is it communicated to the next cell, which could be another neuron, a muscle cell, or perhaps a secretory cell?

45.3 How Do Neurons Communicate with Other Cells?

Neurons communicate with each other and with other cells at synapses. The most common type of synapse in the nervous system is the **chemical synapse**, in which neurotransmitters released from a presynaptic cell induce changes in a postsynaptic cell. In **electrical synapses** the action potential spreads directly from presynaptic to postsynaptic cell. We will begin this section with a discussion of the synapses between neurons and muscle cells. We will then consider the diversity in synapses, how they integrate information, and how they are involved in learning and memory.

The neuromuscular junction is a model chemical synapse

Neuromuscular junctions are synapses between neurons and the skeletal muscle cells they innervate. They are excellent models for how chemical synaptic transmission works. Like other neurons, a motor neuron has only one axon, but close to its target cell that axon can branch into numerous axon terminals that form many synapses with muscle cells. At each axon terminal an enlarged knob or buttonlike structure contains vesicles filled with neurotransmitter molecules. The neurotransmitter used by all vertebrate neuromuscular synapses is **acetylcholine (ACh)**. ACh is released by exocytosis when the membrane of a vesicle fuses with the presynaptic membrane of the axon terminal.

Where does the neurotransmitter come from? Some neurotransmitters, such as ACh, are synthesized in the axon terminal and packaged in vesicles. The enzymes required for ACh biosynthesis, however, are produced in the cell body of the motor neuron and are transported along microtubules down the axon to the terminals. In contrast, peptide neurotransmitters are produced in the cell body and packaged into membrane-bound vesicles by the Golgi apparatus. These vesicles are rapidly transported down the axon to the terminals.

The postsynaptic membrane of the neuromuscular junction is a modified part of the muscle cell plasma membrane called a **motor end plate** (Figure 45.13). It appears as a depression in the muscle cell membrane, and the terminals of the motor neuron sit in the depression. The space between the presynaptic membrane and the postsynaptic membrane is the **synaptic cleft**, which in chemical synapses is about 20 to 40 nanometers wide. ACh released into the cleft by the presynaptic cell diffuses across to the postsynaptic membrane.

The arrival of an action potential causes the release of neurotransmitter

Neurotransmitter is released when an action potential arrives at the axon terminal and causes the opening of voltage-gated Ca^{2+} channels in the presynaptic membrane. Because the Ca^{2+} concentration is greater outside the cell than inside, Ca^{2+} enters the axon terminal near the sites of vesicle exocytosis. The increase in Ca^{2+} inside the axon terminal causes the vesicles con-

taining neurotransmitter to fuse with the presynaptic membrane and empty their contents into the synaptic cleft.

In neuromuscular synapses, vesicle fusion and emptying is all-or-none. The vesicle membrane is incorporated into the presynaptic membrane, which actually gets larger as a result—at least until the extra membrane is recycled through endocytosis. The recycled membrane is processed through endosomes to become new vesicles that are then refilled with neurotransmitter.

Synaptic functions involve many proteins

The description above of the release of neurotransmitter from the presynaptic membrane may seem simple, but it involves hundreds of proteins that are responsible for various aspects of the process: vesicle formation, transport of neurotransmitter into vesicles, anchoring of vesicles to cytoskeletal elements, docking of the vesicles with the presynaptic membrane, fusion of the vesicular and cell membranes, and endocytosis of the vesicle membrane for recycling.

Some of these proteins are the targets of toxins. For example, toxins from bacteria of the genus *Clostridium* are proteases that destroy several of the proteins necessary for the docking of

vesicles to the presynaptic membrane. These toxins cause botulism and tetanus, frequently fatal diseases that involve muscle impairment because of loss of transmitter release. Poisons can also become medicines, however. You have surely heard about the use of botulinum toxin (Botox) for decreasing muscle spasms for cosmetic (removal of wrinkles) or therapeutic purposes.

The postsynaptic membrane responds to neurotransmitter

When ACh is released at a synapse, some of it diffuses across the synaptic cleft and binds to ACh receptors on the postsynaptic membrane (**Figure 45.14**). The postsynaptic membrane of the motor end plate is highly folded. ACh receptors are on the crests of the folds, and voltage-gated cation channels are at the bottoms of the folds and in the surrounding muscle cell membrane (see **Figure 45.13**). The ACh receptors are channels that allow both Na^+ and K^+ to flow through, but since the electrochemical gradients favor a net influx of Na^+ , the response of the motor end plate to ACh is to depolarize. That graded potential reflecting the number of receptors activated spreads to the depths of the folds of the motor end plate membrane and to sur-

rounding muscle cell membrane, which contain voltage-gated Na^+ channels.

If the axon terminal of a motor neuron releases sufficient amounts of ACh to adequately depolarize a motor end plate, that spreading depolarization will activate the voltage-gated Na^+ channels and cause the firing of an action potential. This action potential is then conducted throughout the muscle cell's system of membranes, causing the cell to contract. We discuss muscle membrane action potentials and the contraction of muscle cells in greater detail in Section 48.1.

How much neurotransmitter is enough? Neither a single ACh molecule nor the contents of an entire vesicle (about 10,000 ACh molecules) will bring the plasma membrane of a muscle cell to threshold. However, a single action potential in an axon terminal releases the contents of about 100 vesicles, which is more than enough to fire an action potential in the muscle cell and cause it to contract.

Synapses between neurons can be excitatory or inhibitory

In vertebrates, the synapses between motor neurons and muscle cells are always **excitatory**; that is, motor end plates always respond to ACh with a graded potential that is less negative than the resting potential. However, synapses between neurons can also be inhibitory. For example, recall that there are more chloride ions (Cl^-) outside the cell than inside it. If the receptor on the postsynaptic membrane is a Cl^- channel opened by a neurotransmitter, the effect of that neurotransmitter will be to cause Cl^- ions to enter the postsynaptic cell and hyperpolarize it. Hyperpolarization will take the membrane farther from the threshold potential for the voltage-gated Na^+ channels, and therefore make it less likely that the cell will fire action potentials. A synapse that causes hyperpolarization of the postsynaptic membrane is **inhibitory**.

45.14 Chemically Gated Channels The motor end plate contains acetylcholine receptors, which are chemically gated ion channels. When one of these receptors binds ACh, its channel pore opens and Na^+ ions move into the postsynaptic cell, depolarizing its plasma membrane. The enzyme acetylcholinesterase breaks down ACh in the synapse, closing the channel; the breakdown products (acetate and choline) are then taken up by the presynaptic membrane and resynthesized into more ACh.

Recall that a neuron may have many dendrites. Axon terminals from many other neurons may form synapses with those dendrites and with the cell body. The axon terminals of different presynaptic neurons may store and release different neurotransmitters, and the plasma membrane of the dendrites and cell body of a postsynaptic neuron may have receptors for a variety of neurotransmitters. The mix of synaptic activity impinging on a cell will cause it to have a graded membrane potential that may be either more positive or more negative than its resting potential.

The postsynaptic cell sums excitatory and inhibitory input

What determines when an individual neuron will fire an action potential? As we just learned, the sum of excitatory and inhibitory postsynaptic potentials creates a graded membrane potential in the postsynaptic cell body. This summation ability is the major mechanism by which the nervous system integrates information. Each neuron may receive 1,000 or more synaptic inputs, but it has only one output: an action potential in a single axon. At any one time, the information from all of the active inputs are translated into the rate at which that neuron generates action potentials in its axon.

For most neurons, summation takes place in the axon hillock at the base of the axon. The plasma membrane of the axon hillock is not insulated by glia and has many voltage-gated Na^+ channels. Excitatory and inhibitory postsynaptic potentials from synapses anywhere on the dendrites or the cell body may spread to the axon hillock by local current flow. If the resulting graded potential depolarizes the axon hillock to threshold, it fires an action potential. Because postsynaptic potentials decrease in strength as they spread from the site of the synapse, a synapse at the tip of a dendrite has less influence than a synapse on the cell body, near the axon hillock.

Excitatory and inhibitory postsynaptic potentials are summed over space and over time. **Spatial summation** adds up the simultaneous influences of synapses at different sites on the postsynaptic cell (**Figure 45.15A**). **Temporal summation** adds up postsynaptic potentials generated at the same site in a rapid sequence (**Figure 45.15B**).

Synapses can be fast or slow

Most neurotransmitter receptors induce changes in postsynaptic cells by opening or closing ion channels. How they do so is the basis for grouping receptors into two general categories:

- **Ionotropic receptors** are ion channels themselves. Neurotransmitter binding to an ionotropic receptor causes a direct

45.15 The Postsynaptic Neuron Sums Information Individual neurons sum excitatory and inhibitory postsynaptic potentials over space (A) and time (B). When the sum of the potentials depolarizes the axon hillock to threshold, the neuron generates an action potential.

at electrical synapses is very fast and can proceed in either direction, whereas transmission at chemical synapses is slower and unidirectional.

Electrical synapses are less common in the nervous systems of vertebrates than are chemical synapses for several reasons. First, electrical continuity between neurons does not allow temporal summation of synaptic inputs. Second, an effective electrical synapse requires a large area of contact between the presynaptic and postsynaptic cells. This condition rules out the possibility of thousands of synaptic inputs to a single neuron—which is the norm in complex nervous systems. Third, electrical synapses cannot be inhibitory. Thus, electrical synapses are useful for rapid

communication, but they are less useful for processes of integration and learning.

change in ion movement across the plasma membrane of the postsynaptic cell. These proteins enable fast, short-lived responses.

The ACh receptor of the motor end plate is an example of an ionotropic receptor. It consists of five subunits, each of which extends through the plasma membrane. When assembled, the subunits create a central pore that allows ions to pass through (see Figure 45.14). Of several different kinds of subunits, only one kind has the ability to bind ACh. Each functional receptor has two of the ACh-binding subunits and three other subunits.

- **Metabotropic receptors** are not ion channels, but they induce signaling cascades in the postsynaptic cell that secondarily lead to changes in ion channels (see Figure 7.10A). Postsynaptic cell responses mediated by metabotropic receptors are generally slower and longer-lived than those induced by ionotropic receptors.

Metabotropic receptors are also transmembrane proteins, but instead of acting as ion channels, they initiate an intracellular signaling process that can result in the opening or closing of an ion channel. An example is shown in Figure 7.19.

Electrical synapses are fast but do not integrate information well

Electrical synapses are different from chemical synapses because they couple neurons electrically. Electrical synapses contain numerous *gap junctions* (see Figure 7.21A). At these synapses, the presynaptic and postsynaptic cell membranes are separated by a space of only 2 to 3 nanometers, and membrane proteins called *connexons* link the two neurons by forming pores that connect the cytoplasm of the two cells. Ions and small molecules can pass directly from cell to cell through these pores. Transmission

The action of a neurotransmitter depends on the receptor to which it binds

More than 50 neurotransmitters are now recognized, and more will surely be discovered. ACh, as we have seen, is an important neurotransmitter because it is how the nervous system commands muscles to contract. ACh also plays roles in certain synapses between neurons in the CNS, but it accounts for only a small percentage of the total neurotransmitter content of the CNS.

The workhorse neurotransmitters of the CNS are simple amino acids: glutamate (excitatory) and glycine and γ -aminobutyrate (GABA) (inhibitory). Another important group of neurotransmitters in the CNS is the monoamines, which are derivatives of amino acids. They include dopamine and norepinephrine (derivatives of tyrosine) and serotonin (a derivative of tryptophan). Peptides also function as neurotransmitters; for example, *endorphins* and *enkephalins* are the body's opiates and modulate the sensation of pain. Another peptide, *substance P*, transmits pain sensations. Even a gas, nitric oxide, is used by neurons as an intercellular messenger (see Figure 7.17).

Neurotransmission is complex in part because each neurotransmitter has multiple receptor types. ACh, for example, has two receptor types: *nicotinic receptors*, which are ionotropic, and *muscarinic receptors*, which are metabotropic. Both types of ACh receptors are found in the CNS, where nicotinic receptors tend to be excitatory and muscarinic receptors tend to be inhibitory. ACh actions can differ outside the CNS as well. ACh acting through nicotinic receptors causes the smooth muscle of the gut to increase its motility, but ACh acting through muscarinic receptors causes cardiac muscle to hyperpolarize and therefore to slow down. We could give many more examples of neurotrans-

45.16 Two Ionotropic Glutamate Receptors (A) AMPA receptors allow rapid influx of Na⁺ into the postsynaptic cell. (B) NMDA receptors allow both Na⁺ and Ca²⁺ to enter the cell, but respond to synaptic input more slowly. Strong activation of the AMPA receptor leads to unblocking of the NMDA receptor, which results in longer-term effects on the cell because of Ca²⁺ entry.

the cell and can trigger a variety of cellular changes, such as activation of certain protein kinases.

Figure 45.16 shows how the AMPA and NMDA receptors can work in concert. At resting potential, the NMDA receptor is blocked by a magnesium ion (Mg²⁺). Strong depolarization of the neuron due to other inputs—such as the activation of AMPA receptors—displaces Mg²⁺ from the NMDA receptors and allows Na⁺ and Ca²⁺ to pass through them when they are activated by glutamate. These special properties of the NMDA receptor are probably involved in learning and memory.

mitters that have different effects in different tissues, but the important thing to remember is that the action of a neurotransmitter depends on the receptor to which it binds.

Glutamate receptors may be involved in learning and memory

Glutamate is a neurotransmitter that can bind to a variety of receptors, including both metabotropic and ionotropic receptors. The glutamate receptors are divided into several classes because they can be differentially activated by other chemicals that mimic the action of glutamate. One class of ionotropic glutamate receptors is the *NMDA receptors*, which can be activated by the chemical *N*-methyl-D-aspartate. Another class of ionotropic glutamate receptors is activated by a different chemical, abbreviated as *AMPA* (which stands for α -amino-3-hydroxy-5-methyl-4-isoxazole propionate, demonstrating why biologists are fond of abbreviations).

Glutamate is an excitatory neurotransmitter, so activation of ionotropic glutamate receptors always results in Na⁺ entry into the neuron and depolarization. But the *timing* of the response to activation by these different types of receptors differs significantly. The AMPA receptors allow a rapid influx of Na⁺ into the postsynaptic cell, whereas the NMDA receptors allow a slower and longer-lasting influx of Na⁺. The NMDA receptors require that the cell be somewhat depolarized through the action of other receptors before their pores will open and permit Na⁺ influx. When they do open, these receptors also allow Ca²⁺ as well as Na⁺ to enter the cell. Calcium ions act as second messengers in

have studied so far happen very quickly. It is therefore a special challenge to understand how the messages carried by action potentials can result in long-term events such as learning and memory. Our understanding of these processes has been greatly enhanced by investigation of a phenomenon called **long-term potentiation (LTP)**, which has been studied extensively by neurobiologists working with slices of brain kept alive in dishes of culture medium. Using these brain slice preparations, it is possible to stimulate and record from specific brain regions, and even specific neurons.

In the studies leading to the discovery of LTP, experimenters repeatedly stimulated synaptic inputs to a particular neuron and observed the usual action potential response. When the neuron was stimulated many times in rapid succession, however, they found that the properties of the neuron changed. The magnitude of the postsynaptic response was enhanced, or *potentiated*, and this change lasted for days or weeks.

How does potentiation of a synapse occur? The answer, at least for some areas of the brain, now seems clear. With low-frequency stimulation, the glutamate released by presynaptic cells activates only AMPA receptors, and the postsynaptic membrane simply responds with action potentials. With higher frequency stimulation, however, NMDA receptors are also activated, allowing both Na⁺ and Ca²⁺ ions to enter the postsynaptic neuron. The Ca²⁺ ions induce long-term changes in the postsynaptic membrane that make it more sensitive to synaptic input (**Figure 45.17**).

To turn off responses, synapses must be cleared of neurotransmitter

Turning off the action of neurotransmitters is as important as turning it on. If released neurotransmitter molecules simply re-

mained in the synaptic cleft, the postsynaptic membrane would become saturated with neurotransmitter, and receptors would be constantly activated. As a result, the postsynaptic cell would remain hyperpolarized or depolarized and would be unresponsive to short-term changes in the presynaptic cell. The more rapidly neurons can respond to input, the more information they can process in a given time. Thus, neurotransmitter must be cleared from the synaptic cleft shortly after it is released by the axon terminal.

Neurotransmitter action may be terminated in several ways. First, enzymes may destroy the neurotransmitter. ACh, for example, is rapidly destroyed by the enzyme acetylcholinesterase, which is present in the synaptic cleft in close association with the ACh receptors on the postsynaptic membrane (see Figure 45.14). Some of the most deadly nerve gases developed for chemical warfare work by inhibiting acetylcholinesterase. As a result, ACh lingers in the synaptic cleft, causing the victim to die of spastic (contracted) muscle paralysis. Some agricultural insecticides, such as malathion, also inhibit acetylcholinesterase and can poison farm workers if used without safety precautions.

Neurotransmitter also may simply diffuse away from the cleft, or be taken up via active transport by nearby cell membranes. The drug commonly prescribed under the brand name Prozac to treat depression slows the reuptake of the neurotransmitter serotonin, thus enhancing its activity at the synapse.

The diversity of receptors makes drug specificity possible

Many drugs used to treat the nervous system act by modulating specific synaptic interactions. Drugs that mimic or potentiate the effect of a neurotransmitter are called *agonists*; those that block the actions of neurotransmitters are called *antagonists*. For example, morphine is an agonist at the endorphin receptor and therefore blocks pain. Propranolol, known as a β -blocker, is an antagonist of certain adrenergic receptors and therefore decreases panic attacks and anxiety. A major emphasis in neurobiology is to identify neurotransmitter receptor subtypes and design drugs that selectively bind to them to have highly specific effects on nervous system activity.

INVESTIGATING LIFE

45.17 Repeated Stimulation Can Cause Long-Term Potentiation

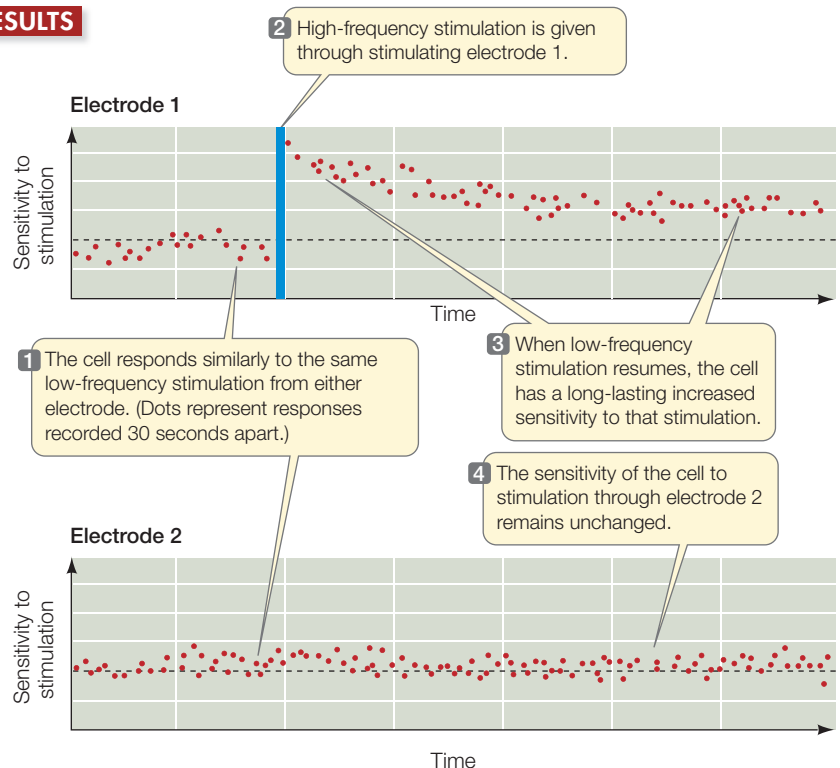

When a cell receives low-frequency synaptic input, the resulting postsynaptic response remains constant. If that same synaptic pathway is stimulated briefly at a high frequency, however, the subsequent sensitivity of the postsynaptic cell to the original level of synaptic input is potentiated for a longer period.

HYPOTHESIS Repeated stimulation can change the properties of a synapse.

METHOD Stimulate a cell through two separate input pathways (two sources of stimulus) and record responses.

RESULTS

CONCLUSION High-frequency stimulation of synapses can result in a long-lasting change in the sensitivity of these synapses (long-term potentiation, or synaptic memory).

45.3 RECAP

Chemical synapses involve the release of neurotransmitter molecules stored in vesicles in the presynaptic terminal. Action potentials reaching that terminal cause the fusion of vesicles with the presynaptic membrane, releasing neurotransmitter that can then bind to receptors on the postsynaptic membrane and influence its membrane potential. There is a great diversity of neurotransmitters and their receptors.

- Describe the role of Ca^{2+} channels in synaptic events. **See pp. 956–957 and Figure 45.13**
- How can some synapses be excitatory and others inhibitory? **See p. 958**
- How do neurons integrate the input from various synapses? **See p. 958 and Figure 45.15**

CHAPTER SUMMARY

45.1 What Cells Are Unique to the Nervous System?

- Nervous systems include **neurons** and **glia**. Neurons are organized in circuits with sensory inputs, integration, and outputs to effectors. Glia serve support functions. **Review Figures 45.1 and 45.3**
- In vertebrates, the **brain** and **spinal cord** form the **central nervous system (CNS)**, which communicates with the rest of the body via the **peripheral nervous system (PNS)**. The CNS increases in complexity from invertebrates to vertebrates and from fishes to mammals. **Review Figures 45.1 and 45.2**
- Neurons generally receive information via their **dendrites**, of which there can be many, and transmit information via their single **axons**, which end in **axon terminals**. **Review Figure 45.3**
- Where neurons and their target cells meet, information is transmitted across specialized junctions called **synapses**.
- Glia include **Schwann cells** and **oligodendrocytes**, both of which generate **myelin** sheets on axons. Glia also include **astrocytes**, which support neurons metabolically and contribute to the **blood–brain barrier**. **Review Figure 45.4**

45.2 How Do Neurons Generate and Transmit Electrical Signals?

SEE ANIMATED TUTORIAL 45.1

- Neurons have an electric charge difference across their plasma membranes, the **membrane potential**. The membrane potential is created by ion transporters and channels. When a neuron is not active, its membrane potential is a **resting potential**. **Review Figures 45.5 and 45.6**
- The **sodium–potassium pump** concentrates K^+ on the inside of a neuron and Na^+ on the outside. Potassium channels allow K^+ to diffuse out of the neuron, leaving behind unbalanced negative charges. **Review Figures 45.6 and 45.7**
- **Patch clamping** allows the study of single ion channels. **Review Figure 45.8**
- The resting potential is perturbed when ion channels open or close, changing the permeability of the plasma membrane to charged ions. Through this mechanism, the plasma membrane can become **depolarized** or **hyperpolarized** and therefore have a **graded membrane potential** response to input. **Review Figure 45.9**
- An **action potential** is a rapid reversal in charge across a portion of the plasma membrane resulting from the sequential opening

and closing of **voltage-gated channels** of Na^+ and K^+ . These changes in voltage-gated channels occur when the plasma membrane depolarizes to a **threshold** level. **Review Figure 45.10, ANIMATED TUTORIAL 45.2**

- Action potentials are all-or-none, self-regenerating events. They are conducted down axons because local current flow depolarizes adjacent regions of membrane and brings them to threshold. **Review Figure 45.11**
- In myelinated axons, action potentials appear to jump between **nodes of Ranvier**, patches of axonal plasma membrane that are not covered by myelin. **Review Figure 45.12**

45.3 How Do Neurons Communicate with Other Cells?

- Neurons communicate with each other and with other cells by transmitting information over **chemical synapses** (with neurotransmitters) or **electrical synapses**.
- The neuromuscular junction is a well-studied chemical synapse between a motor neuron and a skeletal muscle cell. Its neurotransmitter is **acetylcholine (ACh)**, which causes depolarization of the postsynaptic membrane when it binds to its receptor. **Review Figure 45.13, ANIMATED TUTORIAL 45.3**
- When an action potential reaches an axon terminal, it causes the release of neurotransmitters, which diffuse across the **synaptic cleft** and bind to receptors on the postsynaptic membrane. **Review Figures 45.13 and 45.14**
- Synapses between neurons can be either **excitatory** or **inhibitory**. A postsynaptic neuron integrates information by summing excitatory and inhibitory postsynaptic potentials in both space and time. **Review Figure 45.15**
- **Ionotropic receptors** are ion channels or directly influence ion channels. **Metabotropic receptors** influence the postsynaptic cell through various signal transduction pathways and result in the opening or closing of ion channels. The actions of ionotropic synapses are generally faster than those of metabotropic synapses.
- There are many different neurotransmitters and even more types of receptors. The action of a neurotransmitter depends on the receptor to which it binds. **SEE WEB ACTIVITY 45.1**
- With repeated stimulation, a neuron can become more sensitive to its inputs through **long-term potentiation (LTP)**. The properties of the NMDA glutamate receptor appear to explain LTP. **Review Figures 45.16 and 45.17**

SELF-QUIZ

- The rising phase of an action potential is due to the
 - closing of K^+ channels.
 - opening of chemically gated Na^+ channels.
 - closing of voltage-gated Ca^{2+} channels.
 - opening of voltage-gated Na^+ channels.
 - spread of positive current along the plasma membrane.
- The resting potential of a neuron is due mostly to
 - local current spread.
 - open Na^+ channels.
 - synaptic summation.
 - open K^+ channels.
 - open Cl^- channels.
- Which statement about synaptic transmission is *not* true?
 - The synapses between neurons and skeletal muscle cells use ACh as their neurotransmitter.
 - A single vesicle of neurotransmitter can cause a muscle cell to contract.
 - The release of neurotransmitter at the neuromuscular junction causes the motor end plate to depolarize.
 - In vertebrates, the synapses between motor neurons and muscle fibers are always excitatory.
 - Inhibitory synapses cause the resting potential of the postsynaptic membrane to become more negative.
- Which statement accurately describes an action potential?
 - Its magnitude increases along the axon.
 - Its magnitude decreases along the axon.
 - All action potentials in a single neuron are of the same magnitude.
 - During an action potential, the membrane potential of a neuron remains constant.
 - An action potential permanently shifts a neuron's membrane potential away from its resting value.
- A neuron that has just fired an action potential cannot be immediately restimulated to fire a second action potential. The short interval of time during which restimulation is not possible is called
 - hyperpolarization.
 - the resting potential.
 - depolarization.
 - repolarization.
 - the refractory period.
- Graded membrane potentials
 - can be more negative than resting potential.
 - can be less negative than resting potentials.
 - integrate the many synaptic inputs to a cell.
 - are important means of summing sensory inputs.
 - are all of the above.
- The binding of an inhibitory neurotransmitter to the postsynaptic receptors results in
 - depolarization of the membrane.
 - generation of an action potential.
 - hyperpolarization of the membrane.
 - increased permeability of the membrane to sodium ions.
 - increased permeability of the membrane to calcium ions.
- The difference between slow and fast synapses is
 - the width of the synaptic cleft.
 - the size of the synapse.
 - whether or not the neurotransmitter acts directly on ion channels.
 - the density of receptors on the postsynaptic membrane.
 - the amount of neurotransmitter that is released.
- Whether a synapse is excitatory or inhibitory depends on the
 - type of neurotransmitter.
 - presynaptic axon terminal.
 - size of the synapse.
 - nature of the postsynaptic receptors.
 - concentration of neurotransmitter in the synaptic space.
- Which of the following is a likely mechanism for long-term potentiation?
 - When glutamate binds to postsynaptic AMPA receptors, it activates intracellular changes.
 - When glutamate binds to NMDA receptors, it allows magnesium ions to enter the cell, which initiate intracellular changes.
 - When sufficient glutamate is released by the presynaptic neuron, it dislodges Mg^{2+} from the AMPA receptors and allows Ca^{2+} to leave the cell.
 - When sufficient glutamate is released, both AMPA and NMDA receptors are activated, and NMDA receptors allow Ca^{2+} as well as Na^+ to enter the cell, thus initiating intracellular changes.
 - When both glutamate and ACh are released together, they create a long-lasting depolarization of the postsynaptic cell.

FOR DISCUSSION

- The language of the nervous system consists of one "word," the action potential. How can this single message convey a diversity of information, how can that information be quantitative, and how can it be integrated?
- If you stimulate an axon in the middle, action potentials are conducted in both directions. Yet when an action potential is generated at the axon hillock, it goes only toward the axon terminals and does not backtrack. Explain why action potentials are bidirectional in the first example and unidirectional in the second.
- The nature of synapses presents various opportunities for plasticity in the nervous system. Discuss at least four synaptic mechanisms that could be altered to change the response of a neuron to a specific input.
- Benzodiazepines are drugs that potentiate the effects of GABA on its receptor. What effects would you expect these drugs to have?

ADDITIONAL INVESTIGATION

The patch clamping technique shown in Figure 45.8 produces an "inside-out" patch because the cytoplasmic side of the membrane faces away from the pipette tip and the surface side of the membrane is exposed to the solution in the pipette. Another patch preparation is the "outside-out" patch in which the cyto-

plasmic side of the membrane is exposed to the solution in the pipette. Describe what kind of experiments you could conduct with the "inside-out" patch and what kind you could conduct with the "outside-out" patch.

46

Sensory Systems

Out of range

A rattlesnake can see to strike and kill a running rodent in complete darkness. How can this be, when “seeing” means using the eyes to detect light, and “complete darkness” means the absence of any light? It is possible because these definitions are based on human capabilities. What we call “light” is actually only a small portion (red, orange, yellow, green, blue, indigo, and violet) of the spectrum of electromagnetic radiation. Other animals see wavelengths we cannot. Insects and birds see patterns on flowers that reflect ultraviolet wavelengths invisible to us. Similarly, rattlesnakes can “see” infrared wavelengths that are invisible to us (although at high enough levels of intensity, humans feel these wavelengths as heat).

It is not the snake’s eyes that perceive infrared wavelengths. Rattlesnakes and their relatives have *pit organs*

containing high densities of infrared-sensitive neurons. The two pits, located between the nostrils and the eyes on each side of the skull, are positioned in such a way that sensory receptor cells in the pits receive directional information. The fields of “view” of the bilateral pits are overlapping and thus convey a three-dimensional perspective. Information from the pit organs goes to the same region of the brain as information from the eyes, so rattlesnakes actually do “see” the world in a range of electromagnetic radiation that is different from the human visual spectrum.

Our definition of silence is as arbitrary as our definition of darkness. “Sound” is actually pressure waves in the environment, and many animals are sensitive to pressure waves with frequencies (*itches*) we cannot hear. Elephants communicate in sound waves that are below human hearing range; such long waves travel great dis-

tances, an advantage to large animals that roam over extensive areas.

Bats emit incredibly loud, brief sound pulses, the frequencies of which are above our range of hearing, and a flying bat hears echoes of these pulses bouncing off objects in the environment. The pulses are so loud and the echoes so weak that it is rather like a construction worker trying to overhear

Sensing Infrared Radiation The “hole” to the right of this diamondback rattlesnake’s eye is one of its bilateral pit organs. Pit organs detect infrared radiation from the snake’s preferred prey—small rodents—with unerring precision, even in total darkness. The forked tongue also provides positional information, picking up molecular signals that are transmitted to the brain by a specialized organ in the roof of the snake’s mouth.

Echolocating around an Obstacle Course A bat's ability to echolocate using sound waves is so precise that, in a totally dark room strung with fine wires, bats can capture small insects while avoiding the wires.

a whispered conversation while using a pneumatic drill. Why don't the loud pulses "drown out" the weak echoes for the bat? Small muscles in the bat's ears contract to dampen their hearing sensitivity while the sounds are being emitted, but relax in time for the bat to hear the echo—a truly remarkable ability, since the pulses are emitted at rates of 20 to 80 per second.

Our senses are our windows on the world. "Reality" is what our eyes see, our ears hear, our noses smell, and what we touch and taste. But human beings sense only a limited range of the information available. Animals with different ranges of sensitivity process different sources of information and may perceive "reality" quite differently.

IN THIS CHAPTER we will examine how sensory receptor cells convert environmental stimuli into the electrochemical signals of nervous systems. We will examine in detail the diversity of cells responsible for our senses and see how they are incorporated into sensory systems that provide the central nervous system with information about the world around and within us. We will also learn about the unusual sensory abilities of other animals.

CHAPTER OUTLINE

- 46.1** How Do Sensory Cells Convert Stimuli into Action Potentials?
- 46.2** How Do Sensory Systems Detect Chemical Stimuli?
- 46.3** How Do Sensory Systems Detect Mechanical Forces?
- 46.4** How Do Sensory Systems Detect Light?

46.1 How Do Sensory Cells Convert Stimuli into Action Potentials?

Sensory receptor cells, sometimes simply called *sensors* or *receptors*, transduce (convert) physical and chemical stimuli such as light and sound waves, touch, and odorant and taste molecules into neural signals. These signals are then transmitted to the central nervous system for processing and interpretation. We will examine several sensory systems. In each case, we ask the same general question: How do sensory receptor cells transduce energy from a stimulus into a change in membrane potential?

Sensory receptor proteins act on ion channels

As discussed in Section 45.2, cells use energy to create gradients of charged ions across their plasma membranes. In this way, cells are like batteries: batteries store potential energy by separating electrical charges between their poles, and cells store potential energy in the ionic gradients across their plasma membranes. If the two poles of a battery are connected by a wire and a switch, current flows through the wire when the switch is closed. Ion channels are like switches. When they open, charged ions can flow down their electrochemical gradient. When the ion channel is selective for one type of ion, the flow of that charged ion creates a change in the electrical potential across the membrane.

Sensory transduction begins with a **receptor protein** or some other mechanism in a sensory cell that can detect a specific stimulus modality such as heat, light, chemicals, mechanical force (including sound waves), or electrical fields. The receptor protein then directly or indirectly opens or closes ion channels in that sensory cell, leading either to an action potential or to the release of neurotransmitter.

Section 45.3 notes that synaptic receptor proteins are either *ionotropic* or *metabotropic*; the same distinction can be applied to sensory receptor proteins. Ionotropic sensory receptor proteins are either ion channels themselves or directly affect the opening of an ion channel. Examples are receptors that respond to physical force (*mechanoreceptors*) and those that respond to temperature (*thermoreceptors*). *Electrosensors* most likely have no receptor protein at all, but they are grouped with the ionotropic receptors; the plasma membrane of electrosensory cells is sensitive to the voltage across it and releases neurotransmitter in response to slight changes in membrane potential. Metabotropic sensory receptor proteins influence ion channels indirectly, through G proteins and second messengers as described in Chapter 7. Examples are most *chemoreceptors* and *photoreceptors* (**Figure 46.1**).

46.1 Sensory Cell Membrane Receptor Proteins Respond to Stimuli

The receptor proteins in mechanoreceptors are ion channels. The activated receptor proteins of metabotropic chemoreceptors and photoreceptors initiate signal transduction cascades that eventually open or close ion channels.

Sensory transduction involves changes in membrane potentials

A change in the resting membrane potential of a sensory receptor cell in response to a stimulus is called a **receptor potential**. Receptor potentials are graded membrane potentials that spread over only short distances. To travel long distances in the nervous system, receptor potentials must generate action potentials, which they can do in two ways:

- The receptor potential may generate action potentials within the receptor cell itself.
- The receptor potential may trigger the release of a neurotransmitter that induces a postsynaptic neuron to generate action potentials.

A good example of a sensory receptor cell that can generate action potentials is the stretch receptor of a crayfish (**Figure 46.2**). By placing an electrode in the cell body of a crayfish stretch receptor, we can record the receptor potential that results from stretching the muscle to which the cell's dendrites are attached. These receptor potentials spread to the base of the cell's axon (the axon hillock), which contains voltage-gated Na^+ channels. Action potentials generated here travel down the axon to the central nervous system (CNS). The rate at which action potentials are fired by the axon depends on the magnitude of the

receptor potential; that, in turn, depends on how much the muscle is stretched.

In a receptor cell that does not fire action potentials, the spreading receptor potential reaches a presynaptic patch of plasma membrane and induces the release of a neurotransmitter. The intensity of the stimulus influences how much neurotransmitter is released. That neurotransmitter binds to receptor proteins on an associated sensory neuron, altering its membrane

46.2 Stimulating a Sensory Cell Produces a Receptor Potential

Signal transduction in the stretch receptor of a crayfish can be investigated by measuring the membrane potential at different places on the stretch receptor neuron while stretching the muscle innervated by that sensory neuron.

potential and causing it to increase or decrease its rate of firing action potentials. In a few cases, this second cell also responds by changing the rate at which it releases neurotransmitter onto another neuron. Eventually, however, the stimulation of the sensory cell is coded as a change in firing of action potentials in a sensory circuit.

Sensation depends on which neurons receive action potentials from sensory cells

All sensory systems process information in the form of action potentials. But the sensations we perceive—such as heat, pressure, light, smell, and sound—differ because the messages from different kinds of sensory cells arrive at different places in the CNS. Action potentials arriving in the visual cortex of the brain are interpreted as light, in the auditory cortex as sound, in the olfactory bulb as smell, and so forth.

A small patch of skin on your arm contains some sensory receptor cells that increase their firing rates when the skin is warmed and others that increase their activity when the skin is cooled. Other types of sensory cells in the same patch of skin respond to touch, movement of hairs, irritants such as mosquito bites, and painful stimuli. These receptor cells transmit their messages through axons that enter the CNS at the spinal cord. The synapses made by those axons in the spinal cord and the subsequent pathways of transmission determine whether the stimulation of the patch of skin on your arm is perceived as warmth, cold, touch, tickle, itch, or pain. So even though the action potentials carried by all of these sensory axons look the same, the connectivity of each axon is specific for a given sensory modality.

How is the intensity of the stimulus encoded if, as Section 45.2 describes, each action potential is an all-or-none event? Intensity of sensation is coded as the frequency of the action potentials.

Some sensory cells transmit information about internal conditions in the body, but we may not be consciously aware of that information. The brain continuously receives information about body temperature, blood carbon dioxide and oxygen concentrations, arterial pressure, muscle tension, and the positions of the limbs—all of which are important for homeostasis. All sensory cells produce information that the nervous system can use, but that information does not always result in conscious sensation.

Some sensory receptor cells are assembled with other types of cells into *sensory organs*, such as eyes, ears, and noses, that enhance the ability of the sensory cells to collect, filter, and amplify stimuli. We therefore refer to **sensory systems**, which include the sensory cells, the associated structures, and the neural networks that process the information.

Many receptors adapt to repeated stimulation

Some sensory cells give gradually diminishing responses to maintained or repeated stimulation. This phenomenon is known as **adaptation**, and it enables an animal to ignore background or unchanging conditions while remaining sensitive to changes or to new information. (Note that this use of the term

“adaptation” is different from its application in an evolutionary context.) When you dress, you feel each item of clothing touch your skin, but the sensation of clothes touching your skin is not constantly on your mind throughout the day. You are immediately aware, however, when a seam rips, your shoe comes untied, or someone touches your back.

Animals can discriminate between continuous and changing stimuli partly because some sensory cells adapt; it is also a result of information processing by the CNS. Some sensory cells adapt very little or very slowly; examples are some types of pain receptors and the mechanoreceptors for balance. You do not want to ignore pain that is signaling that something is wrong in your body, and to maintain equilibrium you must continuously know the tensions and forces on all of your joints and muscles.

46.1 RECAP

Sensory receptor cells have receptor proteins that respond to specific stimuli from the external or internal environment by opening or closing ion channels, which results in the generation of action potentials in sensory neurons.

- Explain the difference between ionotropic and metabotropic sensory receptor proteins. **See p. 965 and Figure 46.1**
- How are we able to perceive action potentials—which are all essentially the same—as different sensations? **See p. 967**

Now that we have a general view of how sensory systems code and process information, we will discuss how sensory systems gather and filter stimuli, transduce specific stimuli into action potentials, and transmit action potentials to the central nervous system. We will look in more depth at specific sensory modalities, beginning with chemosensation, the basis of smell and taste.

46.2 How Do Sensory Systems Detect Chemical Stimuli?

A colony of corals responds to a small amount of meat extract in seawater by extending bodies and tentacles and searching for food; a solution of a single amino acid can stimulate this response. Conversely, a small amount of seawater in which corals were crushed will stimulate a defensive retraction of the coral polyps. Humans also react strongly to certain chemical stimuli. When we smell freshly baked bread, we salivate and feel hungry; when we smell rotting meat, we feel nauseated.

All animals receive information about chemical stimuli through **chemoreceptors**, which are receptor proteins that bind to various molecules — their *ligands*—and are responsible for smell and taste. Chemoreceptors are also responsible for monitoring aspects of the internal environment such as the level of carbon dioxide in the blood. Information from chemore-

ceptors can cause powerful physiological and behavioral responses during activities such as feeding, mating, fighting, and recognizing individuals.

Arthropods are good models for studying chemoreception

A chemical signal used in communication among members of a species is a **pheromone**. Arthropods use pheromones to attract mates. These signals demonstrate the sensitivity of chemosensory systems, and one of the best-studied examples is that of the silkworm moth *Bombyx mori*.

To attract a mate, the female silkworm moth releases a pheromone called *bombykol* from a gland at the tip of her abdomen. The male silkworm moth has receptors for this molecule on his antennae (Figure 46.3). Each feathery antenna carries about 10,000 bombykol-sensitive hairs. A single molecule of bombykol may be sufficient to generate action potentials in the antennal nerve that transmits the signal to the CNS. Because of the male's great sensitivity, the sexual message of a female moth is likely to reach any male within a huge downwind area. When approximately 200 hairs per second are activated, the male orients upwind in search of the female. Because the rate of firing in the male's sensory nerves is proportional to the bombykol concentration in the air, he can follow the airborne concentration gradient and home in on the signaling female.

Olfaction is the sense of smell

The sense of smell, **olfaction**, depends on chemoreceptors. In vertebrates, the olfactory sensors are neurons embedded in a layer of epithelial tissue at the top of the nasal cavity. The axons from these neurons extend to the olfactory integration area of the brain (the olfactory bulb), whereas their dendrites end in ol-

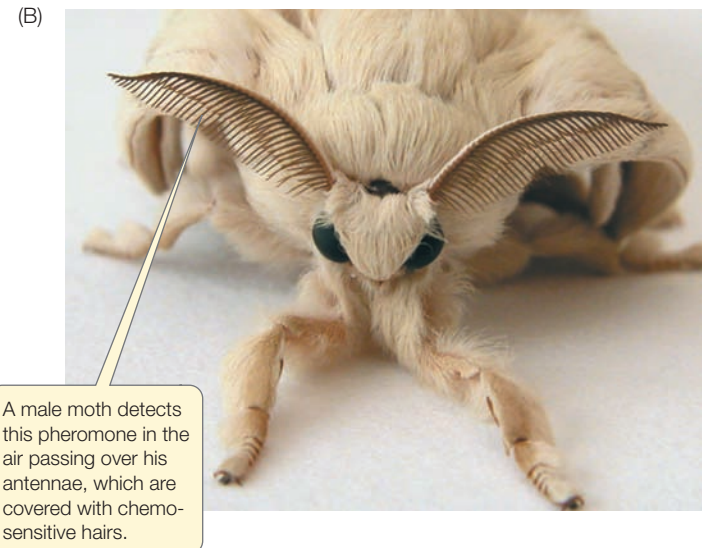

factory cilia on the surface of the nasal epithelium. A protective layer of mucus covers the epithelium. Molecules from the environment must diffuse through this mucus to reach the receptor proteins on the olfactory cilia. When you have a cold, the amount of mucus in your nose increases, and the epithelium swells. With this in mind, study Figure 46.4, and you will easily understand why respiratory infections can cause you to lose your sense of smell.

Humans have a sensitive olfactory system, but we are unusual among mammals in that we depend more on vision than on olfaction. A typical dog's nasal epithelium is 15 to 20 times larger than a human's and has around 1 billion receptors, compared with around 20 million in humans. For some scents, the threshold sensitivity of the dog is 100 million times lower. A dog's nose reveals a huge amount of information not available to us.

An **odorant** is a molecule that activates an olfactory receptor protein. Odorants bind to receptor proteins on the olfactory cilia of the olfactory neurons. Olfactory receptor proteins are specific for particular odorant molecules. When an odorant molecule binds to its receptor on an olfactory neuron, it activates a G protein. The G protein in turn activates an enzyme that causes an increase of a second messenger (cAMP in vertebrates) in the cytoplasm (see Figure 7.19). The second messenger binds to cation channels in the sensory cell's plasma membrane and opens them, causing an influx of Na^+ . The sensory neuron depolarizes to threshold and fires action potentials.

The olfactory world has an enormous number of odors, and accordingly, there are a large number of olfactory receptor proteins. In the 1990s, Linda Buck and Richard Axel discovered in mice a family of about 1,000 genes (about 3 percent of the genome) that code for olfactory receptor proteins. Humans have about one-third that number of functional olfactory receptor genes. Each receptor protein that is expressed is found in a limited number of receptor cells in the olfactory epithelium, and each cell expresses just one receptor type. Using a combination of patch clamping (see Figure 45.8) and molecular techniques, the investigators were able to match specific gene prod-

46.3 Some Scents Travel Great Distances Mating in silkworm moths of the genus *Bombyx* is coordinated by a pheromone called bombykol.

46.4 Olfactory Receptors Communicate Directly with the Brain The receptor cells of the human olfactory system are embedded in epithelial tissues lining the nasal cavity and send their axons to the olfactory bulb of the brain.

ucts with the odorants they detect. For their discoveries of the molecular nature of the olfactory system, Buck and Axel received the Nobel prize in 2004.

Olfactory sensitivity enables discrimination of many more odorants than there are olfactory receptors. An odorant molecule can be quite complex, and different regions of that molecule may bind to different receptor proteins. The next stage of processing olfactory information is in the olfactory bulb, where axons from neurons expressing the same receptor protein cluster together on olfactory bulb neurons, forming structures called *glomeruli* (see Figure 46.4). Therefore, a complex odorant molecule can activate a unique combination of glomeruli in the olfactory bulb, so an olfactory system with hundreds of different receptor proteins can discriminate an astronomically large number of smells. How does the olfactory receptor cell signal the intensity of a smell? The more odorant molecules that bind to receptors, the greater the frequency of action potentials and the greater the intensity of the perceived smell.

In vertebrates, odorants and other chemoreceptor molecules can stimulate strong responses. Many vertebrate species have separate olfactory epithelia that are dedicated to the detection of pheromones.

The vomeronasal organ contains chemoreceptors

The **vomeronasal organ (VNO)** is a small, paired tubular structure embedded in the nasal epithelium of amphibians, reptiles, and many mammals (although probably not humans). In mammals, the VNO is located on the septum dividing the two nostrils (see Figure 53.5).

The vomeronasal organ has a pore that opens into the nasal cavity. When the animal sniffs, the VNO pulsates and draws a sample of nasal fluid over the chemoreceptors embedded in its walls. The information from these chemoreceptors goes to an accessory olfactory bulb in the brain, and information from there goes to brain regions involved in sexual and other instinctive behaviors.

In snakes, the VNO opens into the roof of the mouth cavity. Each time the snake's forked tongue darts in and out, the forks fit into the VNO openings and present the chemoreceptors located there with a sample of molecules from the surrounding air (see the chapter-opening photo). Thus the snake uses its

tongue to smell its environment, not to taste it. Why doesn't the snake simply use the flow of air to and from its lungs, as we do, to smell the environment? In reptiles, air flows to and from the lungs slowly (and can even stop entirely for long periods of time), but the tongue can dart in and out many times in a second. It is a quick source of olfactory information.

Studies on mice have led to the hypothesis that the mammalian VNO is a specialized olfactory organ that detects pheromones. Lawrence Katz and his colleagues at Duke University recorded the activity of neurons in the mouse accessory olfactory bulb, which receives input from chemosensors in the VNO. These accessory olfactory neurons were activated when a mouse attached to recording electrodes sniffed another mouse placed in the same cage. However, the neurons fired differentially, depending on the gender and strain of the "intruder" mouse. Other studies on mouse behavior have supported a role for the VNO in gender identification and sexual behaviors that are linked to pheromone perception (see Section 53.2).

Gustation is the sense of taste

The sense of taste, or **gustation**, in humans and other vertebrates depends on clusters of chemoreceptors called **taste buds**. The taste buds of terrestrial vertebrates are confined to the mouth cavity, but some fishes have taste buds in the skin that enhance their ability to sense their environment. Some fishes living in murky water are very sensitive to small amounts of amino acids in the water around them and can find food without the use of vision. The duck-billed platypus, a prototherian mammal (see Figure 33.24), has similar talents as a result of taste buds on the sensitive skin of its bill.

A human tongue has approximately 10,000 taste buds. The taste buds are embedded in the epithelium, and most are found on the papillae (**Figure 46.5**). (Look at your tongue in a mirror—the papillae make it look fuzzy.) Each papilla has many taste

buds, mostly on the sides. The outer surface of a taste bud has a pore that exposes the tips of the sensory receptor cells. Microvilli (tiny hairlike projections) increase the surface area of these cells where their tips converge at the pore. These sensory cells generate action potentials and release neurotransmitter at their bases, where they form synapses with sensory neurons that convey the signals into the central nervous system.

The tongue does a lot of hard work, so its epithelium, along with cells of its taste buds, are shed and replaced at a rapid rate. Individual taste bud cells last about 10 days before they are replaced, but the sensory neurons associated with them live on, always forming new synapses as new taste buds form.

You may have heard that humans can perceive only four tastes: sweet, salty, sour, and bitter. However, taste buds can distinguish among a variety of sweet-tasting molecules and a variety of bitter-tasting molecules. Recently, small families of genes for receptor proteins responding to sweet and bitter tastes have been discovered. In addition, we now recognize a fifth taste, *umami*, which is a savory, meaty taste that originates from receptors for amino acids, including monosodium glutamate (MSG). The full complexity of the chemosensitivity that enables us to enjoy the subtle flavors of food comes from the combined activation of gustatory and olfactory receptors, which is why you lose much of your sense of taste when you have a cold.

Gustation begins with receptor proteins in the membranes of the microvilli of the taste bud sensory cells (see Figure 46.5). The nature of these proteins and the mechanisms by which they depolarize the sensory receptor cell differ for the different basic tastes. Saltiness receptors are ionotropic and simply respond to Na^+ diffusing through open Na^+ channels depolarizing the sensory cell. Sourness receptors are also probably ionotropic. Depolarization of these receptors is similarly due to a direct

effect of H^+ ions on Na^+ channels. In contrast, sweetness and bitterness involve families of receptor proteins similar to those involved in olfaction, and they are metabotropic. The bitter taste probably evolved as a protective mechanism enabling animals to detect and avoid toxic plant compounds such as quinine, caffeine, and nicotine. Since plants have evolved many such molecules to repel herbivorous predators, a variety of receptors is essential. Similarly, a large number of molecules in food could indicate nutritional value, so a variety of receptors is of value. The diversity of sweet receptors helps explain why it has been possible to invent many different artificial sweeteners.

Regardless of the mechanism of taste transduction by the sensory cells of the taste buds, all these cells release neurotransmitter onto sensory neurons. These neurons then conduct that information to the CNS, where it is interpreted as specific taste sensations.

46.2 RECAP

All animals receive information about chemical stimuli through chemoreceptors, which have diverse structures and bind to a tremendous variety of stimulus molecules. Chemoreceptors are the basis of the sensations of olfaction and gustation and the reception of pheromones. They also monitor some aspects of an animal's internal environment.

- Why are we able to distinguish so many different smells? Why do some people and some animals experience more or different odors than others?
See pp. 968–969 and Figure 46.4
- Describe how different substances in food are transduced into action potentials in taste buds.
See pp. 969–970 and Figure 46.5

46.3 How Do Sensory Systems Detect Mechanical Forces?

Let's turn now to **mechanoreceptors**, the sensory cells that respond to mechanical forces. Physical distortion of a mechanoreceptor's plasma membrane causes ion channels to open, altering the membrane potential of the cell to create a graded potential, which in turn leads to the release of neurotransmitter or the generation of action potentials. The rate of action potentials tells the CNS the strength of the stimulus to the mechanoreceptor. A considerable diversity of mechanosensory cells and mechanisms has evolved. Involved in many sensory systems, their functions range from interpreting skin sensations to sensing blood pressure to hearing and maintaining balance.

Many different cells respond to touch and pressure

Human skin (and that of other mammals) is packed with diverse mechanoreceptors that generate varied sensations (**Figure 46.6**). The most important tactile receptors, found in both hairy and nonhairy skin, are *Merkel's discs*, which adapt rather

46.6 The Skin Feels Many Sensations Even a very small patch of skin contains a variety of sensory cells, making the skin a multi-modal receptor that can sense temperature, pressure, texture, pain, touch, and itch.

slowly and provide continuous information about things touching the skin. *Meissner's corpuscles*, found primarily in nonhairly skin, are very sensitive but adapt rapidly, so they provide information about *changes* in things touching the skin. The rapid adaptation of Meissner's corpuscles is why you roll a small object between your fingers (rather than holding it still) to discern its shape and texture: as you roll it, the object continues to stimulate Meissner's corpuscles.

Two other kinds of mechanoreceptors are found deeper in the skin. *Ruffini endings* adapt slowly and are good at providing information about vibrating stimuli of low frequencies. *Pacinian corpuscles*, which adapt rapidly, provide information about vibrating stimuli of higher frequencies. Even deeper in the skin, dendrites of sensory neurons wrap around hair follicles. When the surface hairs are displaced, those neurons are stimulated.

46.7 Stretch Receptors Stretch receptors provide information about the stresses on muscles and joints in an animal's limbs. (A) Signals from muscle spindles to the CNS initiate muscle contraction. (B) Golgi tendon organs in tendons and ligaments inhibit a contraction that becomes too forceful, triggering a reduction in muscle tension and protecting the muscle from tearing.

A *two-point spatial discrimination test* reveals that the density of tactile mechanoreceptor cells varies across the body's surface. By touching someone's skin with two toothpicks simultaneously, you can determine how far apart two stimuli have to be before the person can tell whether the sensations are produced by one toothpick or by two. On the back, the stimuli have to be relatively far apart before they are perceived as two discrete stimuli. But when the same test is applied to the person's lips or fingertips, the person can identify as separate two stimuli that are quite close together, meaning receptor density is much greater in these regions.

Mechanoreceptors are found in muscles, tendons, and ligaments

An animal receives information from mechanoreceptors about the position of its limbs and the stresses on its muscles and joints. These mechanoreceptors supply information continuously to the CNS, and this information is essential for postural control and the coordination of movements.

The mechanoreceptors found in skeletal muscle are called *muscle spindles*. These are **stretch receptors**, modified muscle cells that are embedded in connective tissue in muscles and innervated by sensory neurons (**Figure 46.7**). Whenever the muscle is stretched, muscle spindles are also stretched, and the neurons

transmit action potentials to the central nervous system. The CNS uses this information to adjust the strength of the muscle contraction to match the load put on the muscle. Thus a bartender can hold a beer mug in the same position as he fills it from the tap, as seen in Figure 46.7A. In Figure 46.2, we saw how crayfish stretch receptors transduce physical force into action potentials. The actions of muscle spindles are similar.

Another type of mechanoreceptor, the *Golgi tendon organ*, is found in tendons and ligaments and provides information about the force generated by a contracting muscle (see Figure 46.7B). When a contraction becomes too forceful, action potentials from the Golgi tendon organ inhibit the spinal cord motor neurons innervating that muscle, causing it to relax and protecting it from tearing. (You may recall a cell organelle called the Golgi apparatus. What these two cellular structures have in common is their discovery by the Italian anatomist Camillo Golgi, who received a Nobel prize in 1906.)

Auditory systems use hair cells to sense sound waves

The stimuli that animals perceive as sounds are pressure waves. **Auditory systems** use mechanoreceptors to convert pressure waves into receptor potentials. Auditory systems include special structures that gather sound waves, direct them to the sensory organ, and amplify their effect on the mechanoreceptors.

Human hearing provides a good example of an auditory system. The organs of hearing are the ears. The two prominent structures on the sides of our heads are the *pinnae*. The pinna of an ear collects sound waves and directs them into the *auditory canal*, which leads to the actual hearing apparatus in the *middle ear* and the *inner ear* (Figure 46.8A). If you have ever watched a cat or dog change the orientation of its ears to focus on a particular sound, then you have witnessed the role of pinnae in hearing.

46.8 Structures of the Human Ear (A) The pinnae direct sound waves down the auditory canal to impinge on the tympanic membrane. The tympanic membrane mechanically transmits these pressure waves into movements of the ossicles in the middle ear. (B) The ossicles transmit their movement into pressure waves in the fluid of the cochlea at the oval window. (C) The cochlea is divided into fluid-filled chambers; pressure waves from the ossicles cause the membranes between the chambers to flex. (D) Flexing of the basilar membrane bends stereocilia on hair cells in the organ of Corti.

yourBioPortal.com

GO TO Web Activity 46.1 • Structures of the Human Ear

The eardrum, or **tympanic membrane**, covers the end of the auditory canal. The tympanic membrane vibrates in response to pressure waves traveling down the auditory canal. The middle ear, an air-filled cavity, lies on the other side of the tympanic membrane.

MIDDLE EAR The middle ear is open to the throat at the back of the mouth through the *eustachian tube*. Because the eustachian tube is also filled with air, pressure equilibrates between the middle ear and the outside world. When you have a cold or allergy, the tube can become blocked by mucus or by tissue swelling, so you have difficulty “clearing your ears,” or equilibrating the pressure in the middle ear with the outside air pressure, which you have to do when ascending or descending in a plane or when scuba diving.

The middle ear contains three delicate bones called the **ossicles**, individually named the *malleus* (Latin, “hammer”), *incus* (“anvil”), and *stapes* (“stirrup”) (**Figure 46.8B**). The ossicles transmit the vibrations of the tympanic membrane to another flexible membrane called the **oval window**. The ossicles act as a lever—like a hammer pulling out a nail—translating a large movement of the tympanic membrane into a smaller movement of the oval window, but a movement of greater force. Also, because the oval window is much smaller than the tympanic membrane, the pressure the stapes transmits to the oval window is more than 20 times greater than the pressure exerted by the sound wave on the tympanic membrane. Behind the oval window lies the fluid-filled inner ear. Movements of the oval window impart pressure changes to that enclosed fluid. These pressure waves are transduced into action potentials. To see how, let’s take a closer look at the inner ear.

INNER EAR The inner ear is a bony structure consisting of two sets of canals. One is the organ of balance, the **vestibular system**, and the other is the organ of hearing, the **cochlea**. The cochlea (Latin and Greek, “snail” or “spiral shell”) is a long, tapered, coiled canal. A cross section of the cochlea reveals that it is composed of three parallel canals separated by two membranes: **Reissner’s membrane** and the **basilar membrane** (**Figure 46.8C**). Sitting on the basilar membrane is the **organ of Corti**, which transduces pressure waves into action potentials. The organ of Corti contains *hair cells* with *stereocilia*. The tips of the hair cells are embedded in a gelatinous overhanging shelf called the *tectorial membrane* (**Figure 46.8D**).

Stereocilia are fingerlike extensions of the cell plasma membrane that are stiffened by cross-linked actin filaments. They are not motile, but because their tips are attached to the more rigid tectorial membrane, stereocilia bend when the basilar membrane flexes. The response of the hair cell is a graded membrane potential. The hair cells do not fire action potentials, but the changes in their membrane potential alter the rate at which the hair cells release neurotransmitter onto sensory neurons whose axons make up the auditory nerve and transmit action potentials to the brain.

What causes the basilar membrane to flex, and how does this mechanism distinguish sounds of different frequencies? In **Figure 46.9**, the cochlea is shown uncoiled to make it easier to un-

46.9 Sensing Pressure Waves in the Inner Ear Pressure waves of different frequencies flex the basilar membrane at different locations. Information about sound frequency is specified by which hair cells are activated. For simplicity, this representation illustrates the cochlea as uncoiled, and leaves out the middle ear.

derstand its structure and function. The upper and lower canals separated by the basilar membrane are joined at the distal end of the cochlea (the end farthest from the oval window), making one continuous canal that turns back on itself. Just as the oval window is a flexible membrane at the beginning of the upper canal of the cochlea, the **round window** is a flexible membrane at the end of the lower canal.

Air is highly compressible but fluids are not. Therefore, a pressure wave can travel through air without much displacement of the air, whereas a pressure wave in fluid displaces that

fluid. When the stapes pushes on the oval window, the fluid in the upper canal of the cochlea is displaced. If this movement of the oval window occurs slowly, the cochlear fluid pressure wave travels down the upper canal, around the bend, and back through the lower canal. At the end of the lower canal, the displacement pressure is dissipated by the outward bulging of the round window.

BASILAR MEMBRANE AND PITCH If the oval window vibrates in and out rapidly, the waves of fluid pressure create traveling waves, or *flexions*, in the basilar membrane. The basilar membrane is not uniform; it is thicker and stiffer at its base and wider and thinner at its apical end. Pressure waves in the cochlear fluid have different frequencies and set up different patterns of traveling waves. High-frequency waves cause maximal flexion at the basal end of the basilar membrane, whereas low-frequency pressure waves result in maximal flexion at its apical end. Thus different pitches of sound flex the basilar membrane at different locations and activate different sets of hair cells. Action potentials stimulated by the mechanoreceptors at different positions along the organ of Corti travel to different regions of the *auditory cortex* along the auditory nerve.

HEARING LOSS There are two general types of hearing loss, or deafness. *Conduction deafness* is caused by the loss of function of the tympanic membrane and/or the ossicles of the middle ear. Repeated infections of the middle ear can cause scarring of the tympanic membrane and stiffening of the connections between the ossicles. The consequence is less efficient conduction of sound waves from the tympanic membrane to the oval window. With increasing age, the ossicles stiffen, resulting in a gradual loss of the ability to hear high-frequency sounds.

Nerve deafness is caused by damage to the inner ear or the auditory pathways. A common cause of nerve deafness is damage to the hair cells of the delicate organ of Corti by exposure to loud

sounds such as jet engines, pneumatic drills, or highly amplified music. Consistent exposure to sounds above 85 decibels can damage hearing; this damage is cumulative and irreversible. Even using earphones can put you at risk for hearing loss because they generate high-pressure sound waves close to the tympanic membrane. Personal stereo earphones can reach 120 decibels, and people commonly use them at 100 decibels (equivalent to being at a rock concert).

Hair cells are sensitive to being bent

Hair cells are the mechanoreceptors in both the organs of hearing and equilibrium. Stereocilia project from the surface of each hair cell like a set of organ pipes (**Figure 46.10A**). The bending of stereocilia alters ion channels in the hair cell's plasma membrane. Bending in one direction causes the plasma membrane to depolarize, and bending in the other direction causes it to hyperpolarize (**Figure 46.10B**). Graded potentials in the hair cell plasma membrane control its release of neurotransmitter onto the sensory neuron associated with it, and the sensory neuron sends action potentials to the CNS.

How does the bending of the stereocilia open ion channels? The ion channels that are opened are at the ends of the stereocilia. This was discovered by exploring the areas around the stereocilia with microelectrodes, and seeing that local currents were created near the tips of the stereocilia when they were bent. Then, careful electron microscopic work revealed minute filaments that connected the tip of each stereocilium to its taller neighbor. It is hypothesized that these filaments are fine molecular attachments to the ion channels in the stereocilium plasma membrane, and they act like springs that open the channels. If the taller neighboring stereocilium is bent away, the spring tightens and the ion channel is opened. If the taller neighbor bends toward its shorter neighbor, the spring is relaxed and the channel closes (see Figure 46.10B).

46.10 Hair Cells Have Mechanosensors on Their Stereocilia (A) Hair cells have stereocilia that are connected with each other by small filaments. (B) When a cilium is bent in one direction, the filament opens a mechanosensory ion channel at the tip of the neighboring cilium. The depolarized hair cell releases neurotransmitter onto a sensory neuron.

Hair cells detect forces of gravity and momentum

In the mammalian inner ear, the vestibular system consists of three bony **semicircular canals** and two bony chambers called the **saccul**e and the **utricle**. Hair cells in the vestibular system detect the position and movement of the head—information that is essential for maintaining balance (equilibrium). The information from the vestibular system is also crucial for the control of eye movements. When you look at something, you can move your head while staying focused on the object because of your vestibulo-ocular reflex.

The entire vestibular system is filled with a fluid called endolymph. In the semicircular canals, the endolymph shifts when the head changes position. Since the three semicircular canals have different orientations, they respond differentially to the direction of movement. Projecting into the base of each canal is a gelatinous swelling called a **cupula** (plural **cupulae**) that encloses a cluster of hair cell stereocilia. When the shifting endolymph pushes on the cupulae, it bends the stereocilia and causes a graded potential in their hair cell plasma membranes (**Figure 46.11A**). The stereocilia in the saccule and utricle are bent in a different way. These stereocilia are embedded in **otoliths** (Latin for "ear stones"), gelatinous structures containing crystals of calcium carbonate. When the head changes position or when it accelerates or decelerates, gravitational forces are exerted on the otoliths and bend the stereocilia (**Figure 46.11B**).

46.11 Organs of Equilibrium The vestibular system consists of bony chambers and fluid-filled canals. (A) Each semicircular canal has a cupula containing stereocilia. When fluid moves against the cupula, the stereocilia bend. (B) In the saccule and utricle, stereocilia are bent by gravitational forces on the otoliths.

As in the cochlea, the hair cells of the vestibular system do not fire action potentials, but they release neurotransmitter at synapses with sensory neurons, which in turn fire action potentials.

Hair cells are evolutionarily conserved

An early evolutionary use of hair cells to measure movement can be seen in the **lateral line** sensory system of fishes. The lateral line is a canal just under the surface of the skin that runs down each side of the fish (**Figure 46.12**). Hair cells line the canal, and their stereocilia, protected by cupulae, project into the stream of water that flows through the lateral line canal when the fish moves through the water. Forward movement of the fish puts pressure on the cupulae, causing the stereocilia to bend in the direction that depolarizes the hair cells. Since water is incompressible, disturbances in the water around the fish are translated into pressure waves that can be picked up by the lateral line stereocilia. Thus, the lateral line system provides

46.12 The Lateral Line Acoustic System Contains

Mechanosensors Hair cells in the lateral line of a fish detect movement of the water around the animal, giving the fish information about its own movements and the movements of objects nearby.

information about the fish's movements as well as about other moving objects, such as predators or prey.

46.3 RECAP

Sensations that derive from mechanoreceptors include touch, tickle, pressure, joint position, muscle load, hearing, and equilibrium.

- Describe some of the different mechanoreceptors in the skin and their properties. See pp. 970–971 and Figure 46.6
- How do different frequencies of sound result in action potentials being fired in different acoustic neurons? See pp. 972–973 and Figures 46.8 and 46.9
- How do hair cells transduce force into action potentials? See p. 974 and Figure 46.10

Chemoreception gave us good examples of metabotropic sensory receptors, and mechanoreception has given us good examples of ionotropic sensory receptors. Now let's turn to another example of metabotropic sensory reception—one in which light is the stimulus. We will see how light energy is converted into action potentials.

46.4 How Do Sensory Systems Detect Light?

Sensitivity to light—**photosensitivity**—confers on the simplest animals the ability to orient to the sun and sky and gives more complex animals rapid and extremely detailed information about objects in their environment. It is not surprising that both simple and complex animals can sense and respond to light. What is remarkable is that across the entire range of animal species, evolution has conserved the same basis for photosensitivity: a family of pigments called **rhodopsins**.

In this section we will learn how rhodopsin molecules respond when stimulated by light energy and how that response is transduced into neural signals. We will also examine the structures of eyes, the organs that gather light energy and focus it onto **photoreceptor cells**, the metabotropic sensory receptors that transform light energy into action potentials, and the routes those impulses travel to the brain.

yourBioPortal.com

GO TO Animated Tutorial 46.2 • Photosensitivity

Rhodopsins are responsible for photosensitivity

Photosensitivity depends on the ability of rhodopsins to absorb photons of light and to undergo a change in conformation. A rhodopsin molecule consists of a protein, **opsin** (which alone is not photosensitive), and an associated nonprotein light-absorbing group, **11-*cis*-retinal**, cradled in the center of the opsin and bound covalently to it. The entire rhodopsin molecule sits within the plasma membrane of a photoreceptor cell.

When 11-*cis*-retinal absorbs a photon of light energy, it changes into a different isomer of retinal, called all-*trans*-retinal. This change puts a strain on the bonds between retinal and opsin, changing the conformation of opsin. This change signals the detection of light. In vertebrate eyes, the retinal and the opsin eventually separate from each other—a process called **bleaching**, which causes the molecule to lose its photosensitivity. A series of enzymatic reactions is then required to return the all-*trans*-retinal to the 11-*cis* isomer, which then recombines with opsin so that it once again becomes the photosensitive pigment rhodopsin (Figure 46.13).

How does the conformational change of rhodopsin transduce light into a cellular response? After retinal is converted from the 11-*cis* to the all-*trans* form, its interactions with opsin pass through several unstable intermediate stages. One of these stages triggers a cascade of reactions involving a G protein signaling mechanism that results in the alteration of membrane potential that is the photoreceptor cell's response to light.

Rod cells respond to light

To get a better idea of how rhodopsin alters the membrane potential of a photoreceptor cell and how that photoreceptor cell signals that it has been stimulated by light, let's look at one type of vertebrate photoreceptor cell, the rod cell. The rod cell, named for its shape, is a modified neuron that does not produce action potentials. Rod cells release neurotransmitter from their bases

46.13 Light Changes the Conformation of Rhodopsin The light-absorbing molecule 11-cis-retinal bonds with the protein opsin to form the pigment rhodopsin, the molecular agent of photosensitivity.

where they form synapses with the next neurons in the visual pathway (**Figure 46.14**). Each rod cell has an outer segment, an inner segment, and a synaptic terminal. The outer segment is highly specialized and contains a stack of discs of plasma membrane densely packed with rhodopsin. The function of the discs is to capture photons of light passing through the rod cell. The inner segment contains the cell nucleus, mitochondria, and other organelles. The synaptic terminal is where the rod cell communicates with other neurons.

To see how a rod cell responds to light, we can penetrate a single rod cell with an electrode and record its membrane potential in the dark and in the light. From what we have learned about other types of sensory receptors, we might expect stimulation of the rod cell by light would make its membrane potential less negative. But the opposite is true—it becomes more negative.

When a rod cell is kept in the dark, it has a relatively depolarized resting potential compared with other neurons. In fact, the plasma membrane of the rod cell is almost as permeable to Na^+ as to K^+ . In the dark, Na^+ continually enters the outer segment of the cell—the dark current. When light is flashed on the dark-adapted rod cell, its membrane potential becomes more negative—it hyperpolarizes (see **Figure 46.14**). The rate of neu-

INVESTIGATING LIFE

46.14 A Rod Cell Responds to Light

The plasma membrane of a rod cell hyperpolarizes—becomes more negative—in response to a flash of light. Rod cells do not fire action potentials, but in response to the absorption of light energy, the neuron experiences a change in membrane potential.

HYPOTHESIS When a rod cell absorbs photons (light energy), its membrane potential changes in proportion to the strength of the light stimulus.

METHOD

1. Record membrane potentials from the inner segment of a rod cell.
2. Stimulate the rod cells with light flashes of varying intensity and record the results.

RESULTS

CONCLUSION The membrane potential of rod cells is depolarized in the dark and hyperpolarizes (becomes more negative) in response to light.

FURTHER INVESTIGATION: How would you investigate the effect of background illumination on the rod cell's response to light?

Go to yourBioPortal.com for original citations, discussions, and relevant links for all INVESTIGATING LIFE figures.

rotransmitter release changes as membrane potential changes. As the rod cell hyperpolarizes, its release of neurotransmitter decreases.

How does the absorption of light by rhodopsin hyperpolarize the rod cell? When rhodopsin is excited by light, it initiates a cascade of events. The dark-adapted rod cell has open Na^+ channels, allowing a depolarizing dark current (Figure 46.15A). Light photoexcites rhodopsin, which activates a G protein called *transducin*. Activated transducin in turn activates a phosphodiesterase (PDE) (Figure 46.15B). Activated PDE converts cyclic GMP (cGMP) to GMP, which causes the Na^+ channels to close. Na^+ is pumped out and the cell hyperpolarizes (Figure 46.15C).

This mechanism may seem like a roundabout way of doing business, but its advantage is its enormous amplification ability. Each molecule of photoexcited rhodopsin can activate several hundred transducin molecules, thus activating a large number of PDE molecules. The catalytic capacity of PDE is great: one molecule can hydrolyze several hundred molecules of cGMP per second. The bottom line is that a single photon of light can cause a huge number of Na^+ channels to close.

Invertebrates have a variety of visual systems

Photoreceptors using rhodopsin are incorporated into a variety of visual systems, from simple to complex. Flatworms obtain directional information about light from photoreceptor cells that are organized into **eye cups**. The eye cups are paired bilateral

structures, each partly shielded from light by a layer of pigmented cells lining the cup. The photoreceptors on the two sides of the animal are unequally stimulated unless the animal is facing directly toward or away from a light source. The flatworm generally uses directional information from the eye cups to move away from light.

Arthropods have **compound eyes** that provide them with information about patterns or images in the environment. These eyes are called compound because each eye consists of many optical units called **ommatidia** (singular *ommatidium*), each with its own narrow-angle lens (Figure 46.16). In contrast, a vertebrate eye consists of just one optical unit with a wide-angle lens. The number of ommatidia in a compound eye varies from only a few in some ants, to 800 in fruit flies, to 30,000 in some dragonflies.

Each ommatidium has a lens structure that directs light onto photoreceptor cells. Flies, for example, have eight elongated photoreceptors in each ommatidium. The inner borders of the photoreceptors are covered with microvilli that contain rhodopsin and trap light. Axons from the photoreceptors send the light information to the nervous system. Since each ommatidium of a compound eye is directed at a slightly different part of the visual world, only a low-resolution or pixillated image can be communicated from the compound eye to the CNS.

46.15 Light Absorption Closes Sodium Channels The absorption of light by rhodopsin initiates a signaling cascade that hyperpolarizes the rod cell. In the dark, Na^+ channels in the plasma membrane of the rod cell's outer segment are held open by cGMP, allowing positive charges to enter the cell (panel A, upper right). When the rod cell is stimulated by light, it activates transducin (lower portion of panel A). (B) Transducin activates a molecule of phosphodiesterase (PDE). (C) Activated PDE catalyzes the breakdown of cGMP to GMP. The depletion of cGMP results in closure of the Na^+ channels and hyperpolarization of the cell.

iris controls the amount of light that reaches the photoreceptor cells at the back of the eye, just as the diaphragm of a camera controls the amount of light reaching the film. The central opening of the iris is the **pupil**. The iris is under neural control. In bright light, the iris constricts and the pupil is very small. As light levels fall, the iris relaxes and the pupil enlarges.

GO TO Web Activity 46.2 • Structure of the Human Eye

Image-forming eyes evolved independently in vertebrates and cephalopods

Both vertebrates and cephalopod mollusks have *image-forming eyes*—eyes with exceptional abilities to form detailed images of the visual world. Like cameras, both these eye types focus inverted images on an internal surface that is sensitive to light. Considering that they evolved independently, their degree of similarity is remarkable (**Figure 46.17**).

The vertebrate eye is a spherical, fluid-filled structure bounded by a tough connective tissue layer called the **sclera**. At the front of the eye, the sclera forms the transparent **cornea**, through which light passes to enter the eye. Just inside the cornea is the pigmented **iris**, which gives the eye its color. The

Behind the iris is the crystalline protein **lens**, which makes fine adjustments in the focus of images falling on the photosensitive layer—the **retina**—at the back of the eye. The cornea and the fluids within the eye bend light rays passing through them so that they are focused on the retina. The lens makes fine adjustments to the focus and allows the eye to *accommodate*—that is, to focus on objects at various locations in the near visual field. To focus a camera on objects close at hand, you adjust the distance between the lens and the internal surface sensitive to light. Fishes, amphibians, and reptiles accommodate in a similar manner, moving the lenses of their eyes closer to or farther from their

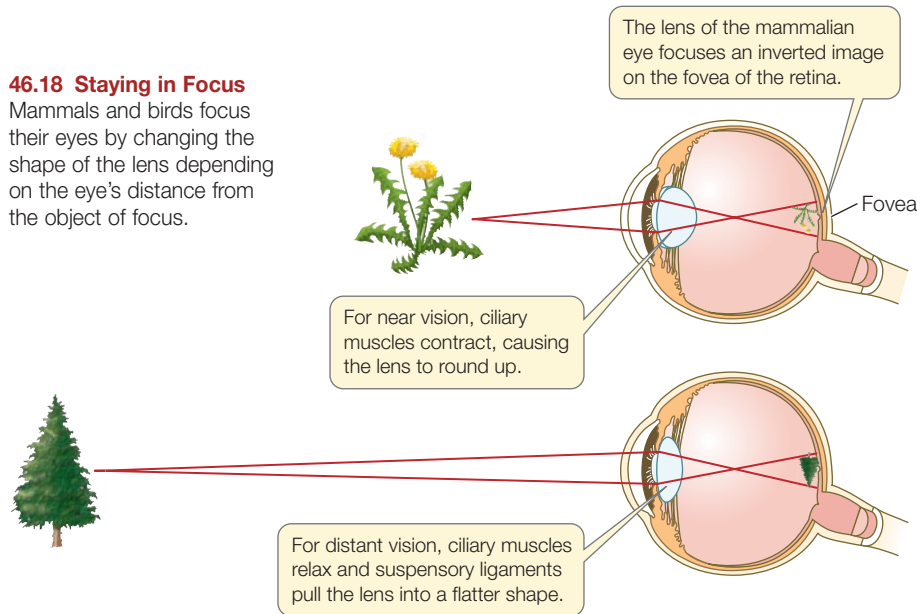

46.17 Convergent Evolution of Eyes The lenses of vertebrate (A) and cephalopod (B) eyes focus images on layers of photoreceptor cells.

The eye of the octopus is very similar in structure to the vertebrate eye, but it evolved independently—an example of convergent evolution.

46.18 Staying in Focus

Mammals and birds focus their eyes by changing the shape of the lens depending on the eye's distance from the object of focus.

retinas. Mammals and birds use a different method: they alter the shape of the lens.

The mammalian lens is contained in a connective tissue sheath that tends to keep it in a spherical shape, but it is attached to suspensory ligaments that pull it into a flatter shape. Circular *ciliary muscles* counteract the pull of the suspensory ligaments, permitting the lens to round up. When the ciliary muscles are at rest, the flatter lens has the correct optical properties to focus distant images on the retina. Contracting the ciliary muscles rounds up the lens, changing its light-bending properties to bring close images into focus (**Figure 46.18**).

Lenses become less elastic with age, so we lose the ability to focus on objects close at hand without the help of corrective lenses. Most people over the age of 45 need the assistance of reading glasses or bifocal lenses.

The vertebrate retina receives and processes visual information

During embryonic development, neural tissue grows out from the brain to form the retina. In addition to a layer of photoreceptor cells, the retina includes four additional layers of cells that process visual information from the photoreceptors. Light must pass through all the layers of retinal cells before being captured by rhodopsin. In humans and other day-active animals, the light that is not captured by rhodopsin is absorbed by a black pigment in a layer of epithelial cells behind the retina. In contrast, nocturnal animals such as deer and raccoons have a white reflective layer behind their retinas that maximize the capture of photons by reflecting them back onto the photoreceptors. Therefore, a deer in the headlights appears to have bright white eyes. Since we do not have the white reflective layer in our retinas, photographic flashes produce the red eye appearance on photos because the light is being reflected by the abundant blood vessels in the retina.

The pigmented epithelium also plays a role in the renewal of the photoreceptors. The photoreceptor cells are always shedding discs from their distal ends as new ones are being gener-

ated by the inner segments of those cells. The pigmented epithelial cells phagocytose the shed discs. Each outer segment is totally renewed about every two weeks.

THE PHOTORECEPTORS OF THE RETINA Until now we have referred to only one kind of photoreceptor—the rod cell. The other major class of vertebrate photoreceptor, the **cone cell**, is also named for its shape (**Figure 46.19**). Whereas rod cells are responsible for highly sensitive black-and-white vision, cone cells are responsible for the less sensitive color vision. A human retina has about 5 million cones and about 100 million rods, but their density is not the same across the entire retina.

In humans, light coming from the center of the visual field falls on the **fovea**, where the density of cone cells is highest. The human fovea has about 160,000 cones per mm². The fovea of a hawk has almost twice that number, making the hawk's vision much sharper than ours. The hawk also has *two* foveae in each eye. One receives light from straight ahead, the other from a more lateral field of vision. The forward-looking foveae make binocular vision possible, while the lateral-looking foveae provide high-acuity vision. Birds use both sets of foveae by frequently turning their heads slightly; they cannot move their eyes in the sockets as humans can.

Cones have low sensitivity to light and contribute little to night vision. Night vision depends mostly on rod cells, and therefore vision in dim light is mostly in shades of gray and acuity is low. You may have trouble seeing a small object such as a keyhole at night when you are looking straight at it—that is, when its image is falling on your fovea. If you look a little to the side, so that the image falls on a rod-rich area of your retina, you

46.19 Rods and Cones This scanning electron micrograph of photoreceptors in the retina of a mud puppy (an amphibian) shows cylindrical rods and tapered cones.

46.20 Absorption Spectra of Cone Cells The three kinds of cone cells contain slightly different opsin molecules, which absorb different wavelengths of light.

see the object better (astronomers looking for faint objects in the sky learned this trick a long time ago). The retinas of nocturnal animals, such as flying squirrels, contain a high percentage of rods. By contrast, some animals that are active only during the day (such as chipmunks) have mostly cones in their retinas.

COLOR VISION The human retina has three kinds of cone cells, each containing slightly different opsin molecules, which differ in the wavelengths of light they absorb best. Although the same 11-*cis*-retinal group is the light absorber in all three kinds of cones (see Figure 46.13), its molecular interactions with opsin determine the spectral sensitivity of the rhodopsin molecule

as a whole (**Figure 46.20**). Because different wavelengths of light are differentially absorbed by the different visual pigments, the brain can interpret the relative inputs from the different classes of cones as a full range of color. Some mammals have only one or two classes of cones, whereas birds have four.

Color blindness results from the absence or dysfunction of one or more classes of cone cells. By far the most common form is red–green color blindness, which occurs in about 10 percent of men of European descent. A genetic condition that affects a person’s perception of red and green, its inheritance is sex-linked because the defective gene is on the X chromosome (see Figure 12.24).

INFORMATION FLOW IN THE RETINA The human retina is organized into five layers of neurons (including the photoreceptor cells) that receive visual information and process it before sending it to the brain (**Figure 46.21**). A first step in understanding how the retina tells the brain what it is seeing is to study how these layers are interconnected and how they influence one another. From our discussion of rod cells, we know that the photoreceptor cells at the back of the retina hyperpolarize in response to light and do not generate action potentials. The cells at the front of the retina (the cells closest to the lens) are **ganglion cells**. They do fire action potentials, and their axons form the optic nerve that travels to the brain. The layers of cells between the photoreceptors and the ganglion cells process information about the visual field.

The photoreceptors and ganglion cells are connected by **bipolar cells**. Changes in the membrane potential of rods and cones in response to light alter the rates at which the rods and cones release neurotransmitter at their synapses with the bipolar cells. In response to this neurotransmitter, the membrane potentials

46.21 The Human Retina Five layers of neurons receive and process visual information. The rods and cones are photoreceptors. The other four layers are the ganglion cells, the bipolar cells, the horizontal cells, and the amacrine cells, all of which are involved in transmitting light signals received by the photoreceptors to the brain.

yourBioPortal.com

GO TO Web Activity 46.3 • Structure of the Human Retina

of the bipolar cells change, altering the rate at which they release neurotransmitter onto ganglion cells. The rate of neurotransmitter release from the bipolar cells determines the rate at which the ganglion cells fire action potentials. Thus, the direct flow of information in the retina is from photoreceptor to bipolar cell to ganglion cell. The ganglion cells send the information to the brain.

The other two cell layers, the horizontal cells and the amacrine cells, consist of interneurons that communicate laterally across the retina. *Horizontal cells* form synapses with neighboring photoreceptors and bipolar cells. Thus, light falling on one photoreceptor can influence the sensitivity of its neighbors to light. This lateral flow of information enables the retina to sharpen the perception of contrast between light and dark patterns. *Amacrine cells* form local interconnections between bipolar cells and ganglion cells. Some amacrine cell types are highly sensitive to changing illumination or to motion. Others assist in adjusting the sensitivity of the eyes according to the overall level of light falling on the retina. When background light levels change, amacrine cell connections to the ganglion cells help the ganglion cells remain sensitive to temporal changes in stimulation. Thus, even with large changes in background illumination, the eyes are sensitive to smaller, more rapid changes in the pattern of light falling on the retina.

46.4 RECAP

A family of photopigments called rhodopsins are responsible for light sensitivity in all animals. Receptor cells, including rod and cone cells in humans, transduce the photosensitivity of rhodopsins to light and use it to form images of the environment.

- Explain how a photon of light affects the membrane potential in a rod cell. **See pp. 976–978 and Figures 46.14 and 46.15**
- What is the mechanism of color vision? **See p. 981 and Figure 46.20**
- Describe the flow of signals that occurs in the eye in response to light. **See pp. 981–982 and Figure 46.21**

Knowing the path of information in the retina still does not tell us how that information is processed by the brain. What does the eye tell the brain in response to a pattern of light falling on the retina? In Chapter 47 we will describe how the brain reassembles that information into our view of the world.

CHAPTER SUMMARY

46.1 How Do Sensory Cells Convert Stimuli into Action Potentials?

- Sensory receptor cells, also known as sensors or receptors, transduce information about an animal's external and internal environment into action potentials. Some sensors do not fire action potentials, but respond with graded membrane potentials that control release of neurotransmitter onto sensory neurons that do fire action potentials.
- The interpretation of action potentials as particular sensations depends on which neurons in the CNS receive them.
- Sensory receptor cells have membrane **receptor proteins** that cause ion channels to open or close, affecting the resting potential of the cell. Metabotropic receptors act through signal transduction pathways to generate **receptor potentials**. Mechanoreceptors are ionotropic sensory receptors that open ion channels physically through forces such as pressure or stretch. **Review Figure 46.1**
- Receptor potentials initiated by a sensory cell can spread to regions of the cell's plasma membrane that generate action potentials, or they can release neurotransmitter in response to changes in membrane potential. **Review Figure 46.2**
- **Adaptation** enables the nervous system to ignore irrelevant or continuous stimuli while remaining responsive to relevant or new stimuli.

46.2 How Do Sensory Systems Detect Chemical Stimuli?

- **Chemoreceptors** are responsible for **olfaction**, **gustation**, and the sensing of **pheromones**.

- Mammalian olfactory sensors project directly to the olfactory bulb of the brain. Sensors for the same **odorant** project to the same area of the olfactory bulb.
- Each olfactory receptor cell expresses one receptor protein that can bind a specific molecule or ion. Binding causes a second messenger to open ion channels, which creates an action potential. **Review Figure 46.4**
- In vertebrates, **taste buds** in the mouth cavity are responsible for gustation. The five basic tastes are sweet, salty, sour, bitter, and umami. **Review Figure 46.5**

46.3 How Do Sensory Systems Detect Mechanical Forces?

- The skin contains a variety of ionotropic **mechanoreceptors** that respond to touch and pressure. The density of mechanoreceptors in any skin area determines the sensitivity of that area. **Review Figure 46.6**
- **Stretch receptors** in muscle spindles and in the Golgi tendon organ found in tendons and ligaments inform the CNS of the positions of and loads on parts of the body. **Review Figure 46.7**
- In mammalian **auditory systems**, ear pinnae collect and direct sound waves to the **tympanic membrane**, which vibrates in response to sound waves. The movements of the tympanic membrane are amplified through a chain of **ossicles** that conduct the vibrations to the **oval window**. Movements of the oval window create pressure waves in the fluid-filled **cochlea**. **Review Figure 46.8, WEB ACTIVITY 46.1**
- The **basilar membrane** running down the center of the cochlea is distorted by pressure waves at specific locations that depend on the frequency of the wave. These distortions cause the bending of hair cells in the **organ of Corti**. Receptor potentials

in hair cells cause them to release neurotransmitter, which creates action potentials in the **auditory nerve**. **Review Figure 46.9, ANIMATED TUTORIAL 46.1**

- **Hair cells** are also mechanoreceptors. The bending of their stereocilia alters receptor proteins and therefore their membrane potentials. Hair cells are found in the auditory organs and organs of equilibrium such as the **lateral line** system of fishes and the **semicircular canals** and **vestibular system** of mammals. **Review Figures 46.10, 46.11, and 46.12**

46.4 How Do Sensory Systems Detect Light?

- **Photosensitivity** depends on the absorption of photons of light by **rhodopsin**, a photoreceptor molecule that consists of a protein called **opsin** and a light-absorbing group called retinal. Absorption of light by retinal is the first step in a cascade of intracellular events leading to a change in the membrane potential of the **photoreceptor cell**. **Review Figure 46.13, ANIMATED TUTORIAL 46.2**
- When excited by light, vertebrate photoreceptor cells hyperpolarize and release less neurotransmitter onto the neurons with which they form synapses. They do not fire action potentials. **Review Figures 46.14 and 46.15**
- Visual systems range from the simple **eye cups** of flatworms, which sense the direction of a light source, to the **compound eyes** of arthropods, which detect shapes and patterns, to the **image-forming eyes** of vertebrates and cephalopods. **Review Figures 46.16 and 46.17, WEB ACTIVITY 46.2**
- Vertebrate and cephalopod eyes focus detailed images of the visual field onto dense arrays of photoreceptors that transduce the visual image into neural signals. **Review Figure 46.18**
- Vertebrates have two types of photoreceptors, **rod cells** and **cone cells**. In humans, the **fovea** contains almost exclusively cone cells, which are responsible for color vision but are not very sensitive in dim light. Color vision arises from three types of cone cells with different spectral absorption properties. **Review Figures 46.19 and 46.20**
- The vertebrate **retina** consists of five layers of neurons lining the back of the eye. The light-absorbing photoreceptor cells are at the back of the retina. **Review Figure 46.21, WEB ACTIVITY 46.3**
- The axons of the **ganglion cells**, in the innermost layer of the retina, are bundled together in the optic nerve. Between the photoreceptors and the ganglion cells are neurons that process information from the photoreceptors.

SELF-QUIZ

- Which statement about sensory systems is *not* true?
 - Sensory transduction involves the conversion (direct or indirect) of a physical or chemical stimulus into changes in membrane potentials.
 - In general, a stimulus causes a change in the flow of ions across the plasma membrane of a sensory receptor cell.
 - The term “adaptation” refers to the process by which a sensory system becomes insensitive to a continuing source of stimulation.
 - The more intense a stimulus, the greater the magnitude of each action potential fired by a sensory neuron.
 - Sensory adaptation plays a role in the ability of organisms to discriminate between important and unimportant information.
- The female silkworm moth releases a chemical called bombykol from a gland at the tip of her abdomen. Bombykol is
 - a sex hormone.
 - detected by the male only when present in large quantities.
 - not species-specific.
 - detected by hairs on the antennae of male silkworm moths.
 - a chemical basic to the taste process in arthropods.
- Which statement about olfaction is *not* true?
 - In general, mammals depend more on vision than on olfaction as their dominant sensory modality.
 - Olfactory stimuli are recognized by the interaction between odorant molecules and receptor proteins on olfactory hairs.
 - The more odorant molecules that bind to receptors, the more action potentials are generated.
 - The greater the number of action potentials generated by an olfactory receptor, the greater the intensity of the perceived smell.
 - The perception of different smells results from the activation of different combinations of olfactory receptors.
- In general, the touch receptors located close to the surface of both hairy and nonhairy skin
 - are relatively insensitive to light touch.
 - adapt very quickly to stimuli.
 - are uniformly distributed throughout the surface of the body.
 - are called Pacinian corpuscles.
 - adapt slowly and provide almost continuous information.
- The membrane that is most directly responsible for the ability to discriminate different pitches of sound is the
 - round window.
 - oval window.
 - tympanic membrane.
 - tectorial membrane.
 - basilar membrane.
- Which statement is *not* true?
 - The transmembrane potential of a rod cell becomes more negative when the rod cell is exposed to light.
 - A photoreceptor releases the most neurotransmitter when in total darkness.
 - Whereas in vision the intensity of a stimulus is encoded by the degree of hyperpolarization of photoreceptors, in hearing the intensity of a stimulus is encoded by changes in firing rates of sensory neurons.
 - Stiffening of the ossicles in the middle ear can lead to deafness.
 - The interaction among hammer (malleus), anvil (incus), and stirrup (stapes) conducts sound waves across the fluid-filled middle ear.
- In humans, the region of the retina where the central part of the visual field falls is the
 - central ganglion cell.
 - fovea.
 - optic nerve.
 - cornea.
 - pupil.

8. Which of the following statements about information flow in the vertebrate visual system is *true*?
 - a. Action potentials in bipolar cells cause the release of neurotransmitter onto ganglion cells.
 - b. Amacrine cells integrate the activity of neighboring rod and cone cells.
 - c. When photons of light enter the eye, the first cells in the retina they encounter are ganglion cells.
 - d. The highest density of rod cells in the human retina is centrally located in the fovea, resulting in high acuity dim light vision.
 - e. Pigmented epithelial cells at the back of the retina provide information about the level of ambient light for contrast adjustments.
9. Which statement about the cone cells in a human eye is *not* true?
 - a. They are responsible for our sharpest vision.
 - b. They are responsible for color vision.
 - c. They are more sensitive to light than rods are.
 - d. They are fewer in number than rods.
 - e. They exist in high numbers at the fovea.
10. The color in color vision results from the
 - a. ability of each cone cell to absorb all wavelengths of light equally.
 - b. lens of the eye acting like a prism and separating the different wavelengths of light.
 - c. differential absorption of wavelengths of light by different kinds of rod cells.
 - d. three different isomers of opsin in cone cells.
 - e. absorption of different wavelengths of light by amacrine and horizontal cells.

FOR DISCUSSION

1. Compare and contrast the functioning of olfactory receptors and photoreceptors. How do these sensory cells enable the central nervous system to discriminate between an apple and an orange?
2. Amplification of signal is an important feature of sensory systems. Compare the mechanisms of amplification found in olfactory, visual, and auditory systems.
3. If you were blindfolded and sitting in a wheelchair, how would you know if you were being pushed forward or backward?
4. Animals can use visual, olfactory, tactile, and auditory signals to communicate. From what you know about these sensory systems, discuss the relative advantages and disadvantages of these systems for communication.

ADDITIONAL INVESTIGATION

A certain region of the brain contains neurons that are sensitive to the osmolarity of the blood. You could imagine that these cells are sensitive to the concentration of a particular solute such as NaCl or to tension in their plasma membranes if they take up

or lose water osmotically. Using a slice of this brain region in a culture dish, and patch pipettes, how could you investigate the mechanism of signal transduction in these neurons?

WORKING WITH DATA (GO TO yourBioPortal.com)

Rod Cell Response In this exercise based on the experiments illustrated in Figure 46.14, you will analyze the data generated by electrode recordings from rod cells stimulated by light of

varying intensities. You will then use the data to generate a maximum-response curve for the rod cell.

The Mammalian Nervous System: Structure and Higher Function

Drive a cab, grow your brain

Go to Google Maps and compare London with New York City at the same scale. In which city is it easier to drive a taxi? In the city with numbered avenues and streets at right angles to each other, or the city with a maze of named streets going in every which direction?

Eleanor Maguire at University College London was so impressed with the navigational abilities of London taxi drivers, she decided to see if there was anything “special” about their brains. Using the brain imaging technique known as MRI (*magnetic resonance imaging*), Maguire and her colleagues examined the brains of taxi drivers with varying years of experience and compared them with each other and with the brains of control subjects who were not taxi drivers. The studies revealed significant changes in the anatomy of the hippocampus among taxi drivers.

The hippocampus is an area of the brain involved in learning and memory. The posterior hippocampus in par-

ticular is implicated in the memory of spatial relationships among objects in the environment. Maguire found that the posterior hippocampi of taxi drivers was larger than that of the control subjects and that, among the cab drivers themselves, there was a positive correlation between the size of the posterior hippocampus and years of driving experience.

At the Massachusetts Institute of Technology, Matt Wilson and his colleagues can record the hippocampal activity of lab rats as the animals navigate a maze. By placing electrodes in the rats’ hippocampi, Wilson has located specific neurons, sometimes referred to as “place cells,” that fire only when the rat is at a particular location in the maze. In a sense he can even see what they are thinking, because when the rats are not moving through the maze, the neurons will occasionally fire in the same pattern as when the animal is running the maze—or they will fire in

the reverse sequence, representing where the animal has just been. In a maze that had a choice point (go right or go left), the firing pattern seen when the animal was held at the start position predicted which direction it would turn. Similar firing patterns occur when the rats are sleeping. Are they dreaming about the maze, or are they transferring memory of today’s experience into long-term memory?

Neural firing patterns that correlate with the hippocampal sequences are also seen in the visual cortex at the back of the brain

A Mind-Expanding Maze The extraordinary ability of taxicab drivers in London to navigate its mazelike warren of streets and byways prompted a study that revealed London cabbies to have larger than normal posterior hippocampi—a brain region implicated in the memory of spatial relationships in the environment.

Seeing What a Rat Thinks By recording from many neurons in the hippocampus of a rat while it runs a maze, a sequence of “place cell” activities that correspond to different locations in the maze can be described. After the rat has learned the maze, a similar sequence of neural activity can be recorded from its visual cortex.

and in the prefrontal cortex at the front of the brain. In humans, the prefrontal cortex is involved in planning and decision-making.

The extensive ability of humans to remember, to learn, to communicate, and to feel emotions—the “higher functions” of the mammalian brain—is a fascinating subject that brings together the fields of neurobiology, psychology, and medicine. Are these functions simply the product of molecular changes in brain cells? To what extent can we reverse damage to the brain that interferes with higher functioning? These and countless other questions are only beginning to be articulated and studied.

IN THIS CHAPTER we will explore the cellular basis of important subsystems of the human nervous system. The human brain has about 100 billion neurons and probably a thousand times as many synapses, which account for its ability to handle vast amounts of information. But the ability of the brain to carry out specific functions—evaluating sensory input, controlling emotions, generating motor output, learning and remembering—arises from functional subsystems.

CHAPTER OUTLINE

- 47.1** How Is the Mammalian Nervous System Organized?
- 47.2** How Is Information Processed by Neural Networks?
- 47.3** Can Higher Functions Be Understood in Cellular Terms?

47.1 How Is the Mammalian Nervous System Organized?

We can describe the organization of the mammalian nervous system anatomically or functionally. In anatomical terms, all vertebrate nervous systems consist of three parts: a brain, a spinal cord, and a set of peripheral nerves that reach to all parts of the body. As discussed in Section 45.1, the brain and spinal cord are referred to as the *central nervous system*, or *CNS*, and the cranial and spinal nerves that connect the CNS to all the tissues of the body are referred to as the *peripheral nervous system*, or *PNS*. An additional division of the nervous system exists in the gut: the enteric nervous system, which we discuss in Chapter 51.

Recall from Section 45.1 that a *neuron* is an electrically excitable cell that communicates via an axon, and a *nerve* is a bundle of axons that carries information about many things simultaneously. Some axons in a nerve may be carrying information to the CNS, while other axons in the same nerve are carrying information from the CNS to the body’s organs. In this chapter, we will further divide the anatomy of the brain, spinal cord, and PNS into smaller functional units.

A functional organization of the nervous system is based on flow and type of information

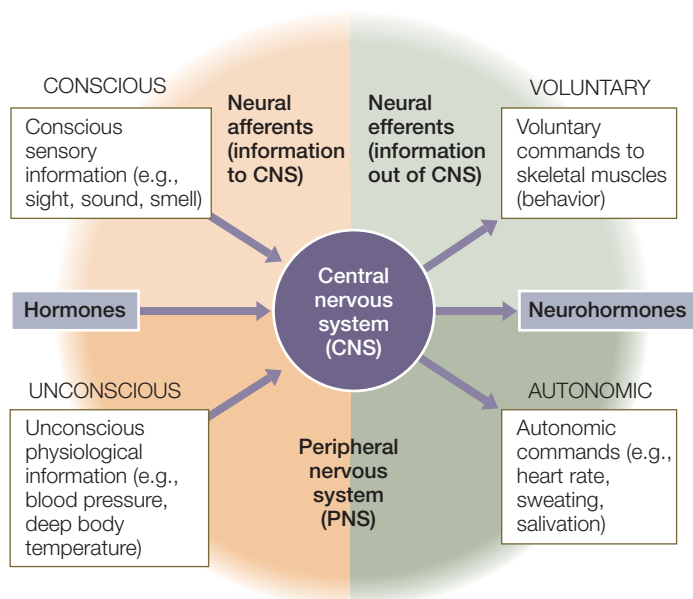

Figure 47.1 illustrates the major avenues of information flow through the nervous system. The *afferent* portion of the PNS carries sensory information to the CNS. We are conscious of much of this information (e.g., light, sound, skin temperature, the position of limbs), but we are usually not conscious of the information involved in physiological regulation (e.g., blood pressure, deep body temperature, blood oxygen levels).

The *efferent* portion of the PNS carries information from the CNS to the muscles and glands of the body. Efferent pathways can be divided into a voluntary division, which executes our conscious movements, and an involuntary, or *autonomic*, division, which controls physiological functions.

In addition to the neural information it receives from the PNS, the CNS receives chemical information from hormones circulating in the blood. In turn, *neurohormones* released by neurons enter the circulation and affect neurons and other cells distant from the site of release (see Figure 41.1).

The vertebrate CNS develops from the embryonic neural tube

Early in the development of a vertebrate embryo, a tube of neural tissue forms (see Section 44.3). At its anterior end, this *neural tube* forms three swellings that become the **hindbrain**, **midbrain**, and **forebrain**. The rest of the neural tube becomes the

47.1 Organization of the Nervous System The peripheral nervous system (beige, green) carries information both to (afferent) and from (efferent) the central nervous system (purple). The CNS also receives hormonal inputs and produces hormonal outputs (lavender).

spinal cord. Peripheral nerves sprout from the midbrain and hindbrain (the cranial nerves) and from the spinal cord (the spinal nerves). From these early stages we see the linear axis of information flow in the nervous system. Although the developing brain will fold and become a complex structure, the information flow in the adult nervous system will follow paths that emerge from the simple linear neural tube.

Each of the three regions of the embryonic brain develops into several structures in the adult brain (**Figure 47.2**). From the embryonic midbrain come structures that process aspects of visual and auditory information. From the hindbrain come the **medulla**, the **pons**, and the **cerebellum**. The medulla is continuous with the spinal cord, the pons is in front of the medulla, and the cerebellum is a dorsal outgrowth of the pons. The medulla and pons contain distinct groups of neurons involved in controlling physiological functions such as breathing and circulation and basic motor patterns such as swallowing and vomiting. All information traveling between the spinal cord and higher brain areas must pass through the pons, the medulla, and the midbrain, which are collectively known as the **brainstem**.

The cerebellum is involved in coordinating muscle activity and maintaining balance. It is like the conductor of an orchestra; the cerebellum receives “copies” of the commands going to the muscles from higher brain areas, and it receives information coming up the spinal cord from the joints and muscles. It compares the motor “score” with the actual behavior of the muscles and refines the motor commands accordingly.

The embryonic forebrain develops a central region called the **diencephalon** and a surrounding structure called the **telencephalon**. The diencephalon is the core of the forebrain and consists of an upper structure called the **thalamus** and a lower structure called the **hypothalamus**. The thalamus is the final relay station for sensory information going to the telencephalon. The

47.2 Development of the Central Nervous System In vertebrate embryos, the anterior end of the hollow neural tube differentiates into forebrain, midbrain, and hindbrain. Each of these regions develops into several structures in the adult brain. The remainder of the neural tube becomes the spinal cord.

hypothalamus regulates many physiological functions and biological drives such as hunger and thirst; it receives a lot of physiological information of which we are not conscious.

The telencephalon—also called the **cerebrum**—consists of two **cerebral hemispheres**, left and right. The outer layer of the telencephalon is the **cerebral cortex**, a thin layer rich in cell bodies. If we compare the classes of vertebrates from fishes through amphibians, reptiles, birds, and mammals, the telencephalon increases in size, complexity, and importance—an evolutionary trend called *telencephalization* (see Figure 45.2). In humans, the telencephalon is by far the largest part of the brain and plays major roles in sensory perception, learning, memory, and conscious behavior.

The spinal cord transmits and processes information

The spinal cord conducts information in both directions between the brain and the body's organs. It also integrates much of the information coming from the PNS and responds to that information by issuing motor commands.

A cross section of the spinal cord reveals a central area of gray matter in the shape of a butterfly, surrounded by an area of white matter (Figure 47.3). In the nervous system, **gray matter** is rich in neural cell bodies, and **white matter** contains axons. The gray matter of the spinal cord contains the cell bodies of the spinal neurons; the white matter contains the axons that conduct information up and down the spinal cord. The white appearance is due to the myelin that wraps most of the axons.

Spinal nerves extend from the spinal cord at regular intervals on each side. Each spinal nerve has two roots, one connecting with the *dorsal horn* of the gray matter, the other with the *ventral horn*. The afferent (sensory) axons in a spinal nerve enter the spinal cord through the *dorsal root*, and the efferent (motor) axons leave through the *ventral root*.

The conversion of afferent to efferent information in the spinal cord without participation of the brain is called a **spinal reflex**. The simplest type of spinal reflex involves only two neurons and one synapse and is therefore called a **monosynaptic reflex**. An example is the knee-jerk reflex, which your physician checks with a mallet tap just below your knee. We can diagram the wiring of a monosynaptic reflex by following the flow of information through the spinal cord, as shown in Figure 47.3.

In the knee-jerk reflex, sensory information comes from stretch receptors in the leg muscle that is suddenly stretched when the mallet strikes the tendon running over the knee. Each stretch receptor initiates action potentials that are conducted by the axon of a sensory neuron through the dorsal horn of the spinal cord and all the way to the ventral horn. In the ventral horn, the sensory neuron synapses with motor neurons, causing them to fire action potentials that are then conducted back to the leg extensor muscle, causing it to contract. The function of this simple circuit is to sense an increased load on the limb and to increase the strength of muscle contraction to compensate for the added load and thereby keep muscle length constant.

Most spinal circuits are more complex than this monosynaptic reflex, as we can demonstrate by building on the circuit we just traced. Limb movement is controlled by *antagonistic* sets of muscles—muscles that work against each other. When one member of an antagonistic set of muscles contracts, it bends, or flexes, the limb; it is therefore called a *flexor*. The antagonist to this muscle, the *extensor*, straightens, or extends, the limb. For a limb to move, one muscle of the pair must relax while the other contracts. Thus, sensory input that activates the motor neuron of one muscle also inhibits its antagonist. This coordination is achieved by an *interneuron*, which makes an inhibitory synapse onto the motor neuron of the antagonistic

47.3 The Spinal Cord Coordinates the Knee-Jerk Reflex Sensory (afferent) information enters the spinal cord through the dorsal horns (red pathway), and motor (efferent) output leaves it via the ventral horns (blue pathways). Information travels to the brain in white matter tracts. Interneurons make connections within the spinal cord that result in a complex, coordinated behavior pattern.

muscle (see Figure 47.3). Thus the reciprocal inhibition of antagonistic muscles involves an interneuron between the sensory cell and the motor neuron of the inhibited muscle, and therefore at least two synapses.

The withdrawal reflex is an example of a polysynaptic spinal reflex that involves many interneurons. When you step on a tack, you immediately pull back your foot: the tack stimulates pain receptors in the foot, and the sensory neurons transmit action potentials into the dorsal horn of the spinal cord on the same side of the body. In the dorsal horn, these neurons synapse with interneurons that send information through their axons to the brain, resulting in the conscious sensation of pain. Before the brain is aware of the pain, however, synapses of the sensory neurons with other interneurons stimulate and inhibit a variety of different motor neurons in the spinal cord. Interneurons on the same side of the spinal cord coordinate the activity of the muscles that withdraw the foot and leg. To pull away, however, the other leg has to extend, and balance must be shifted. The coordination of these actions involves interneurons that make connections across the spinal cord to motor neurons on the opposite side. Thus a rather complex suite of movements is coordinated in the spinal cord without the brain's participation.

The reticular system alerts the forebrain

Sensory information ascending the spinal cord to final destinations in the forebrain passes through the brainstem. Many sensory axons give off branches in the brainstem that form

synapses with a network of brainstem neurons called the **reticular system**. Within this highly complex network of axons and dendrites are many discrete groups of neurons that share a common characteristic such as the neurotransmitter they produce and release. Such an anatomically distinct group of neurons in the CNS is called a **nucleus** (not to be confused with the nucleus of a single cell).

As axons carrying sensory information ascend through the reticular formation, they make connections with nuclei that are involved in controlling many functions of the body. Information from joints and muscles, for example, is directed to nuclei in the pons and cerebellum that are involved in balance and coordination. Sensory information also goes to reticular formation nuclei that control sleep and wakefulness. High reticular formation activity produces waking; in the absence of such stimulation, sleep occurs. Therefore, the reticular core of the brainstem is called the *reticular activating system*.

The core of the forebrain controls physiological drives, instincts, and emotions

As mentioned above, the diencephalon consists of the thalamus and the hypothalamus. The thalamus communicates sensory information to the cerebral cortex; the hypothalamus receives information about physiological conditions in the body and regulates many homeostatic functions. Section 40.4 describes how the hypothalamus is involved in regulating body temperature, and Section 41.2 discusses the intimate association between the hypothalamus and the pituitary gland and its control of many homeostatic functions.

Surrounding the diencephalon of all vertebrates are phylogenetically older structures of the telencephalon called the **limbic system** (Figure 47.4). The limbic system is responsible for basic physiological drives such as hunger and thirst, instincts, long-term memory formation, and emotions such as fear. Within the limbic system are areas that, when stimulated with small electric currents, can cause intense sensations of pleasure, pain, or rage. If a rat is given the opportunity to stimulate its own pleasure centers by pressing a switch, it will ignore food, water, and even sex, pushing the switch until it is exhausted. Pleasure and pain centers in the limbic system are believed to play roles in learning and in physiological drives.

As described in the introduction to Chapter 45, one component of the limbic system—the **amygdala**—is involved in fear and fear memory. If a certain portion of the amygdala is damaged or chemically blocked, an animal cannot learn to be afraid of a stimulus or a situation that would normally induce a strong fear reaction.

Another part of the limbic system, the **hippocampus**, is necessary in humans for the transfer of short-term memory to long-term memory, as we'll discuss in Section 47.3.

47.4 The Limbic System The evolutionarily primitive parts of the telencephalon are referred to as the limbic system. The hippocampus is involved in forming long-term memory. The amygdala triggers fear emotions and fear memories (see p. 943).

47.5 The Human Cerebrum (A) Each cerebral hemisphere is divided into four lobes. (B) Different functions are localized in particular areas of the cerebral lobes.

Regions of the telencephalon interact to produce consciousness and control behavior

The cerebrum is the dominant structure in the mammalian brain. In humans, it is so large that it covers all other parts of the brain except the cerebellum (**Figure 47.5A**). The cerebral cortex covering the cerebrum is only about 4 millimeters thick, but it covers a surface area larger than 1 m² because it is folded into ridges (*gyri*; singular *gyrus*) and valleys (*sulci*; singular *sulcus*). These foldings, or *convolutions*, allow the cortex to fit into the skull.

A curious feature of our nervous system is that the left side of the body is served (in both sensory and motor aspects) mostly by the right side of the brain, and the right side of the body is served mostly by the left side of the brain. Thus, sensory input from the right hand goes to the left cerebral hemisphere, and sensory input from the left hand goes to the right cerebral hemisphere. The exception is the head, where the left side is controlled by the left cerebral hemisphere and the right side by the right cerebral hemisphere. The two hemispheres are not symmetrical with respect to all functions. Language abilities, for example, reside predominantly in the left hemisphere.

Different regions of the cerebral cortex have specific functions (**Figure 47.5B**). Some of those functions are easily defined, such as receiving and processing sensory information or generating motor commands, but most of the cortex is involved in higher-order information processing that is less easy to define. These latter areas are given the general name of **association cortex**, so named because they integrate, or *associate*, information from different sensory modalities and from memory.

To understand the cerebral cortex, it helps to have an anatomical road map. Viewed from the left side, the left cerebral hemisphere looks like a boxing glove for the right hand with the fingers pointing forward, the thumb pointing out, and the wrist at

the rear. The “thumb” area is the **temporal lobe**, the fingers the **frontal lobe**, the back of the hand the **parietal lobe**, and the wrist the **occipital lobe** (see **Figure 47.5A**). The right cerebral hemisphere shows a mirror image of this arrangement. Let’s look at each lobe separately.

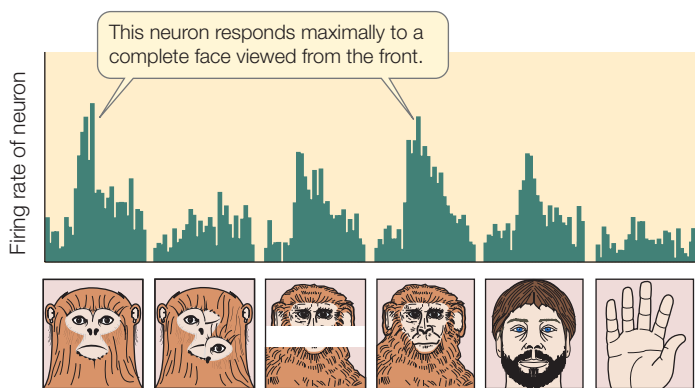

As we explore the functions of the cerebral cortex and other parts of the brain, you will note frequent mention of persons whose brains were damaged by accidents or other unfortunate events. Until recently, the study of such individuals has been the main source of functional information about the human brain, but new imaging technologies such as positron emission tomography (PET) and magnetic resonance imaging (MRI) are providing a wealth of new information and opportunities to study the human brain.

THE TEMPORAL LOBE The upper region of the temporal lobe receives and processes auditory information. The association areas of this lobe are involved in recognizing, identifying, and naming objects. Damage to the temporal lobe results in disorders called *agnosias*, in which the individual is aware of an object but cannot identify it.

Damage to a certain area of the temporal lobe results in the inability to recognize faces. Even old acquaintances cannot be identified by facial features, although they may be identified by other attributes such as voice, body features, and posture. Using monkeys, it has been possible to record the activity of neurons in this region that respond selectively to faces in general. These neurons do not respond to other stimuli in the visual field, and their responsiveness decreases if some of the facial features are missing or appear in inappropriate locations (**Figure 47.6**). Damage to other association areas of the temporal lobe causes deficits in understanding spoken language, although speaking, reading, and writing abilities may be intact.

—yourBioPortal.com—

GO TO Web Activity 47.1 • The Human Cerebrum

47.6 “Face Neurons” in One Region of the Temporal Lobe The electrode traces represent the firing rate of a neuron in the temporal lobe of a monkey in response to the pictures shown below them. Highest firing is stimulated by the appearance of a complete face.

THE FRONTAL LOBE The frontal and parietal lobes are separated by a deep valley called the *central sulcus*. A strip of the frontal lobe cortex just in front of the central sulcus is called the **primary motor cortex** (see Figure 47.5B). The neurons in this region control muscles in specific parts of the body; the parts of the body have been mapped onto the primary motor cortex largely during neurosurgical procedures. As part of these procedures, electrodes were used to stimulate small areas of cortex. In the area just anterior to the central sulcus, stimulation causes specific muscles to contract. Parts of the body with fine motor control, such as the face and hands, have disproportionate representation (**Figure 47.7A**). Stimulation of neurons in the primary motor cortex causes twitches of muscles, not coordinated movements.

The association functions of the frontal lobe are diverse and are best described as having to do with feeling and planning. They contribute significantly to personality. People with frontal lobe damage have drastic alterations of personality

47.7 The Body Is Represented in Primary Motor and Primary Somatosensory Cortex

Neurons in the primary motor cortex (A) control muscles in specific parts of the body, while neurons in the primary somatosensory cortex (B) receive information from specific parts of the body. The locations of these neurons in the cortex correspond to “maps” on which regions of the body are represented in proportion to the amount of primary cortical area devoted to them.

and difficulty planning future events. A dramatic case of frontal lobe damage is the story of Phineas Gage, who in 1848 was an industrious and responsible young railroad construction foreman. Then a blasting accident shot a meter-long, 3-centimeter-wide iron tamping rod through his brain. The rod entered Gage’s head below his left eye, passed through his frontal lobe, and exited the top of his head (**Figure 47.8**).

Remarkably, Gage survived, but he was a completely different person. He was quarrelsome, impatient, obstinate, and used profane language, which he had never done before. He lost his railroad job and spent his days as a drifter, earning money by telling his story and exhibiting his scars (and the tamping iron). He died of a seizure in 1860, at the age of 38. If you are in Boston, you can pay him a visit—his skull, death mask, and the tamping iron are on display in the Warren Anatomical Museum of Harvard Medical School.

THE PARIETAL LOBE The strip of parietal lobe cortex just behind the central sulcus is the **primary somatosensory cortex** (see Figure 47.5B). This area receives touch and pressure information relayed from the body through the thalamus.

The entire body surface can be mapped onto the primary somatosensory cortex (**Figure 47.7B**). Areas of the body that have a high density of tactile mechanoreceptors and are capable of making fine discriminations in touch (such as the lips and fingers) have disproportionately large representation. If a very small area of the primary somatosensory cortex is stimulated electrically, the subject reports feeling specific sensations, such as touch, in a localized part of the body.

47.8 A Mind-Altering Experience Phineas Gage miraculously survived a nineteenth-century railroad construction accident in which an explosion blew an iron rod through his brain. His personality, however, was permanently altered. The path of the iron rod through Gage's brain is superimposed on this reconstruction of his skull.

not cause the same degree of neglect of the right side of the body. We will see similar asymmetries in cortical function later in the chapter when we discuss language.

THE OCCIPITAL LOBE The occipital lobe receives and processes visual information. The association areas of the occipital cortex are essential for making sense of the visual world and translating visual experience into language. Some deficits resulting from damage to these areas are specific. In one case, a woman with limited damage was unable to see motion. Her vision was intact, but she could see a waterfall only as a still image, and an approaching car only as a series of a stationary objects at different distances.

The human brain is off the curve

Humans are sometimes called “big-brain primates,” and that is an accurate characterization. Across vertebrate species there is a correlation between body size and brain size (**Figure 47.9**). Higher primates such as chimpanzees, baboons, and gorillas all fall above this regression line, but humans stand out because they are so far above the regression line. Gorillas are much larger than humans, but they have smaller brains. Elephants and whales have large brains, but they fall closer to the regression line. Dolphins and humans stand out as having bigger brains than would be predicted by their body sizes.
